PASSMEDICINE CARDIOLOGY PART 2

Question 1 of 328

A 31-year-old woman comes to the emergency department complaining of palpitations and dizziness. She has had palpitations before, but this is the first time she is feeling dizzy.

On examination, she is afebrile. Her heart rate is 140 bpm, and her blood pressure is 110/90 mmHg. She has a respiratory rate of 12 breaths per minute, and oxygen saturation is 96% on air. The rest of her examination is normal.

A 12-lead ECG shows polymorphic ventricular tachycardia, QTc 510ms. Her laboratory studies show:

Which of the following is the best next step in the management of this patient?

A. Intravenous amiodarone
B. Intravenous lidocaine
C. Intravenous magnesium sulphate
D. Immediate defibrillation
E. Synchronised DC cardioversion

C. Intravenous magnesium sulphate

IV magnesium sulfate is used to treat torsades de pointes Important

This patient is presenting with an acute episode of torsades de pointes. Her ECG shows polymorphic ventricular tachycardia with a prolonged QT interval, which is consistent with torsades de pointes. It is characterised by rapid, irregular QRS complexes, which appear to be twisting around the ECG baseline. Torsades de pointes is treated with IV magnesium sulphate, even when the serum magnesium levels are normal.

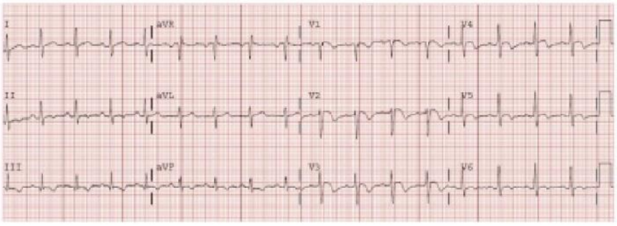
Immediate defibrillation is indicated in patients with pulseless torsades de pointes. This patient is conscious and has a pulse.

Synchronised DC cardioversion is indicated in patients with haemodynamically unstable torsades de pointes. This patient is haemodynamically stable.

IV amiodarone and IV lidocaine can be used to treat monomorphic ventricular tachycardia. Torsades de pointes is a polymorphic ventricular tachycardia.

Question 2 of 328

A 35-year-old man presents to his GP with a five day history of dyspnoea, cough, chest pain and palpitations. He describes the chest pain as being worse when he takes a deep breath in and the only relieving factor is ibuprofen. There has been no sputum production or haemoptysis. He has no significant past medical history of note. On examination his pulse is 102/min, blood pressure is 124/78 mmHg and oxygen saturations are 95% on room air. Auscultation of his chest is normal. An ECG is taken:



What is the most likely diagnosis?

A. Pulmonary embolism
B. Acute coronary syndrome
C. Pericarditis
D. Musculoskeletal chest pain
E. Viral pleurisy

A. Pulmonary embolism

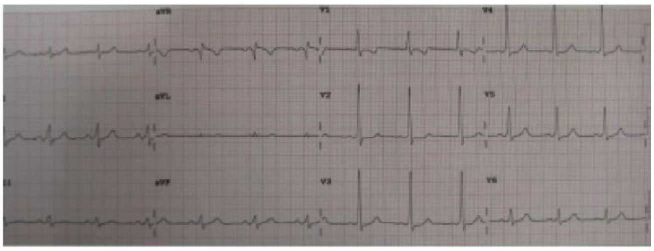
S1Q3T3 is a classic but uncommon ECG finding in PE

The unifying diagnosis here is pulmonary embolism. He has dyspnoea and pleuritic chest pain. The tachycardia and low oxygen saturations are also suggestive. Low oxygen saturations in someone who is otherwise fit and well are unusual and need explaining. Acute coronary syndrome, pericarditis, viral pleurisy and musculoskeletal chest pain would not normally drop your saturations unless complications develop.

The ECG however is the clincher - he has the classic S1Q3T3 changes.

Question 3 of 328

A 26-year-old female presents with a third episode of palpitations associated with shortness of breath and chest discomfort. She has no other past medical history, thyroid function tests unremarkable. She denies taking any recreational drugs and has no significant family history. Her ECG is as follows:



Which of the following drugs would be safe to administer immediately if she becomes tachycardic?

A. Adenosine
B. Digoxin
C. Diltiazem
D. Verapamil
E. Procainamide

E. Procainamide

The ECG demonstrates Wolff-Parkinson-White (WPW) syndrome, with a delta wave upstroke as a result of pre-excitation prior to the QRS complex. WPW is an atrioventricular re-entry tachycardia, activity, and subsequently stimulates a ventricular response.VVI pacemaker is incorrect.

A VVI pacemaker is a single lead pacemaker that senses and paces the ventricles only. The 'I' stands for 'inhibition' and indicates that if the pacemaker senses ventricular activity it inhibits its pacing output. VVI pacemakers, also known as ventricular demand pacemakers, are commonly used for ventricular bradycardia such as atrial fibrillation with a slow ventricular response.

AAI pacemaker is incorrect. An AAI pacemaker is a single lead pacemaker that senses and paces the atria only. The 'I' stands for 'inhibition' and indicates that if the pacemaker senses atrial activity it inhibits its pacing output. It is used only for patients with sinus node dysfunction.

Transcutaneous pacing would be used for patients who were unstable as a stop-gap measure whilst they awaited pacemaker insertion. This would not be appropriate in this case as we have a stable and well patient.

Ablation is used to prevent aberrant electrical signalling from causing arrhythmias. In the case of Mobitz type II, the issue is non-conduction rather than aberrant conduction, ablation is therefore not appropriate.

Question 7 of 328

A 28-year-old woman attended the emergency department and was subsequently referred to the cardiology team due to concerns about the risk of potential cardiac arrhythmia. The patient presented to the emergency department due to ongoing nausea and vomiting secondary to hyperemesis gravidarum. The patient stated she was 10 weeks pregnant with her first child and had been suffering from these symptoms for the past 6 weeks. Clinical records indicated the patient had also attended the emergency department 3 weeks previously with the same presenting complaint.

On the initial occasion the patient had presented to the emergency department with hyperemesis gravidarum, she had been rehydrated with intravenous fluids and prescribed vitamin B6 and ginger capsules four times daily on the advice of the obstetric team. The patient reported that this treatment had given her only a modest improvement in her symptoms and she had stopped taking these medications after a few days. Subsequently, she had attended an out-of-hours medical centre and been prescribed ondansetron (4 mg three times daily). The patient had found a more significant benefit from ondansetron and had been taking it regularly over the past 2 weeks. In addition to her symptoms of nausea and vomiting, the patient reported feeling tired, lethargic and dehydrated.

Haemoglobin	123 g / dL
Mean cell volume	84.9 fl
White cell count	11.7 x 10>3 / microlitre
Platelets	187 x 10>3 / microlitre
Urea	9.0 mmol / L
Creatinine	82 micromol / L
Sodium	139 mmol / L
Potassium	3.6 mmol / L

Presentation	Relative date ofECG	Corrected QT interval / ms
2nd ED attendance for hyperemesis	Today	490
1st ED attendance for hyperemesis	3 weekspreviously	430
Unrelated ED attendance	4 yearspreviously	415

However, she denied experiencing any other symptoms, including palpitations or pre-syncopal episodes.

The patient's past medical history included a period of intravenous drug use in her early twenties. Three years previously the patient had successfully managed to stop her use of illicit drugs after being enrolled in a methadone treatment program. The patient was now on a consistent methadone dose of 80 mg once daily. There was no other significant past medical history and the patient took no other regular medications.

During the patient's assessment after attending the emergency department, concern was raised over a prolonged corrected QT interval on an ECG performed due to borderline hypokalaemia. The patient's ECG was otherwise unremarkable and was compared to previous ECGs the patient had undergone on her previous visits to the emergency department. Please see below for blood results and data from the patient's current and previous ECG.

With regard to the patient's prolonged corrected QT interval, what is the most appropriate strategy for managing her medications?

A. Continue both methadone and ondansetron and admit for cardiac monitoring
B. Stop both methadone and ondansetron
C. Continue both methadone and ondansetron and arrange outpatient ambulatory ECG
D. Continue methadone, stop ondansetron
E. Continue ondansetron, stop methadone

D. Continue methadone, stop ondansetron

The upper limit of normal for corrected QT interval is considered to be 450 ms in men and 460 ms in women. QT prolongation is associated withtorsades de pointes (TdP) and sudden cardiac death. However, the presence of a prolonged QT interval does not inevitably lead to TdP and TdP can occur in the presence of a normal QT interval. Each 10 ms increase in QT interval increases the risk of TdP by around 5-7 % and once corrected QT interval exceeds 500 ms, the risk of TdP is markedly increased and intervention is necessary.

The patient is taking 2 medications that are known to prolong the QT interval and these can be seen to have had an additive effect in prolonging the patient's QT interval. Specifically, the corrected QT interval increased from 430 ms when the patient was taking methadone to 490 ms when the patient was taking methadone and ondansetron. The normal baseline ECG suggests that the patient does not have a congenital condition causing QT prolongation. At the time of presentation, the patient's borderline hypokalaemia is a factor increasing the risk of TdP in the setting of her drug-induced prolonged QT interval.

Few recommendations exist for managing the risk of drug-induced prolonged QT interval. Expert advice suggests that when a QT prolonging drug is associated with a corrected QT interval of 480-500 ms in a woman (470-500 ms in a man), or when an increase of 60 ms or greater occurs, dose reduction or discontinuation is advised. If the corrected QT interval exceeds 500 ms then the drug should be discontinued and expert advice sought.

The use of methadone alone does not appear to cause a prolonged QT interval in this patient, whereas her QT interval increased by 60 ms following the addition of ondansetron. Given the importance to the patient's long-term health of adequate opiate replacement therapy, the risks associated with opiate withdrawal to a foetus in early pregnancy and the availability of other anti-emetic medications the most sensible course of action out of the available options is to discontinue ondansetron and continue methadone treatment.

Advice from the cardiology team could be sought to determine if the patient should be admitted for cardiac monitoring. The only available answer to include admission as an option also requires the patient to continue with both medications that prolong the QT interval and so is incorrect. Continuing both medications and discharging the patient for an outpatient ambulatory ECG (presumably to assess for TdP) is not an advisable management plan.

Question 8 of 328

A 65-year-old man is admitted with central chest pain that has been ongoing for two hours. It radiates to the left arm and is associated with nausea and vomiting. He has a past medical history of hypertension and diabetes which is diet controlled. He takes amlodipine and atorvastatin.

On examination his blood pressure is 147/89 mmHg and his heart rate is 110 beats per minute. His saturations are 96% on room air and he is afebrile His cardiovascular and respiratory examinations are unremarkable.

An ECG shows T wave inversion in leads I, V4, V5 and V6. Blood tests are as follows:

Hb	131 g/l	Na	136 mmol/l
Platelets	430 * 10 /l	K	4 mmol/l
WBC	8 * 10 /l	Urea	4 mmol/l
Neuts	6 * 10 /l	Creatinine	84 µmol/l
Lymphs	1 * 10 /l	CRP	41 mg/l
Eosin	0.3 * 10 /l	Trop	130 ng/l

He is diagnosed with non-ST elevation myocardial infarction and commenced on aspirin, clopidogrel and low molecular weight heparin. His pain settles with morphine and glyceryl trinitrate spray within an hour. The following day he is commenced on ramipril and bisoprolol. 3 days later he undergoes an uncomplicated angiogram with stunting of the left circumflex artery.

On systems reviews prior to discharge he comments that he has noticed a rash on his legs and has not been passing much urine despite drinking plenty of water. On examination he has a bluish lacey discolouration over his legs. He has no palpable bladder.

Repeat bloods are as follows:

Hb	12.1 g/l	Na +	137 mmol/l
Platelets	560 * 10 /l	K	5 mmol/l
WBC	10 * 10 /l	Urea	12 mmol/l
Neuts	7 * 10 /l	Creatinine	184 µmol/l
Lymphs	1.2 * 10 /l	CRP	60 mg/l
Eosin	1.5 * 10 /l		

What is the most likely cause of his symptoms and deranged blood tests?

A. Cholesterol embolism
B. Contrast nephropathy
C. Endocarditis
D. Hypovolaemia during NSTEMI
E. Newly started ACE inhibitor

A. Cholesterol embolism

This gentleman as developed an acute kidney injury following angiography. The combination of a lacey rash (livedo reticularis) and raised eosinophils points to a likely diagnosis of cholesterol embolism. Contrast induced nephropathy is also possible following angiography but is not associated with rash or eosinophilia. Although renal function may deteriorate after starting an ACE inhibitor, it is unlikely to cause this degree of derangement so quickly. As the angiogram was uncomplicated, hypovolaemia is unlikely. Endocarditis would be unusual in the absence of fevers and other systemic signs.

Question 9 of 328

A 52-year-old man is asymptomatic but concerned about his risk of having a heart attack. His 58-year-old brother died of a myocardial infarction 2 months ago. He has a past medical history of hypertension, for which he takes perindopril and amlodipine. His sister takes tablets for diabetes and high blood pressure. He successfully quit smoking over 1 year ago and drinks approximately 2 units of alcohol per day.

On examination, his blood pressure is 130/70 mmHg and BMI is 32 kg/m2.
Investigations:

haemoglobin	16g/dL (13-18)
mean corpuscular volume	90 fL (80-96)
serum cholesterol	5.0 mmol/L (<5.2)
serum LDL cholesterol	3.1 mmol/L (<3.36)
serum HDL cholesterol	1.55 mmol/L (>1.55)
fasting serum triglycerides	1.6 mmol/L (0.451.69)
haemoglobin A1c	5.4% (4.06.0)
serum aspartate aminotransferase	19 U/L (131)
plasma thyroid-stimulating hormone	2.4 mU/L (0.45.0)
estimated glomerular filtration rate (MDRD)	85 mL/min (>60)

His QRISK2 score estimates a 13% 10 year risk of myocardial infarction or stroke.

In addition to discussing lifestyle modifications, what treatment should you offer this patient?

A. Aspirin
B. Atorvastatin
C. Indapamide
D. Metformin
E. Omega-3-polyunsaturated fatty acid supplements

B. Atorvastatin

The 2014 NICE guidelines: Cardiovascular disease: risk assessment and reduction, including lipid modification have lowered the UK threshold for offering a statin for primary prevention to a 10% or greater 10year risk of developing cardiovascular disease, according to the QRISK2 score. The previous recommendation advised offering a statin to patients with a 20% 10-year risk. A high-intensity low cost statin should be 1st line in this context, such as atorvastatin 20mg.

Prescribing aspirin for primary prevention is controversial, whether the benefits in primary prevention outweigh the bleeding risks is unclear, therefore most guidelines do not recommend aspirin in primary prevention. Unlike in secondary prevention where the benefits usually outweigh the risks.

The NICE guidelines advise NOT prescribing omega-3-fatty acid supplements for primary or secondary prevention of cardiovascular disease, as they have not shown to be efficacious in reducing cardiovascular risk in meta-analyses. However, guidance continues to encourage consuming regular portions of oily fish, the 2014 nice guidance specifically advises: 2 portions of fish per week, including a portion of oily fish.

Metformin would be inappropriate in this patient as he is not diabetic.

This patients hypertension is well controlled, therefore indapamide would be inappropriate

Question 10 of 328

A 60-year-old man presents to the emergency department with crushing central chest pain. The pain came on suddenly approximately one hour ago. A 12-lead ECG reveals >2mm of ST elevation in all anterior and lateral leads. The nearest centre offering primary angioplasty is 140 minutes away. There is no contraindication to thrombolysis.

In addition to standard acute coronary syndrome treatment (analgesia, aspirin, a heparin and a P2Y12 inhibitor), what is the best management for this patient?

- A. Immediate transfer for acute angioplasty
- B. Non-urgent angioplasty
- C. Thrombolysis
- D. Thrombolysis and immediate transfer for acute angioplasty
- E. Thrombolysis and non-urgent angioplasty

D. Thrombolysis and immediate transfer for acute angioplasty

The recommended door-to-balloon aka door-to-device time for primary percutaneous coronary intervention (PCI) is within 90 minutes. However, many centres do not have provision for primary PCI and are unable to transfer patients to a centre that does in a timely manner.

The NORDISTEMI TRIAL (NORwegian study on DIstrict treatment of STElevation Myocardial Infarction) demonstrated that in centres with a long transfer time (mean transfer time was 130 minutes in this trial) for PCI, patients with STEMI should initially receive thrombolysis, with subsequent immediate transfer for PCI. For patients with STEMI this approach reduced the rate of death, re-infarction, or stroke at 12 months compared to patients treated with a conservative, ischaemia-guided approach (e.g thrombolysis alone or thrombolysis with rescue angioplasty).

Question 11 of 328

A 73-year-old gentleman sees his GP with progressive shortness of breath. He can now walk 10 yards before stopping to catch his breath and he is unable to lie flat. He sleeps upright in his armchair and has stopped sleeping in his bed over the last three months.

He has known hypertension and has had two previous myocardial infarctions. On examination, his apex beat is displaced to the 7th intercostal space in the left mid-axillary line and there are crepitations in the two lung bases. His JVP is raised at 5cm and there is bilateral leg oedema.

Troponin	<20 ng/ml
B-natriuretic peptide	14,000 ng/L (normal range 0-200)
Chest X-ray	cardiomegaly and increased alveolar shadowing in the perihilar areas
ECG	QRS 110ms, large volume complexes in chest leads

Which intervention is proven to reduce mortality in this case?

- A. Cardiac Resynchronisation Therapy (CRT)
- B. Digoxin
- C. Furosemide
- D. Ramipril
- E. Coronary artery bypass graft

D. Ramipril

ACE inhibitors offer prognostic benefit in chronic heart failure

Of the above options, ramipril is proven to reduce mortality in congestive cardiac failure through adjusting remodelling of the heart.Digoxin and furosemide can help symptoms but no trial shows a benefit in mortality. CRT can be helpful in cases of ventricular dyssynchrony but the QRS is narrow and this gentleman would not benefit from it. Coronary artery bypass grafting may be useful if this gentleman had symptoms of angina but he does not

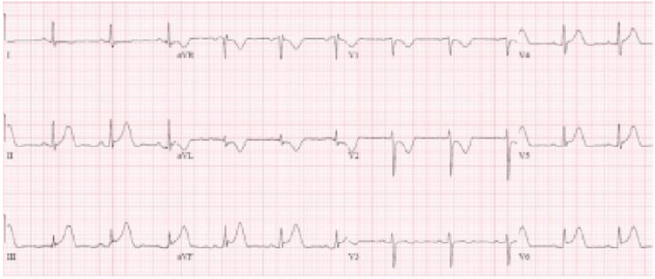
Question 12 of 328

A 75-year-old male presents to the emergency department with central crushing chest pain which has been ongoing for 4 hours. It is associated with shortness of breath.

Blood results are as follows:

Hb	125 g/L	Male: (135-180)Female: (115 - 160)
Platelets	424 * 10 /L	(150 - 400)
WBC	14.6 * 10 /L	(4.0 - 11.0)
Na	135 mmol/L	(135 - 145)
K	4.4 mmol/L	(3.5 - 5.0)
Urea	7.8 mmol/L	(2.0 - 7.0)
Creatinine	134 µmol/L	(55 - 120)
Troponin	8422 ng/L	(< 15)

An ECG is performed:



What is the most likely diagnosis?

- A. Anterolateral STEMI
- B. Inferolateral STEMI
- C. Myocarditis

D. Pericarditis
E. Posterior STEMI

B. Inferolateral STEMI

The ECG demonstrates ST elevation in the inferior (II, III, and aVF) and lateral leads (V5-6) confirming a diagnosis of an inferolateral STEMI. ST depression in V1-2 is suggestive of an associated posterior infarction. This constellation of ECG abnormalities is typically produced by occlusion of the proximal circumflex artery.

Anterolateral STEMI would present with ST elevation in the anterior (V1-V4) and lateral leads.

Posterior STEMI presents with reciprocal changes in the anterior leads including horizontal ST depression and a dominant R wave in V2.

Both myocarditis and pericarditis present with global concave ST elevation. The troponin is usually normal in pericarditis and raised in myocarditis.

Question 13 of 328

A 66-year-old lady attended a cardiology clinic for follow up after a recent hospital admission with pulmonary oedema. She continued to experience significant shortness of breath at rest with exercise tolerance that was limited to a few steps around the house. She had a previous medical history of hypertension, diabetes and myocardial infarction 5 years previously treated with percutaneous coronary intervention. Her medications comprised of bisoprolol 10mg, ramipril 10mg, furosemide 80mg twice daily, spironolactone 25mg, simvastatin 40mg, metformin 1g twice daily and aspirin 75mg. On examination she appeared breathless, the jugular venous pressure was elevated at 7cm, there were bibasal fine crepitations and moderate pitting oedema to her knees. Her heart rate was 68 beats per minute and blood pressure was 95/65mmHg.

Investigations:

Haemoglobin	115 g/L
White cell count	5.6 x10^9/L
Platelet Count	268 x10^9/L
Serum sodium	132mmol/L
Serum potassium	4.3mmol/L
Serum urea	6.7mmol/L
Serum creatinine	68micromol/

Electrocardiogram: normal sinus rhythm. Rate 65 beats per minute. QRS duration 155ms. No acute ST changes.

Echocardiography: left ventricular ejection fraction of 30%. No significant valvular abnormalities.

Coronary angiography: Patent left anterior descending coronary artery stent. Minor diffuse coronary artery disease.

What is the most appropriate next management step?

A. Increase dose of furosemide
B. Cardiac resynchronisation therapy
C. Coronary artery bypass graft
D. Start amlodipine
E. Home oxygen

B. Cardiac resynchronisation therapy

This lady has ischaemic heart disease with New York Heart Association (NYHA) class 4 heart failure and is on maximal medical therapy. Her ECG shows a wide QRS complex which suggests ventricular dyssynchrony (i.e. The left and right ventricle are not beating at the same time). Resynchronisation of the ventricles with cardiac resynchronisation therapy with a paced device (CRT-P) involves simultaneous stimulation of both ventricles to reduce dyssynchrony and therefore increase cardiac output.

Nice supports the use of CRT-P in patients with:

- NYHA class three or four symptoms
- They are in normal sinus rhythm with either → QRS duration of 150 ms or longer estimated by standard electrocardiogram (ECG)
- → QRS duration of 120-149 ms estimated by ECG and mechanical dyssynchrony that is confirmed by echocardiography.
- They have a left ventricular ejection fraction of 35% or less.
- They are receiving optimal pharmacological therapy.

In this selected group of patients, it has been shown to improve symptoms by a reduction of about one NYHA classification, reduce hospitalisations and reduce mortality. These devices can be fitted with an implantable cardiac defibrillator (i.e. A CRT-D where the D stands for defibrillator as opposed to a CRT-P where P stands for paced and thus this device lacks the defibrillator component) for primary or secondary prophylaxis against ventricular dysrhythmias.

Increasing her dose of furosemide is unlikely to significantly improve her symptoms and is, therefore, an incorrect answer. Coronary artery bypass grafting has greater benefit than percutaneous coronary intervention at treating multivessel disease, however, this lady has disease of the left anterior descending artery which has been previously treated and only minor disease in her other coronary vessels; therefore this is an incorrectanswer. She is hypotensive and therefore starting amlodipine is inappropriate. Home oxygen can be used for the palliation of shortness of breath in heart failure and is not appropriate in this case.

Question 14 of 328

A 55-year-old with previous rheumatic heart disease aged 32 presents with an 18-month history of exertional dyspnoea. An initial echo demonstrated significant raised pulmonary arterial pressures of 77 mmHg, she undergoes a left and right heart catheter with results as follows:-

Oxygen saturations		
Right atrium	8 mmHg	71%
Right ventricle	39/8 mmHg	71%
Pulmonary artery	45/12 mmHg	71%
Capillary wedge	20 mmHg	93%
Left ventricle	165/11 mmHg	93%
Aorta	90/58 mmHg	

What is the most likely diagnosis?

A. Aortic stenosis
B. Mitral stenosis
C. Aortic stenosis and mitral stenosis

D. Aortic stenosis and pulmonary hypertension
E. Aortic stenosis, mitral stenosis, pulmonary hypertension

E. Aortic stenosis, mitral stenosis, pulmonary hypertension

The key to questions regarding saturations and cardiac catheters is to spot the 'step-up' in oxygen saturation and abnormalities in gradients across valves. There are no 'step-ups' in oxygen saturations, demonstrating no shunts. However, you will note that the pulmonary arterial pressure is greater than the normal one-fifth of systolic measurements; hence pulmonary hypertension is present. In addition, there is a greater than 25mmHg gradient across the aorta valve, demonstrating moderate aortic stenosis. Lastly, the capillary wedge pressure is equivalent to the left atrial pressure, which should also be the same as the left ventricular diastolic pressure. A normal mitral valve expects less than 5mmHg pressure difference. Using these inferences, the mitral valve gradient is calculated by the capillary wedge pressure of 20mmHg (same as the left atrial pressure) minus the diastolic left ventricular pressure of 11mmHg: the 9mmHg difference thus also demonstrates mitral stenosis.

Question 15 of 328

A 72-year-old female presents with left chest pain associated with sweating in her hands and nausea. Her past medical history includes T2 diabetes mellitus, hypertension and hypercholesterolaemia, with her regular medications including metformin 850mg BD, gliclazide 40mg OD, ramipril 10mg, amlodipine 5mg and atorvastatin 40mg ON. On examination, her heart sounds are normal with a pansystolic murmur. Her ECG demonstrates ST depression in V2 to V5. Her BMs have ranged between 6 and 14 mmol/L since her admission 4 hours ago.

How should you manage her diabetic medications?

A. No changes to medication
B. Increase metformin to 850mg TDS
C. Increase gliclazide to 40mg BD
D. Actrapid PRN 4 units when BM >11mmol/L
E. Stop all medications, start insulin sliding scale

E. Stop all medications, start insulin sliding scale

Patients with acute coronary syndrome demonstrate significantly lower mortality rates at one year when treated with tight glycaemic control than without (19% vs 26%). Metformin has the potential to induce lactic acidosis in the context of any kind of ischaemia. An insulin based regime is recommended by the European Society of Cardiology , on the basis of results from DIGAMI trial . PRN actrapid should never be prescribed routinely.

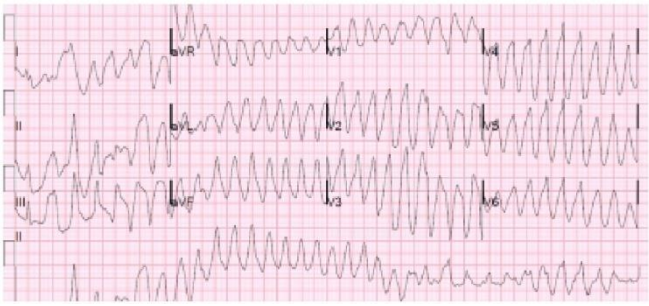
Question 16 of 328

A 25-year-old man presents with a one-week history of feeling generally unwell, reporting myalgia, nausea and weakness.

His observations are:
Respiratory rate: 24/min

- Blood oxygen saturation: 97% on room air
- Heart rate: 109bpm
- Blood pressure: 91/56mmHg
- Temperature: 37.7 C
- GCS 15/15

The patient is given intravenous anti-emetics and a bolus of crystalloid fluid. Whilst the fluid is running, the patient begins to complain of palpitations, chest pain and shortness of breath. An ECG is performed and is shown below.



What electrolyte abnormality is most likely to have precipitated this rhythm?

A. Hypercalcaemia
B. Hyperkalaemia
C. Hypermagnesaemia
D. Hypokalaemia
E. Hyponatraemia

D. Hypokalaemia

The ECG shows polymorphic ventricular tachycardia. This is shown by the broad complexes, and the QRS complexes varying in amplitude, axis and duration. The variation in QRS complexes is due to having multiple ventricular foci.

Hypokalaemia is the correct answer. Symptoms of myalgia and weakness are in keeping with hypokalaemia. Hypokalaemia can cause prolonged QT which can precipitate polymorphic ventricular tachycardia, as seen in the ECG. Hypokalaemia is the only electrolyte abnormality listed above that can precipitate prolonged QT.

Hypercalcaemia is the incorrect answer. Hypocalcaemia can precipitate prolonged QT.

Hyperkalaemia is the incorrect answer. As above, hypokalaemia can precipitate prolonged QT.

Hypermagnesaemia is the incorrect answer. Hypomagnesaemia can precipitate prolonged QT.

Hyponatraemia is the incorrect answer. Sodium derangement is not associated with prolonged QT and polymorphic ventricular tachycardia.

Question 17 of 328

A 25-year-old woman has recently been diagnosed with Marfan's syndrome. She has no other known diagnosis. She undergoes an echocardiogram which demonstrates severe aortic regurgitation, significant aortic root dilatation and a left ventricular ejection fraction of 70%. She is asymptomatic and has no family history of aortic dissection.

What is the most appropriate management of her cardiac problem?

A. Follow-up in six months

B. ACE inhibitor
C. Exercise testing
D. Offer surgery if planning to become pregnant
E. Referral for aortic valve replacement

E. Referral for aortic valve replacement

The correct answer is referral for aortic valve replacement. Surgery for aortic regurgitation is indicated if there is significant enlargement of the ascending aorta, severe regurgitation with symptoms or if severe with an ejection fraction of less than 50%. ACE inhibitors can be useful when there is hypertension, when surgery is contraindicated or when ventricular dysfunction persist following surgery. Exercise testing is more useful in aortic stenosis and follow-up would be acceptable if the aortic root was not dilated.

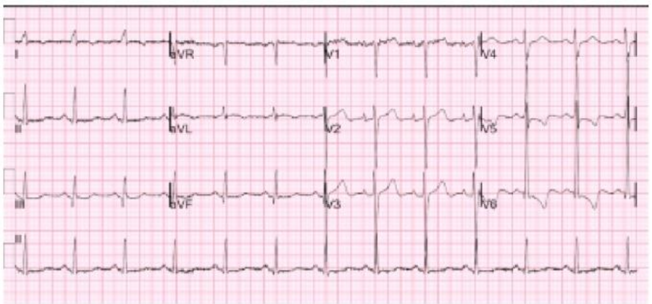
Question 18 of 328

A 52-year-old is brought from the renal outpatient clinic to the emergency department (ED) after appearing very short of breathing having walked up the stair. His breathlessness was associated with some mild, generalised chest discomfort, but the patient puts this down to a recent chest infection he has just recovered from.

When assessed in the ED the patient's breathlessness has improved and he denies any further chest discomfort. He reports he has been experiencing more frequent similar episodes, gradually increasing in severity over several months. He reports he recently had a productive cough with coryzal symptoms for the last 3-4 days but he feels it is improving. On questioning he confirms his symptoms of breathlessness are often worse during and post these chest infections.

He has a past medical history of chronic renal artery stenosis and resultant poorly controlled hypertension for which he is on multiple medications including an ACE inhibitor, beta-blocker and a diuretic.

An ECG is performed as seen below.



What is the patient's most likely diagnosis?

A. Brugada syndrome
B. Hyperkalaemia
C. Left ventricular hypertrophy
D. Pericarditis
E. Wellen's syndrome

C. Left ventricular hypertrophy

This patient has presented with symptoms and typical ECG changes in keeping with left ventricular (LV) hypertrophy. The thickening of the cardiac muscle is most likely a result of chronic uncontrolled hypertension, hence the prolonged, progressive history. LV hypertrophy results in signs and symptoms of LV failure including breathlessness, angina and reduced exercise tolerance. The patient's ECG demonstrates left ventricular hypertrophy with ST elevation in V2-3, without reciprocal lead changes and the combination of the S wave in V1 with the R wave in V5 or V6 clearly exceeding 40 mm.

Brugada syndrome is a genetic cardiac disorder resulting in electrical activity disorders and not structural issues. Features include syncope and sudden cardiac death. There are several types of Brugada syndrome with variation seen on ECG however the only potentially diagnostic ECG abnormality is of coved ST-segment elevation in 2 or more of V1-3 followed by a negative T wave. This is classical of Brugada type 1 syndrome and is commonly known as Brugada sign.

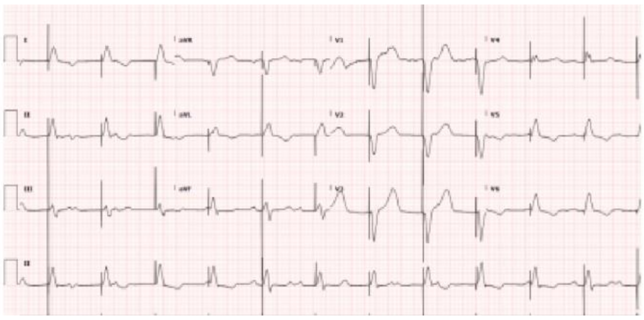
There is no clear reason why this patient would be hyperkalaemia. Although he has renal impairment it is not indicated that he has endstage renal failure or that he is on renal replacement therapy therefore hyperkalaemia would not be expected. Common ECG changes noted in hyperkalaemia included peaked T waves, P wave widening/flattening, PR prolongation progressing to the bradyarrhythmias and conductions blocks. No clear features of hyperkalaemia can be seen on this patient's ECG.

Pericarditis is inflammation of the tissue surrounding the heart and can be due to infections. Patients normally present with pleuritic, constant chest pain and fevers. Although this patient has a very recent chest infection, pericarditis normally develops a few weeks post the resolution of infection as it is an immune response and not a direct result of the infection itself. ECG findings associated with pericarditis include widespread concave ST elevation and PR depression which are not present on this patient's ECG.

Wellen's syndrome is the ECG pattern of biphasic or deeply inverted T waves in the chest leads V2-3. It is highly specific for critical stenosis ofthe left anterior descending (LAD) artery and therefore is normally seen in patients presenting with ischaemic like symptoms. You would expect the patient's chest pain to be continuous and to be more severe if he was experiencing stenosis of the LAD.

Question 19 of 328

A 62-year-old man is recovering from an aortic valve replacement via median sternotomy in the high-dependency unit. You are called to see him overnight as he is experiencing chest pain, worse on breathing. An ECG is performed and displayed below. He had temporary trans-venous pacing wires inserted during the procedure.



What does the ECG show?

A. AAI pacing
B. Complete heart block with loss of capture
C. DDD pacing
D. Myocardial infarction
E. VVI pacing

E. VVI pacing

Although atrial pacing wires are commonly inserted following cardiac surgery, it is particularly important to insert ventricular wires following aortic valve surgery due to the significantly higher incidence of complete heart block postoperatively. The ECG shows pacing spikes immediately preceding QRS complexes, indicating ventricular (VVI) pacing with good capture. This patient has a degree of heart block underlying his paced rhythm, hence the discordance between the p waves and the QRS complexes, and the reason why the patient is paced.AAI pacing would show pacing spikes prior to p waves, and in instances of heart block as shown here there would be abnormal or potentially absent conduction to the ventricles. As the pacing spikes are associated with the QRS complex here, AAI cannot be the mode in use.

Although this patient may have complete heart block, there is good capture as shown by a 1:1 ratio between pacing spikes and subsequent QRS complexes. Therefore loss of capture is an incorrect answer.

DDD pacing refers to the pacing of both the atria and ventricles. Although this can be useful post-operatively to increase cardiac output, it is not being used here. DDD pacing would either show pacing of the atria (pacing spikes before p waves) or tracking of the patient's intrinsic atrial rate (ventricular pacing spikes that follow p waves and immediately precede QRS complexes).

Pain is very common following a sternotomy and is classically sharp and pleuritic. It can be difficult to interpret ischaemia on a paced ECG however the Sgarbossa criteria is a useful tool for this. As this patient does not fit this criterion, and the pain is classical for sternotomy pain rather than cardiac, myocardial infarction is unlikely.

Question 20 of 328

A 68 year-old man with a history of ischaemic heart disease and type 2 diabetes mellitus is 2 days post right curative hemicolectomy for bowel malignancy.

He has developed chest pain and shortness of breath. The surgical team have requested an urgent medical review.

On examination the patient appears distressed and is complaining of chest pain and breathlessness. Capillary refill time is 5 seconds centrally. The pulse rate is 200bpm and the blood pressure is 87/45mmHg. Oxygen saturations are 92% on fiO2 0.4 via Venturi mask.

There are crackles to the midzones bilaterally on chest auscultation.

A 12-lead ECG reveals a regular broad complex tachycardia with a monomorphic waveform.

Blood results from the morning reveal:

Hb	129 g/l
Platelets	564 * 10 /l
WBC	15.8 * 10 /l
Na	128 mmol/l
K	3.3 mmol/l
Urea	12.9 mmol/l
Creatinine	101 µmol/l
Bilirubin	27 µmol/l
ALP	125 u/l
ALT	34 u/l
Albumin	36 g/

What is the most appropriate initial management?

A. Adenosine 6mg IV
B. Amiodarone 300mg IV
C. Magnesium sulphate 2g IV
D. Synchronized DC shock
E. Metoprolol 5mg IV

D. Synchronized DC shock

In the context of a tachyarrhythmia, a systolic BP < 90 mmHg → DC cardioversion

This question outlines a case of ventricular tachycardia with adverse features including shock and heart failure.

According to the Resuscitation Council guidelines, if a patient with a tachyarrhythmia is unstable (i.e. has adverse features likely to be caused or made worse by the tachycardia - shock, syncope, heart failure or myocardial ischaemia) synchronised cardioversion is the treatment of choice.

If cardioversion fails to restore sinus rhythm, and the patient remains unstable, the next step is to give amiodarone 300 mg IV over 10-20 min and re-attempt electrical cardioversion. The loading dose of amiodarone may be followed by an infusion of 900 mg over 24 h.

If the patient is conscious, cardioversion should be carried out under sedation or general anaesthesia in the presence of an anaesthetist.

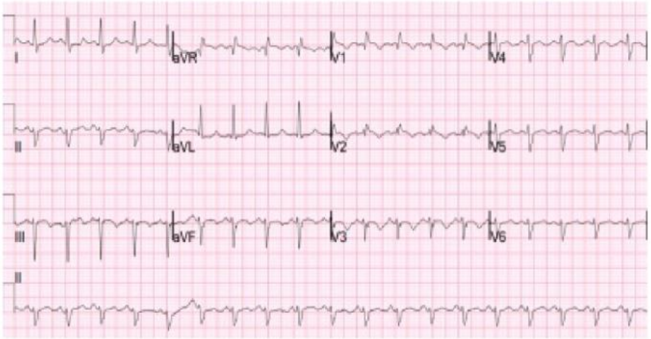
Question 21 of 328

You are called to review a 68-year-old who is complaining of chest pain on the ward. She was admitted 6 days ago after having a stroke which has left her with a mild degree of right-sided hemiparesis. She has some difficultly articulating the nature of the pain but describes it as central.

Her past medical history includes hypertension and hypothyroidism. She has not had a stroke or transient ischaemic attack previously.

On examination, the heart rate is 102/min, blood pressure 122/78 mmHg, respiratory rate 22/min and oxygen saturations 94% on room air.

The nurse recorded an ECG:



What is the most likely diagnosis?

A. Subarachnoid haemorrhage
B. Inferior myocardial infarction
C. Hypokalaemia
D. Posterior myocardial infarction
E. Pulmonary embolism

E. Pulmonary embolism

S1Q3T3 is a classic but uncommon ECG finding in PE

This woman is at risk of a pulmonary embolism given her relative immobility following the stroke.

The tachycardia and tachypnoea are also signs associated with pulmonary embolism.

The ECG shows some of the features that may be associated with pulmonary embolism (sinus tachycardia, RBBB, right ventricular strain). Other features such as the left axis deviation are atypical.

Question 22 of 328

A 76-year-old woman presents to the acute medical assessment unit with a two-month history of palpitations. She reports regularly feeling her heart racing, occasionally associated with pre-syncope. She denies dyspnoea, syncope and chest pain.

She has a medical history significant for asthma, for which she takes regular inhaled beclometasone dipropionate and formoterol, and montelukast, with as required salbutamol. There is no other medical history.

Her observations are:

A. Respiratory rate: 20/min
B. Blood oxygen saturation: 98% on room air
C. Heart rate: 116bpm
D. Blood pressure: 135/68mmHg
E. GCS: 15/15
F. Temperature: 37.4 C

An ECG is performed which shows atrial fibrillation. Blood tests are unremarkable. A transthoracic echocardiogram shows no evidence of valvular heart disease and no evidence of congestive cardiac failure.

What is the most appropriate management?

A. Apixaban + bisoprolol
B. Apixaban + digoxin
C. Apixaban + diltiazem
D. Warfarin + bisoprolol
E. Warfarin + diltiazem

C. Apixaban + diltiazem

Apixaban + diltiazem is the correct answer. This patient has atrial fibrillation with no valvular abnormalities. Her CHA DS -VASc score is 3 and therefore qualifies for anticoagulation with a direct-acting oral anticoagulant (DOAC) such as apixaban. If this patient had mitral stenosis, weighed over 120kg, or had a contraindication to a DOAC, warfarin would be considered. This patient would be suitable for rate control rather than rhythm control - the two-month history suggests this is not acute, there is no clear reversible cause and there is no evidence of heart failure. This patient's asthma is a contra-indication for a betablocker, as beta-blockers can increase airway reactivity. Calcium channel blockers are second-line for rate control in atrial fibrillation. Therefore apixaban + diltiazem is the correct combination of medications.

Apixaban + bisoprolol is the incorrect answer. Beta-blockers are the first-line treatment for rate control in atrial fibrillation, but are relatively contraindicated in asthma - given this patient is on fourth-line treatment for her asthma, beta-blockers are best avoided in this scenario.

Apixaban + digoxin is the incorrect answer. Digoxin is the third-line treatment for rate control in atrial fibrillation. Therefore a calcium channel blocker such as diltiazem is more appropriate. Digoxin would be more appropriate if this patient had evidence of heart failure due to the negative inotropic effects of calcium channel blockers.

Warfarin + bisoprolol is the incorrect answer. DOACs, such as apixaban, are used first line when anticoagulation is indicated for atrial fibrillation. Warfarin is recommended if there is evidence of mitral stenosis however, this patient's echocardiogram has no evidence of valvular disease. As above, diltiazem is more appropriate than bisoprolol due to this patient's asthma.

Warfarin + diltiazem is the incorrect answer. As above, a DOAC is preferable to warfarin in this situation. Diltiazem is the correct drug for rate control in this scenario.

Question 23 of 328

A 78-year-old female was referred to the clinic after several episodes of chest pain. The chest pain came on exertion and was relieved by sitting down. The pain was centrally located and described as crushing in character.

She has a past medical history of hypercholesterolaemia, systemic lupus erythematosus and hypertension.

A myocardial technetium (99mTc) MIBI scan demonstrates the following results:

At rest Normal perfusion Under stress Lateral perfusion defect

What is the most likely explanation of these results?

A. Myocardial infarction of left circumflex artery territory
B. Myocardial infarction of left anterior descending coronary artery territory
C. 70% stenosis of left circumflex artery
D. 70% stenosis of left anterior descending coronary artery
E. Libman-Sacks endocarditis

D. 70% stenosis of left anterior descending coronary artery

If a cardiac MIBI scan shows that the defect is present on stress, but not at rest, this is suggestive of a reversible defect (e.g. myocardial ischaemia secondary to coronary artery stenosis)

A myocardial perfusion (MIBI) scan is carried out to investigate the blood supply to the heart. By comparing the rest with stress images, any areas of ischaemia can classified as reversible or fixed.If the defect is present on stress, but not at rest, then this is suggestive of a reversible defect (e.g. myocardial ischaemia secondary to coronary artery stenosis).

As demonstrated in this case, the defect is present only on stress, which is indicative of a reversible defect such as coronary artery stenosis.

The lateral part of the heart is usually supplied by the left circumflex artery, making this the best answer.

Question 24 of 328

A 46-year-old man is referred to the acute medical assessment unit with a fever of 38.9 C. He reports a three-week history of general malaise, reduced appetite, intermittent sweating, and occasional rigors. The patient has no medical history and has had no previous operations or procedures. He denies any drug allergies.

o

His observations are: Respiratory rate: 24/min

Oxygen saturation: 95% on room air Heart rate: 105bpm BP: 101/62mmHg Temperature: 38.9 C GCS: 15/15

On examination, the patient has a loud early diastolic murmur over the right second intercostal space. Splinter haemorrhages are noted in three of his fingernails.

What is the most appropriate antibiotic to start?

- A. Amoxicillin
- B. Benzylpenicillin
- C. Flucloxacillin
- D. Vancomycin + low-dose gentamicin
- E. Vancomycin + low-dose gentamicin + rifampicin

A. Amoxicillin

IV amoxicillin is the empirical treatment of choice in native valve endocarditis

Fever + a new cardiac murmur raises suspicion of infective endocarditis. A loud early diastolic murmur over the right second intercostal space is suspicious for aortic regurgitation secondary to endocarditis. This will cause the patient's shortness of breath.

Amoxicillin is the correct answer. Given the patient has no medical or surgical history, he should be treated for native valve endocarditis by starting high-dose intravenous amoxicillin. Ideally, six sets of blood cultures should be sent, with as many as possible before the initiation of treatment (although this should not delay treatment if the patient is unstable).

Benzylpenicillin is the incorrect answer. Benzylpenicillin is the treatment for infective endocarditis caused by a fully sensitive Streptococcus organism.

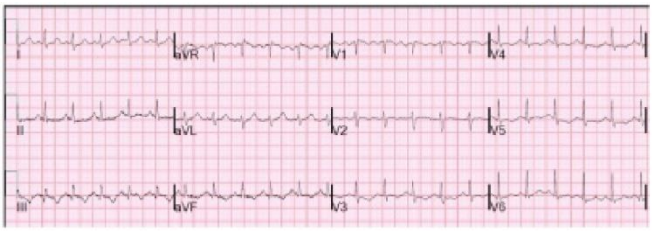
Flucloxacillin is the incorrect answer. Flucloxacillin is used to treat infective endocarditis caused by a fully sensitive Staphylococcus (usually Staphylococcus aureus.)

Vancomycin + low-dose gentamicin is the incorrect answer. Vancomycin + low-dose gentamicin can be used for infective endocarditis in penicillin-allergic patients or patients with methicillinresistant Staphylococcus aureus (MRSA) infective endocarditis.

Vancomycin + low-dose gentamicin + rifampicin is the incorrect answer. Vancomycin + low-dose gentamicin + rifampicin is the treatment for infective endocarditis on a prosthetic valve. This patient has no history of valve replacement.

Question 25 of 328

A 19-year-old student is brought to the Emergency Department by her friends. Around one hour ago she 'collapsed' whilst playing hockey. Her friends describe her complaining that she felt light-headed and then 'fainting' to the ground. She lost consciousness for a few seconds before returning to normal quite quickly. There is no past medical history of note other than the use of Microgynon 30 (a combined oral contraceptive pill). For the past 4-5 days the patient has experienced shortness-of-breath and a central chest pain which is worse when she coughs. On examination her pulse is 120/min, blood pressure 96/60 mmHg and chest auscultation reveals scattered wheezes. An ECG done on admission is shown below:



What is the most likely diagnosis?

- A. Hypertrophic obstructive cardiomyopathy
- B. Vasovagal attack
- C. Acute coronary syndrome
- D. Pulmonary embolism
- E. Asthma attack

D. Pulmonary embolism

It is usual taught that pulmonary embolism (PE) presents with pleuritic chest pain, dyspnoea and haemoptysis. This combination of symptoms is however only found in less than 20% of cases. As PE is a potentially lifethreatening condition it is important to be aware of the wide variety of symptoms and signs that may accompany cases.A lot of patients who develop a PE have risk factors. There is one present in this case - combined oral contraceptive pill use. Tachycardia is also a common sign.

It would be unusual to develop an asthma attack with no previous history of asthma. Occasional wheezes are a relatively common finding in patients following a pulmonary embolism.

The ECG shows a sinus tachycardia and a partial S1Q3T3 - the S wave is not particularly convincing.

Question 26 of 328

A 72-year-old man presents to the emergency department with palpitations. An ECG confirms atrial fibrillation. His CHA2DS2-VASc score is 2 and he is commenced on bisoprolol and edoxaban.

He is referred and attends for catheter ablation, which he undergoes successfully. Post-procedure ECG confirms sinus rhythm.

He is followed up 4 weeks later in the clinic and a repeat ECG confirms the maintenance of sinus rhythm.

What is the best course of action at this stage?

- A. Continue edoxaban for a further 4 weeks then stop
- B. Continue edoxaban for a further 8 weeks then stop
- C. Continue edoxaban long-term
- D. Discontinue edoxaban
- E. Switch to aspirin

C. Continue edoxaban long-term

Patients who've had a catheter ablation for atrial fibrillation still require long-term anticoagulation as per their CHA DS -VASc score

The correct answer is continue edoxaban long-term. Although the ablation has been successful and rhythm control has been achieved, patients in this setting have the same stroke risk as those remaining in atrial fibrillation. Anticoagulation should, therefore, be continued longterm.

Continue edoxaban for a further 4 weeks then stop is incorrect. Continue edoxaban for a further 8 weeks then stop is incorrect.

Question 27 of 328

A 43-year-old lady with a history of schizophrenia presents to the emergency department with palpitations, headaches and dizziness for 3 days. She says that she can feel her heart pounding after which she becomes dizzy and feels faint. She has noted these bouts about three to four times per day. She does not suffer from diabetes and is not hypertensive.

Regarding her headaches, she has had them for a long period of time and is quite convinced that there is some sort of sinister problem with her brain, although her doctors do not believe so. She has a younger sister who has had epilepsy for the last 15 years.

She was diagnosed as having a UTI 4 days ago which is currently being treated with ciprofloxacin. Her medication history includes olanzapine and occasional paracetamol for her headaches.

On examination, her pulse was 135 bpm with an irregular rhythm. Blood pressure was 90/60mmHg. Her systemic examination was unremarkable.

Attachment to a cardiac monitor revealed runs of ill sustained polymorphic tachycardia. She was immediately given IV lidocaine to which there was no response.

Which is the most appropriate next step in management?

A. Immediate DC cardioversion
B. IV amiodarone
C. IV flecainide
D. IV magnesium sulphate
E. IV labetalol

D. IV magnesium sulphate

The scenario above is an acquired long QT syndrome secondary to both ciprofloxacin and olanzapine. Patients with long QT syndromes developsyncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). Episodes may terminate spontaneously which is usual, but may also evolve into fatal ventricular fibrillation. The corrected QT interval in between the arrhythmia is usually >0.5s.

Question 28 of 328

A 78-year-old gentleman is seen in clinic with long-standing heart failure with reduced ejection fraction (32%). He has had numerous admissions this year with heart failure decompensation and is wondering if there is anything else that you can do for him. You review his ECG, which is in sinus rhythm with a heart rate of 64/min with a QRS of 136 msec and left bundle branch block. His blood pressure is: 98/55 mmHg. You also review his bloods:

Hb	128 g/L	Male: (135-180)Female: (115 - 160)
Platelets	335 * 10 /L	(150 - 400)
WBC	6.8 * 10 /L	(4.0 - 11.0)
Na	136 mmol/L	(135 - 145)
K	4.7 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	126 µmol/L	(55 - 120)

He is currently on carvedilol 25 mg BD, enalapril 10 mg BD, bumetanide 2 mg BD, aspirin 75 mg, ivabradine 2.5 mg BD.

What alteration to this gentleman's management could potentially decrease this gentleman's probability of being re-admitted?

A. Arrange cardiac resynchronisation therapy-pacemaker (CRT-P) implantation
B. Increase ivabradine
C. Increase bumetanide
D. Increase spironolactone
E. Initiate sacubitril/valsartan

A. Arrange cardiac resynchronisation therapy-pacemaker (CRT-P) implantation

Cardiac resynchronisation therapy can be used in patients with a QRS duration of >130 msec and LBBB morphology to improve symptomatology

The European society of cardiology (ESC) guidelines have highlighted the importance of cardiac resynchronisation in patients with heart failure. Evidence exists indicating the importance of implantation of such devices in patients with intraventricular delay with most studies focusing on the impact of left bundle branch block. The stronger evidence related CRT-P in such patients include left bundle branch block (LBBB) and QRS >150 msec; however the presence of LBBB on its own provided that the QRS is longer than 120 msec is associated with improved mortality/morbidity. There is no evidence of benefit from CRT for patients with QRS <120 msec, while the presence of right bundle branch block (RBBB) implies a worse disease state where CRT may not necessarily benefit such patients.

The possibility of altering medications in this case remains attractive however one should be aware of the potential of introducing detriment to the patient in doing so.

This patient is already tolerating a relatively slow heart rate therefore ivabradine could potentially cause further slowing.

He is borderline hypotensive with raised potassium (making the possibility of increasing spironolactone less favourable.

Sacubitril/valsartan remains an option, however the ESC guidelines dictate that in such cases with noted intraventricular delay the first port of call would be the provision of cardiac resynchronisation therapy.

Question 29 of 328

A 54-year-old presents to his general practitioner with fatigue and shortness of breath. He has no significant past medical history and is on no medications.

Clinical examination reveals a mid-diastolic murmur, louder in expiration, and a loud S1. There is no peripheral oedema. The jugular venous pressure is not raised and chest auscultation is normal. The pulse is regular.

From the options listed, what is the most likely diagnosis?

A. Tricuspid stenosis
B. Moderate mitral stenosis
C. Mitral regurgitation
D. Severe mitral stenosis
E. Mitral valve prolapse

B. Moderate mitral stenosis

Mitral stenosis - loud S1

Moderate mitral stenosis is the correct answer. This is characterized by a mid-diastolic murmur with a loud S1 heart sound. Left-sided murmurs are louder in expiration. The most common cause is rheumatic fever. This may not always be apparent from the history if it happened in childhood.

Tricuspid stenosis is incorrect. This can also cause a diastolic murmur with a loud S1. However, it will be louder in inspiration as it is a rightsided murmur.

Mitral regurgitation is incorrect. This causes a pansystolic murmur and a soft S1.

6% 63% 6% 19% 6%Severe mitral stenosis is incorrect. In severe mitral stenosis, the S1 is soft due to lack of pliability and acoustic dampening from a severely calcified valve. Furthermore, there are no obvious clinical features of severe mitral stenosis such as evidence of pulmonary hypertension or right heart failure.

Mitral valve prolapse is incorrect. This murmur may be associated with a 'click' but it is a systolic murmur.

Question 30 of 328

A 37-year-old lady presents to the Emergency Department with a 4-hour history of sudden-onset chest pain and dyspnoea. Her symptoms started whilst she was watching television. She describes the pain as severe, central and non-radiating. She denies a cough and haemoptysis. Her past medical history is unremarkable and her only regular medication is the oral contraceptive pill.

Examination reveals an overweight lady with a pulse rate of 114/min and a blood pressure of 101/63mmHg. Her respiratory rate is 22 and her oxygen saturations are 94% on air. Her JVP is 5cm but there is no peripheral oedema. Auscultation of the chest reveals scattered crepitations. Her heart sounds are dual with no audible murmurs. A portable chest x-ray shows clear lung fields.

A short time later the patient's blood pressure is recorded at 90/59mmHg. A bedside echocardiogram shows elevated right ventricular filling pressures with evidence of strain.

What is the most appropriate management?

A. Surgical embolectomy
B. Alteplase
C. Unfractionated heparin
D. Aspirin, clopidogrel, low molecular weight heparin and furosemide
E. Low molecular weight heparin

B. Alteplase

This patient has presented with chest pain and dyspnoea in combination with tachycardia, hypotension, and hypoxia. This, in combination with the history of obesity and exogenous oestrogen, makes PE the most likely diagnosis. It is worth noting that PE does not always present with pleuritic chest pain and crepitations and wheeze can often be heard on auscultation.The management of PE depends on its classification. Intermediate risk (previously 'sub-massive') PE, characterised by the presence of myocardial injury or right ventricular dysfunction, is treated with low molecular weight heparin. High risk (previously 'massive') PE is characterised by shock or hypotension and is best treated by thrombolysis. The patient in this vignette has become hypotensive and would thus benefit from thrombolytic therapy.

Surgical embolectomy is an effective treatment for massive PE but only a few centres are able to offer this. Consequently, thrombolysis remains the preferred first-line treatment for massive PE.

Acute MI with cardiogenic shock would be a key differential, but the clear lung fields on chest x-ray and lack of peripheral oedema go against this. Therefore, treatment with aspirin and clopidogrel would not be beneficial.

Question 31 of 328

A 58-year-old man attends cardiology clinic with retrosternal chest pain on exertion. He reports the onset of his symptoms when walking more than 50 metres on flat ground or when playing on the floor with his grandchildren. The symptoms have been present at the current level for at least the previous 9 months and the patient denied any episodes of pain at rest. The patients GP has previously attempted treatment with bisoprolol and amlodipine but both medications were discontinued for unwanted effects (bradycardia and ankle swelling respectively). The patient has no other medical history except for hypercholesterolaemia. Regular medications are aspirin 75 mg daily and pravastatin 10 mg daily with nitrate spray and sildenafil used as required. He is formerly a heavy smoker but managed to quit the previous year.

Clinical examination is unremarkable with no evidence of cardiac failure. Blood pressure is 102 / 72 mmHg.

Please see below for the results of previous investigations.

Electrocardiogram: sinus rhythm at 58 beats per minute; borderline left axis deviation; normal QRS complex; non-specific lateral ST segment abnormalities; normal T waves.

Transthoracic echocardiogram: normal valvular function; no regional wall motion abnormality; ejection fraction 55-60 %.

Urea 6.7 mmol / L
Creatinine 80 micromol / L
Sodium 138 mmol / L
Potassium 4.1 mmol / L

Cardiac stress magnetic resonance imaging: significant evidence of ischaemia in the region of the lateral left ventricle; estimated 20 % of LV myocardium with significant evidence of ischaemia.

What is the most appropriate management of the patients chest pain?

A. Ticagrelor
B. Nicorandil
C. Percutaneous coronary intervention
D. Ivabradine
E. Long-acting isosorbide mononitrate

C. Percutaneous coronary intervention

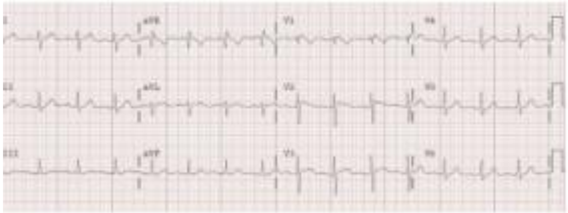
The role of percutaneous coronary intervention in stable angina is a controversial subject. Revascularisation has not been shown to reduce mortality or the rate of myocardial infarction in such patients. However, sub-group analysis of randomised controlled trials suggests some benefit for the above outcomes over medical therapy. Therefore, ESC guidelines recommend offering revascularisation to patients with stable coronary artery disease and ischaemia in > 10 % of the left ventricle. Also, the patient's age and lack of co-morbidities make this the most appropriate strategy in this case.

The other possible answers that are options for the medical management of stable angina are contraindicated in this patient. Both nicorandil and ISMN are contra-indicated for this patient due to his borderline hypotension and use of sildenafil. Ivabradine is contraindicated due to the patient's history of bradycardia. It is also not used in patients with moderate to severe angina symptoms as has been shown to increase the rate of cardiovascular events in such patients.

Ticagrelor is a P2Y12 adenosine diphosphate receptor blocker with utility as an oral antiplatelet agent.

Question 32 of 328

A 30-year-old man is admitted to the Emergency Department after suffering a 'blackout' whilst at work. His colleagues report him collapsing without warning whilst waiting at the water machine. There has never happened before and he is normally fit and well. On examination blood pressure is 102/68 mmHg, pulse 88/min, oxygen saturations 99% on room air and respiratory rate 16/min. An ECG is taken:



What is the most likely diagnosis?

A. Hypertrophic obstructive cardiomyopathy
B. Anterior myocardial infarction
C. Long QT syndrome type 1
D. Arrhythmogenic right ventricular dysplasia
E. Brugada syndrome

E. Brugada syndrome

The ECG shows a Brugada pattern, most marked in V1, which has an incomplete RBBB, a downsloping ST segment and an inverted T wave.

Question 33 of 328

A 66-year-old gentleman presented to the Emergency Department complaining of severe abdominal pain for the last day. The pain occurred immediately after he ate, and he described it as an excruciating pain in the central of his abdomen. It lessened during periods of starvation, and a few hours ago passed dark red blood within his stools on one occasion, leading to his admission. His bowels were otherwise normal and prior to the pain had been relatively well in himself. In addition, he had been feeling unwell for the last couple of days, complaining of night sweats and tiredness. His past medical history comprised angina which had been confirmed three days ago upon undergoing a coronary angiogram which demonstrated diffuse triple vessel disease. In addition, he had a past medical history of hypertension, hypercholesterolaemia and COPD. He smoked 30 cigarettes per day for 25 years and did not consume alcohol and was taking amlodipine 5mg OD, ramipril 7.5mg OD, bisoprolol 2.5mg OD, atorvastatin 20mg OD, beclometasone 200mcg BD & salbutamol PRN.

Examination revealed an obese gentleman with a temperature of 37.6ºC, a heart rate of 118bpm, respiratory rate of 18/min and blood pressure of 142/82 mmHg. Examination of his cardiovascular and respiratory systems revealed the absence of his pedal pulses bilaterally, with no evidence of ulceration or gangrene. A purpuric rash was noted on both halluxes.

Initial investigations revealed the following results:

Hb	122 g/l
Platelets	132 * 10 /l
WBC	11.2 * 10 /l
Eosinophils	0.6 * 10 /l
ESR	52 mm/hr
Na	136 mmol/l
K	5.8 mmol/l
Urea	13.3 mmol/l

Creatinine	158 µmol/l
CRP	38 mg/l

Urinalysis protein +, otherwise nil else

ECG: heart rate 118bpm sinus tachycardia, Q waves II/III/aVR
Blood results 4 weeks ago (done by GP when titrated ramipril)

Na +	142 mmol/l
K +	4.8 mmol/l
Urea	6.6 mmol/l
Creatinine	86 µmol/l

Which one of the following is the most likely diagnosis?

A. Contrast induced nephropathy
B. Cholesterol atheroemboli
C. Polyarteritis nodosa
D. Infective endocarditis
E. Microscopic polyangiitis

B. Cholesterol atheroemboli

Cholesterol atheroemboli may occur as a consequence of manipulation of arteries lined with atheromatous plaques, such as a result of angiography. Cholesterol emboli may involve multiple organs, as a result of widespread dissemination. Signs and symptoms often involve a lowgrade inflammatory response with fever and malaise. Cutaneous emboli lodging may affect the distal extremities (as is evident here by a vasculitic rash). Organs involved include the respiratory system, gastrointestinal system (as is manifest by mesenteric ischaemia here) and the renal system resulting in renal failure, with often proteinuria upon urinalysis. A key differential is contrast nephropathy, but cutaneous involvement and other organ involvement is very uncommon and the renal failure tends to be transient.

Question 34 of 328

A 68 year old gentleman with a past medical history of type 2 diabetes mellitus and hypertension attends the Emergency Department complaining of general malaise and feeling unwell. He had undergone successful primary coronary intervention (PCI) post myocardial infarction 5 weeks previously. He has a temperature of 38.2 degrees Celsius, blood pressure 164/87 mmHg and the doctor notes a lacy reticular rash extending over his legs.

Hb	12.2g/dl
Eosinophils	1.2 * 10 /l9
WBC	14.5 * 10 /l9
Urea	8mmol/l
Creatinine	142µmol/l

What is the most likely cause of his symptoms?

A. Allergic rash to contrast
B. Infected femoral site
C. Cholesterol embolus
D. Infective endocarditis
E. Polyarteritis nodosa

C. Cholesterol embolus

This is a classic story for a cholesterol embolus post an invasive arterial procedure, whereby a plaque has been ruptured and there is lodging of debris in small/medium arteries causing mechanical occlusion, inflammation and end-organ damage. Patients may have the lacy reticular rash of livedo reticularlaris and this, together with acute renal failure and an eosinophilia should lead the clinician to consider this diagnosis.

Patients tend to present with non-specific symptoms such as fever, weight loss and myalgia for weeks to months before developing endorgan damage or stroke.

The current mainstay of treatment is supportive.

Question 35 of 328

A 70-year-old man is admitted to hospital with chest pain associated with nausea and vomiting. There was no recent history of shortness of breath or wheeze. ECG demonstrated inferolateral ST depression and troponin was significantly elevated at 12 hours after symptom onset.

His past medical history included chronic obstructive pulmonary disease, hypertension and a previous MI 3 years previously. The patient reported two exacerbations of his COPD within the last 18 months, neither of which required hospital admission. He had never required intubation or non-invasive ventilation due to his COPD.

Regular medications included bendroflumethiazide 2.5 mg OD, inhaled tiotropium 18 microg OD and inhaled salbutamol 100 microg PRN. There were no known drug allergies. The patient was a retired engineer, an exsmoker and lived independently with his wife.

The initial impression was of non-ST elevation myocardial infarction and treatment was initiated with aspirin, clopidogrel, fondaparinux, ramipril and atorvastatin. The patient subsequently mobilised pain-free on the ward and was discharged home with a plan for outpatient stress echocardiogram.

Recent pulmonary function tests are given in the table below.

Forced vital capacity	105 % predicted
Forced expiratory volume (1s)	67 % predicted
FVC / FEV1	64 % predicted

Transthoracic echocardiogram: no valvular abnormality; mild-moderate systolic impairment of lateral left ventricle; normal right ventricular function

What is the most appropriate plan for beta-blockade therapy for this patient?

A. Low dose bisoprolol with slow up-titration of dose
B. Low dose carvedilol with slow up-titration of dose
C. Low dose bisoprolol
D. Low dose carvedilol
E. Beta-blockade therapy inappropriate

A. Low dose bisoprolol with slow up-titration of dose

NICE guidance on secondary prevention following myocardial infarction includes a recommendation for beta-blocker therapy as it has been shown to reduce mortality. In patients with COPD or asthma, betablockers have sometimes been held due to concerns abut precipitating bronchospasm. However, a large observational study has shown substantial survival benefits for patients with COPD who have suffered a myocardial infarction in starting beta-blockers during hospital admission (adjusted hazard ratio 0.50).

Therefore, beta-blocker therapy is indicated in this patient. The most appropriate choice is the cardio-selective agent (bisoprolol) started at a low dose and slowly up-titrated as per current guidance.

Question 36 of 328

A 34-year-old Afro-Caribbean female presents to the heart failure clinic and would like your advice. Two years ago, she presented with shortness of breath and reduced exercise tolerance three months after her second pregnancy. A chest x-ray demonstrated bilateral alveolar shadowing. The symptoms were improved following diuresis and she remains on an ACE inhibitor, beta blocker and furosemide. She continued to be followed up with echocardiograms, her last demonstrating LV EF of 30%. She would like to try for a third pregnancy.

What would you recommend regarding pregnancy?

A. Pregnancy is advised as normal
B. Pregnancy is not advised
C. Pregnancy is advised with increased ACEi
D. Pregnancy is advised with monthly echocardiograms
E. Pregnancy is advised with increased beta blockade

B. Pregnancy is not advised

The patient presented with peripartum cardiomyopathy, defined as LV ejection fraction reduction in the last month or within 5 months of giving birth, particularly prevalent in black women. The key in this question is whether LV dysfunction was persistent. The last echo demonstrates persistent reduced EF and in this case, pregnancy is NOT advised due to the risk of LV failure progression and significant mortality risk of up to 20% . Those with recovered LV function are likely to also experience deterioration in LV function but pregnancy is not absolutely contraindicated.

Treatment is similar to that of heart failure, consisting of beta blockade, diuretics but avoidance of ACEi due to the risk to the foetus or breastfeeding baby. Digoxin may also have a greater role in PPCM than in classic heart failure. The degree of residual LV dysfunction is difficult to predict but a number of factors appear to be predictive of worse outcomes, namely LVEF <30% at presentation, raised troponin I and LV end-diastolic diameter > 6cm.

Question 37 of 328

A 67-year-old woman with mitral regurgitation attends a cardiology clinic for her regular follow-up. She is asymptomatic, can perform daily tasks, and has a New York heart association (NYHA) functional classification of I. On examination, there is a loud rumbling pan-systolic murmur heard at the apex. She is noted to be in atrial fibrillation, which was not previously known. A recent echocardiogram shows an ejection fraction of 62% with mild left atrial dilatation.

Which feature from the history would be the strongest indication for referral for valve replacement?

A. Age
B. Atrial fibrillation
C. Left atrial dilatation
D. Loud murmur
E. Ejection fraction <65%

B. Atrial fibrillation

New AF in mitral regurgitation -> refer for mitral valve replacement

Surgery is indicated in patients with signs of left ventricular (LV) dysfunction. If LV function is preserved, surgery should be considered in asymptomatic patients with new-onset atrial fibrillation (AF) or pulmonary hypertension. Severe symptomatic mitral regurgitation is also an indication for replacement.

AF develops as a consequence of increased left atrial pressures (due to backflow), resulting in left atrial dilatation. This is, therefore, the strongest indication for replacement.

In the absence of AF, left atrial dilatation only becomes an indication for replacement if it is significant (≥60 mL/m2 body surface area [BSA]).

Age itself is not an indication for mitral valve replacement. Age will be considered alongside other co-morbidities and functional baseline when deciding if she will be suitable for a general anaesthetic for the procedure.

The loudness of a murmur typically doesn't impact the decision to proceed with surgery.

Ejection fraction becomes relevant in asymptomatic patients. 2017 European society of cardiology (ESC) and European association for cardiothoracic surgery (EACTS) guidelines for the management of valvular heart disease suggest that replacement should be considered in asymptomatic patients with an ejection fraction of less than 60%.

Question 38 of 328

An 84-year-old man comes for review. Four weeks ago an opportunistic blood pressure reading was taken and recorded as 150/92 mmHg. You therefore arranged ambulatory blood pressure monitoring (ABPM) along with a standard hypertension work-up. You did not calculate his 10-year cardiovascular risk on account of his age. The following results were obtained:

Na +	141 mmol/l
K +	4.2 mmol/l
Urea	6.5 mmol/l
Creatinine	101 µmol/l
Total cholesterol	4.9 mmol/l
HDL cholesterol	1.2 mmol/l
Fasting glucose	5.5 mmol/l

Urine dipstick was normal. The ECG showed sinus rhythm, 72 bpm and first degree heart block.

The daytime average blood pressure reading was 145/80 mmHg.

What is the most appropriate course of action?

A. Diagnose stage 1 hypertension and advise about lifestyle changes
B. Start treatment with an ACE inhibitor
C. Start treatment with a calcium channel blocker
D. Start treatment with a thiazide-like diuretic
E. Repeat the ABPM

A. Diagnose stage 1 hypertension and advise about lifestyle changes

Stage 1 hypertension is defined by an ABPM reading of >= 135/85 mmHg, with stage 2 hypertension having a cut-off of >= 150/95 mmHg

This patient therefore has stage 1 hypertension. As they are > 80 years they do not need treatment

Question 39 of 328

An 80-year-old lady is brought in by ambulance having been found unresponsive by her granddaughter.

She has a history of vascular dementia, hypertension, atrial fibrillation and mild congestive cardiac failure. She lives alone and is visited by her granddaughter, who is her main carer, once per day. Her granddaughter states she has been more confused recently, finding it hard to know the time of day, or whether she had had meals or medications, but has been otherwise well.

She takes aspirin 75mg once daily, amlodipine 5mg once daily, bisoprolol 5mg once daily, ramipril 2.5mg once daily, and simvastatin 40mg at night.

On examination in the Emergency Department she has a Glasgow coma scale of 10. Her heart rate is 30/min and her blood pressure is 68/36 mmHg. Her saturations are 95% on 60% oxygen with a respiratory rate of 30 breaths per minute.

She has a regular heart rhythm and normal first and second heart sounds with an S3 gallop. Her jugular venous pressure is raised at 6 cm and she has pitting oedema to the knees. Her capillary refill is 4 seconds and she is peripherally cool. She has fine bibasal crepitations in both lungs. Her abdomen is soft and non-tender. Her temperature is 36.1ºC.

Her ECG shows complete heart block with a ventricular rate of 30/min. Her QRS complexes are broad with a right bundle branch block pattern. There are signs of left ventricular hypertrophy but no T wave or ST segment abnormalities.

She is given 3mg of IV atropine in 500 mcg boluses but the heart rate remains 30/min with a blood pressure of 67/40 mmHg.

Which further medication is most likely to result in a sustained improvement in her heart rate?

A. Aminophylline
B. Dopamine
C. Glucagon
D. Isoprenaline
E. Noradrenaline

C. Glucagon

This lady has severe bradycardia and is haemodynamically unstable with signs of acute heart failure.

Resus Council Advanced Life Support Guidelines advocate atropine, up to 3mg, as the initial therapy for this. However, this lady has not responded to this initial measure. The next step would be a choice of a number of drugs or transcutaneous pacing.

This lady had a history of dementia with a recent cognitive decline, lives alone and is on both a beta blocker and a calcium channel blocker. This combined with new complete heart block on her ECG, without signs of new ischaemia, is suggestive of an accidental overdose. This makes glucagon the most logical choice to further improve heart rate as it bypasses the beta blockade.

Aminophylline, isoprenaline and dopamine are all other recommended second-line drugs in unstable bradycardia, along with adrenaline (rather than noradrenaline) and could be administered if there is an unsatisfactory response to glucagon.

In practice, it is worth preparing to transcutaneously pace while furthers drugs are given, in case the bradycardia proves refractory to all medication or the clinical condition worsens further.

Question 40 of 328

A 72-year-old gentleman with previous myocardial infarctions and coronary stents presents with increased leg swelling. This has arisen over two weeks. He is still well and denies any shortness of breath but has an occasional cough at night time. He is managed on aspirin, clopidogrel, ramipril and atorvastatin.

On further questioning, he admits feeling cold at times and feels low in energy for which his GP started citalopram 2 months ago.

He denies any further chest pains. His previous records indicate disease in the circumflex and right coronary arteries previously. He admits to drinking 20-30 units of alcohol a week.

On examination, he appears well. He has bilateral pitting leg oedema with extension into the sacral area. There is a pansystolic murmur over the sternum. His abdomen is soft with a tender hepatomegaly. There is no splenomegaly, ascites, jaundice or asterixis. His JVP is raised with a double flicker pattern which peaks up to the ear lobe on the second flicker. Current blood pressure is 145/86 mmHg.

Hb	95 g/l	Na	137 mmol/l
Platelets	476 * 10 /l	K	4.2 mmol/l
WBC	10.2 * 10 /l	Urea	4.3 mmol/l
Neuts	9.6 * 10 /l	Creatinine	112 µmol/l
Bilirubin	4 µmol/l	ALP	165 u/l
ALT	103 u/l	Albumin	34 g/l
PT 12.2 (14-18 normal range)	APTT 34 (34-42 normal range)		

Chest x-ray	enlarged cardiac shadow, no effusions or lung field shadowing
ECG	sinus rhythm with Q waves in V2-V3
Urine dip	2+ protein, no blood

What is the likely diagnosis?

F. Tricuspid regurgitation
G. Cirrhosis
H. Hypertensive cardiomyopathy
I. Nephrotic syndrome
J. Hypothyroidism

A. Tricuspid regurgitation

Prominent V waves on JVP → tricuspid regurgitation

This gentleman presents with leg swelling and a raised JVP which are both signs of right-sided heart failure. Nephrotic syndrome and hypothyroidism can present with swollen legs but would not have a raised JVP. Hypertensive cardiomyopathy does occur but there is no mention of previous hypertension and we do not know his blood pressure. He does not have cirrhosis given there are no signs of liver disease and his clotting is normal though his LFTs are raised. This leaves tricuspid regurgitation as the answer. He most likely developed this after suffering a posterior myocardial infarction. The gaint V waves on JVP are a classic sign.

Question 41 of 328

A 45-year-old woman develops severe central chest pain. An ECG in the ambulance shows ST segment elevation in leads: I, aVL, V2-6. Shortly after she arrives in hospital the pain resolves and a second ECG is entirely normal. She has had three similar episodes of chest pain in the past. All episodes of chest pain have come on at rest. Blood pressure is 140/80 mmHg, heart rate is 90 beats per minute and hearts sounds are normal. She underwent coronary angiography following a previous episode of chest pain three weeks ago, which showed no significant coronary artery disease. An echocardiogram is normal.

What is the likely diagnosis?

A. Acute anterolateral myocardial infarction
B. Crescendo angina
C. Da Costas syndrome
D. Prinzmetal's variant angina
E. Takotsubo cardiomyopathy

D. Prinzmetal's variant angina

This woman is likely to be suffering from Prinzmetal's variant angina. Classically her pain occurs at rest and the ECG demonstrates ST segment elevation that disappears as the pain abates. Normal coronary angiography supports this diagnosis, however in many Prinzmetal's angina patients there is co-existing coronary artery disease. Symptoms and ECG changes are unlikely to be reproduced with exercise testing in Prinzmetal's angina.

Prinzmetal's angina is caused by coronary artery spasm, however the underlying pathophysiology causing spasm is not currently well understood. In some patients it is associated with other vasospastic disorders such as Raynaud's phenomenon.

The main stay of treatment is:

- Avoiding precipitants of spasm such as smoking.
- Calcium channel blockers, nitrates and/or nicorandil.

Question 42 of 328

You are reviewing in clinic a 67-year-old man who has type 2 diabetes. His glycaemic control is reasonable with metformin therapy; the latest HbA1c is 54 mmol/mol (7.1%). A few weeks ago he was noted to have a clinic blood pressure reading of 152/90 mmHg. A 24 hour blood pressure monitor was requested. The report shows his average blood pressure was 142/88 mmHg.

What is the most appropriate course of action?

A. Do nothing for now, monitor his blood pressure regularly
B. Start an ACE inhibitor
C. Start a calcium channel blocker
D. Repeat the 24 hour blood pressure monitor in 4-8 weeks time
E. Request an ultrasound of his kidneys

B. Start an ACE inhibitor

Hypertension in diabetics - ACE inhibitors/A2RBs are first-line regardless of age

This patient has stage 1 hypertension as defined by NICE. He should however be treated because he has underlying diabetes.

The first-line treatment for a patient aged > 55 years is a calcium channel blocker. However, in patients with diabetes ACE inhibitors are used firstline due to their renoprotective effect.

Question 43 of 328

A 54-year-old woman presents to her general practitioner complaining of a rash on her chest, face and upper arms. The rash is transient and seems to mostly occur in the summertime. She has a past medical history of hypertension, palindromic rheumatism and heart failure with preserved ejection fraction. She takes amlodipine, furosemide, indapamide and hydroxychloroquine.

On examination, there is a maculopapular rash on her chest and distal forearms. It is not itchy.

Bloods tests:

Antinuclear antibody	negative

What is the likely explanation for her symptoms?

A. Furosemide
B. Hydroxychloroquine
C. Indapamide
D. Solar urticaria
E. Systemic lupus erythematosus

C. Indapamide

Thiazides may cause photosensitivity

Indapamide is correct. Thiazide diuretics are a well-recognised cause of a photosensitive rash. The patient's rash occurs mostly in the summertime and on sun-exposed areas and is therefore consistent with this reaction.

Furosemide is incorrect. This is mainly associated with bullous skin reactions.

Solar urticaria is incorrect. The rash, in this case, is maculopapular and non-pruritic and therefore is not consistent with a diagnosis of urticaria.

Hydroxychloroquine is incorrect. This medication is associated with rashes but is actually used to treat conditions associated with photosensitive rashes and is therefore not the likely cause.

SLE is incorrect. Photosensitive rashes are common in lupus. However, the ANA is negative, which makes a diagnosis of the systemic form of lupus, overwhelmingly unlikely.

Question 44 of 328

A 40-year-old man with a family history of sudden cardiac death presents to the emergency department with palpitations and exerciseinduced syncope. There is no associated chest pain.

An ECG is performed and shows T wave inversion in leads V1-3.

What is the most likely underlying pathology is in this case?

A. Arrhythmogenic right ventricular cardiomyopathy
B. Brugada syndrome
C. Hypertrophic obstructive cardiomyopathy
D. Myocardial infarction
E. Pulmonary embolism

A. Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy - T wave inversion in V1-3

The ECG described here is characteristic of **arrhythmogenic right ventricular cardiomyopathy**, which is consistent with the clinical presentation. This includes T wave inversion in precordial leads V1-3 (possibly also V4/5). Epsilon waves (small waves noted immediately after the QRS complex) are also seen in some cases however is not as common as T wave inversion.

Brugada syndrome is a potential hereditary cause of sudden cardiac death but is associated with ST elevation in leads V1-3 rather than the changes described here.

Hypertrophic obstructive cardiomyopathy is another potential cause of sudden cardiac death but is associated with increased precordial voltages and Q waves in the lateral, and possibly inferior, leads rather than the changes described here.

This presentation would be atypical for a **myocardial infarction**. The patient is not suffering from chest pain and instead reports symptoms that are more consistent with an arrhythmic cause. Although a myocardial infarction cannot be ruled out from this information alone, arrhythmogenic right ventricular cardiomyopathy is a more likely explanation, particularly given the strong family history.

Pulmonary emboli are associated with RV strain which can cause the T wave changes in V1-4 described in this question, however, epsilon waves are characteristic of arrhythmogenic right ventricular cardiomyopathy. Pulmonary emboli may also be associated with sinus tachycardia, right bundle branch block, right axis deviation, and S1Q3T3 patterns.

Question 45 of 328

A 52-year-old female who you see regularly represents to your clinic after routine blood tests having recently been started on ramipril for her hypertension. Her blood pressure (BP) prior to initiation of ramipril in the clinic was 145/98mmHg and her baseline creatinine prior to treatment was 100umol/L. On review today her clinic BP appears to be well controlled at 132/84mmHg and her bloods show her creatinine has risen to 125umol/L.

What is the most appropriate step in the management of her hypertension?

A. Reduce dose of ramipril
B. Continue current dose of ramipril
C. Stop ramipril and consider angiotensin receptor blocker
D. Increase dose of ramipril
E. Stop ramipril and consider calcium channel blocker

B. Continue current dose of ramipril

The main consideration here is the renal function, which shows an increase in creatinine by 25%. Her BP appears to be well controlled. The BNF recommends the angiotensin-converting enzyme inhibitors should only be stopped if the creatinine increases by 30% or eGFR falls by 25% or greater. This lady's results are within these limits and have shown good effect. It would therefore be pertinent to continue the ramipril at the current dose and monitor the renal function as per normal protocol

Question 46 of 328

A 43-year-old with no past medical history presents with 6 months history of exertional dyspnoea. Her echocardiogram demonstrated impaired right ventricular function with raised pulmonary arterial pressure of 78 mmHg, good systolic function and ejection fraction 80%. Right and left heart catheterisation demonstrated pulmonary arterial hypertension, with a pulmonary arterial pressure of 49/24 mmHg, V/Q scan demonstrated no chronic pulmonary emboli, CTPA no acute emboli, ultrasound abdomen no portal hypertension. She is at present comfortable at rest but is short of breath on minimal activity.

What is the appropriate management?

A. No treatment
B. IV prostaglandin
C. Oral sildenafil
D. Atrial septostomy
E. List for lung transplantation

C. Oral sildenafil

Treatment for pulmonary arterial hypertension is guided by the patients functional status. Patients with class I require no symptomatic treatment while those with class IV require prostaglandins, most likely intravenously. This patient is short of breath on minimal activity and hence functional class III. Endothelin receptor antagonists (e.g. bosentan) or phosphodiesterase V inhibitor (e.g. sildenafil) are appropriate. Atrial septostomy and lung transplantation are appropriate for patients who remain symptomatic at functional class IV despite intravenous prostaglandins and subsequent combination therapy with bosentan or sildenafil.

Question 47 of 328

A 47-year-old woman presents to an endocrinology clinic with a history of hypertension. She was first diagnosed with hypertension following a private health assessment 8 years ago and at that time underwent testing to exclude any secondary causes of her hypertension. She was subsequently commenced on ramipril, which was up titrated to 10mg. When her blood pressure remained above 150/100mmHg, her GP added amlodipine 10mg and then bendroflumethiazide 2.5mg. During a recent medication review, the patient's blood pressure was noted to be 170/100mmHg. Her GP thus referred her to the endocrine team for a reconsideration of secondary hypertension. On questioning, she denies any chest pain, palpitations, change in vision, or symptoms consistent with postural hypotension. She has no family history of hypertension, does not smoke and drinks minimal alcohol.

On clinical examination, heart sounds are normal and chest clear, abdomen soft and non-tender with no organomegaly.

Her test results are as follows:

Na	137 mmol/L	(135 - 145)
K	4.6 mmol/L	(3.5 - 5.0)
Bicarbonate	25 mmol/L	(22 - 29)
Urea	3.0 mmol/L	(2.0 - 7.0)
Creatinine	68 µmol/L	(55 - 120)
Hba1c	48 mmol/mol	(42-47)

CT chest / abdomen / pelvis shows no abnormalities. Echocardiogram demonstrates left ventricular hypertrophy only. Urine dip:

Blood	-
Protein	-
Glucose	Trace

Given the diagnosis, which of the following agents would be most appropriate?

A. Doxazosin
B. Spironolactone
C. Furosemide
D. No indication for further anti-hypertensive agents
E. Candesartan

A. Doxazosin

Poorly controlled hypertension, already taking an ACE inhibitor, calcium channel blocker and a standard-dose thiazide diuretic. K+ > 4.5mmol/l - add an alpha- or beta-blocker

This patient has resistant hypertension, that is to say, hypertension which has not responded to three appropriately dosed anti-hypertensive agents. Effective treatment is needed given her evidence of end-organ damage (left ventricular hypertrophy).

Given that her potassium is > 4.5, spironolactone would not be recommended.

Furosemide would not be recommended in a patient without evidence of heart failure prior to the trial of alpha blockade.

Candesartan should not be co-prescribed with ramipril.

Doxazosin (an alpha-blocker) or alternatively a beta-blocker, would be the most appropriate 4th line antihypertensive agent.

Question 48 of 328

A 64-year-old male presents sudden onset back pain while painting a wall at home, radiating to his left anterior chest and jaw, associated with nausea and vomiting. It appears to be constant for the past 3 hours since onset and is his first ever episode. His past medical history includes hypertension, hypercholesterolaemia and one previous transient ischaemic attack.

His ECG demonstrates left ventricular hypertrophy by voltage criteria and T-wave inversion in I, aVF and V5 and V6. On examination, his heart sounds are both present with a soft systolic murmur. The chest is clear and abdomen is soft and non-tender without a pulsatile mass. Both radial pulses are intact with no delay. There is a mild radio-femoral delay. His blood pressure is stable at 134/80 mmHg, heart rate 124/min and sinus rhythm. His bloods are as follows:

Hb	123 g/l
MCV	82 fl
Platelets	204 * 10 /l9
WBC	9.2 * 10 /l9
Troponin T	240 (normal range < 32)

His pain settles transiently with 2.5mg of subcutaneous morphine.

What is the most appropriate immediate action?

A. Aspirin 300mg and clopidogrel 300mg and treatment dose low molecular weight heparin
B. Intravenous fluids
C. Blood transfusion
D. Coronary angiogram +/- stent as appropriate
E. CT aorta

E. CT aorta

The combination of an atypical history of back and chest pain, persistent pain, non-specific ECG changes, mildly raised troponin and an unexplained sinus tachycardia should raise suspicion that this is not a simple diagnosis of acute coronary syndrome. The clue lies in the distal pulses: the lack of radial-radial delay suggests any aortic pathology occurs below the subclavian artery origin. The mild radial-femoral delay suggests a descending artery lesion. The patient is unwell but not actively exsanguinating as evidenced by the stable Hb and blood pressure. An underlying diagnosis of acute aortic syndrome, a new term classifying all acute aortic pathology including dissections, ulcers and aneurysms, must be ruled out by high definition CT aorta with contrast.

Question 49 of 328

A 54-year-old man is reviewed on the cardiac ward some 2 days after admission with an acute coronary syndrome event. He has suffered an inferior myocardial infarction some 4 years ago, for which he was stented, and takes aspirin together with atorvastatin, ramipril, bisoprolol and indapamide. Examination on the ward is unremarkable, and he is deemed fit for discharge.

Which of the following is the most appropriate option for anti-platelet therapy on discharge?

A. Aspirin and clopidogrel
B. Aspirin only
C. Aspirin and ticagrelor
D. Aspirin and dipyridamole
E. Aspirin and prasugrel

C. Aspirin and ticagrelor

Nice guidelines now recommend secondary prevention with ticagrelor and aspirin, not clopidogrel and aspirin after ACS

NICE guidance is clear for patients who are medically managed for acute coronary syndrome, it states that:

Prescribe DAPT (dual anti-platelet therapy). This is aspirin 75 mg daily plus ticagrelor 90 mg twice a day for 12 months. Ticagrelor is the preferred choice (even in those previously treated with clopidogrel) unless the bleeding risk outweighs the benefit. For people at high risk of bleeding, continue DAPT for at least one month.

For people with MI at high ischaemic risk who have tolerated DAPT without a bleeding complication, consider treatment with DAPT (ticagrelor 60 mg twice daily) in addition to aspirin for longer than 12 months and up to 36 months. If ticagrelor is not suitable, consider clopidogrel 75 mg daily (as well as aspirin) for longer than 12 months.

Aspirin and prasugrel is only recommended for patients undergoing percutaneous intervention and stenting, and aspirin and dipyridamole was formerly used for secondary prevention of stroke. This has now been replaced for secondary prevention of stroke by clopidogrel alone.

Question 50 of 328

A 58 year-old man with a background of is ischaemic heart disease and Crohn's disease has developed colonic enterocutaneous fistulae. He is admitted to hospital under the surgical team and a temporary ileostomy is formed to defunction the bowel and promote healing.

Two days post-operatively he develops palpitations and the surgical team request your assistance.

On examination the pulse rate is 220bpm and the blood pressure is 135/90mmHg. Oxygen saturations are 96% on 2L nasal oxygen.

The chest is clear to auscultation.

A 12-lead ECG reveals a wide-complex tachycardia with a polymorphic waveform.

Blood tests from the morning reveal:

Hb	129 g/l
Platelets	643 * 10 /l
WBC	13.8 * 10 /l
Na	129 mmol/l
K	3.3 mmol/l
Phosphate	0.63 mmol/l
Mg	0.59 mmol/l
Urea	8.1 mmol/l
Creatinine	97 µmol/l
Bilirubin	15 µmol/l
ALP	143 u/l
ALT	53 u/l
Albumin	31 g/l

What is the most appropriate initial management?

A. Adenosine 6mg IV
B. Magnesium sulphate 2g
C. Metoprolol 5mg IV
D. Synchronised DC shock
E. Amiodarone 300mg IV

B. Magnesium sulphate 2g

In this scenario this patient has developed polymorphic ventricular tachycardia with no adverse features. This is likely to be secondary to electrolyte derangement in this case.

Initial management steps include stopping all drugs known to prolong the QT interval. Correct electrolyte abnormalities, especially hypokalaemia. Give magnesium sulphate 2 g IV over 10 min (= 8 mmol).

If adverse features are present (shock, syncope, myocardial ischaemia or heart failure) arrange immediate synchronised cardioversion.

Question 51 of 328

A 83 year old lady presents to heart failure follow up clinic. She has a history of NSTEMI and gallstones. Her symptoms are reasonably poorly controlled. She is able to walk around her bungalow, but struggles to walk to her local shops 100m away due to breathlessness.

She had recently seen her GP who added spironolactone to her regular medications due to persistent hypokalaemia. Her potassium has since normalised.

Her latest echo reveals an ejection fraction of 25%. Her ECG is sinus rhythm Her last BNP was 1000 pg/ml.

She is currently taking senna, ramipril 10mg, aspirin 75m, frusemide 40mg bd, simvastatin 40mg, and spironolactone 50mg.

Her observations at clinic are:

- oxygen saturations: 94% on room air
- blood pressure: 126/66 mmHg
- heart rate: 84/min

Which additional medication would be beneficial?

A. Ivabradine
B. Bisoprolol
C. Digoxin
D. Diltiazem
E. Atenolol

B. Bisoprolol

This patient is already taking some prognostically beneficial medications; ACE inhibitor and aldosterone antagonist. The additional of a beta blocker would be a beneficial medication; both from a preventative of re-modelling and a reduction in heart rate.

Heart rate is a well established modifiable risk factor, which when appropriately controlled can improve morbidity and mortality in heart failure. This patient's heart rate is not well controlled.

Bisoprolol, carvedilol, nebivolol and metoprolol are the only evidencebased cardioselective beta blockers for heart failure patients.

Ivabradine is an If (funny) channel blocker, which reduces heart rate by blocking the If current in the sinoatrial node. NICE guidelines advocate the use of ivabradine for heart failure in a select group of patients:

- Ejection fraction <35%
- Heart rate >75/min
- Sinus rhythm
- NYHA class 2-4
- Maximally titrated beta blocker therapy.

Since this patient is not on maximal beta blocker therapy, it would not be appropriate to commence ivabradine. Diltiazem may be used as an antianginal medication, but this patient does not have angina. Digoxin may be of benefit in heart rate, especially if the patient has atrial fibrillation, but should only be considered following failure of first and second line therapies.

Question 52 of 328

A 72-year-old man attends the cardiology clinic. He has a past medical history of heart failure. He advises you that he has had worsening shortness of breath over the last few weeks. He is now symptomatic at rest. His regular medications include ramipril, bisoprolol, furosemide and eplerenone. His observations are as follows: heart rate 70 beats per minute, blood pressure 125/75 mmHg, respiratory rate 22 breaths per minute, and SpO2 94% on air. On examination, you note pitting oedema to the mid calves and bilateral coarse crepitations.

An echocardiogram and ECG is performed:

Echo	Left ventricular failure with an ejection fraction of 25%
ECG	Sinus rhythm; QRS 140 msec; Dominant S wave in V1 and a broad monophasic R wave in lateral leads (I, aVL, V5-6)

What treatment is most likely to be beneficial to long-term survival?

A. Bendroflumethiazide
B. Bumetanide
C. Cardiac resynchronisation therapy with defibrillator (CRT-D)

D. Cardiac resynchronisation therapy with pacing (CRT- P)
E. Ivabradine

D. Cardiac resynchronisation therapy with pacing (CRT- P)

Cardiac resynchronisation therapy can be used in patients with a QRS duration of >130 msec and LBBB morphology to improve symptomatology

The patient has symptomatic (NYHA class IV) cardiac failure requiring escalation of treatment. He is already on an ACE-I, beta blocker, mineralocorticoid receptor antagonist, and loop diuretic. He has severe left ventricular systolic dysfunction (LVSD) with an ejection fraction of 25%. It is important to note the presence of LBBB with a significantly prolonged QRS. The dominant S wave in V1 and a broad monophasic R wave in the lateral leads are classic of LBBB.

Cardiac resynchronisation therapy with pacing (CRT- P) is correct. Cardiac resynchronisation therapy (CRT) is recommended as a treatment option for people with heart failure who have left ventricular dysfunction with a left ventricular ejection fraction (LVEF) of 35% or less, and LBBB with a QRS duration > 130 msec. The patient in this clinical case, therefore, fulfils these criteria. Many randomised controlled trials have shown that CRT significantly prolongs survival in patients with heart failure. The NICE guidelines have criteria on whether to choose CRT-D or CRT-P. In patients with NYHA class IV (as seen in this case), CRT-P is the preferred modality. In this case, it would also be important to consider the use of sacubitril/valsartan. The PROVE-HF trial (as well as case reports and observational studies) have shown that sacubitril/valsartan is able to induce reverse cardiac remodeling, which has the potential to avoid ICD or CRT implantation.

Bendroflumethiazide is incorrect. Bendroflumethiazide can be used for mild or moderate heart failure. Although diuretics can have major benefits for patient symptomatology, they have no benefit to long-term survival.

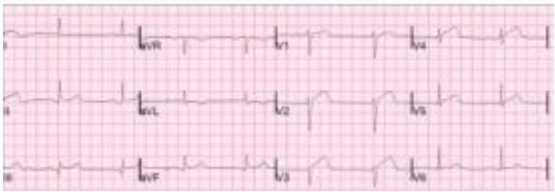
Bumetanide is incorrect. Bumetanide is a type of loop diuretic which has been shown to have greater bioavailability compared to furosemide due to increased absorption in patients who have oedematous bowels. Although diuretics can have major benefits for patient symptomatology, they have no benefit to long-term survival.

Cardiac resynchronisation therapy with defibrillator (CRT-D) is incorrect. As the patient has NYHA class IV symptomatology, CRT-P is the correct option as per NICE guidelines.

Ivabradine is incorrect. Ivabradine is recommended as an option for treating chronic heart failure for patients who are in sinus rhythm with a heart rate of 75 beats per minute or more and who are already on standard therapy with ACE inhibitors, beta-blockers and aldosterone antagonists. The patient in this clinical case has a heart rate of 70 beats per minute and ivabradine is therefore not indicated.

Question 53 of 328

A 79-year-old man presents with severe central chest pain which started around 90 minutes ago. He is known to have ischaemic heart disease and had a coronary artery bypass graft (CABG) five years ago. On arrival in the Emergency Department he is clammy and vomiting. An ECG is taken:



What is the most accurate description of what is shown on this ECG?

(MI = myocardial infarction, STEMI = ST elevation myocardial infarction, NSTEMI = non-ST elevation myocardial infarction)

A. Normal ECG
B. Current inferior NSTEMI
C. Current anterior NSTEMI
D. Current inferior STEMI
E. Current anterior STEMI

A. Current anterior NSTEMI

Ischaemic changes in leads V1-V4 - left anterior descending

In the anterior leads (V2-4) ST elevation can clearly be seen indicating a STEMI. Angiogram revealed an acutely occluded saphenous vein graft to the left anterior descending which was opened with percutaneous coronary intervention.

In the inferior leads there is a pathological Q wave in lead III and nondiagnostic Q waves in leads II and aVF (see below for definitions). These changes suggest that this patient has previously had an inferior MI.

The older and simpler definition of a pathological Q wave:

- Q-wave of >=0.04 s and an amplitude >=25% of the R-wave in that lead

The new (and much more complicated) Joint European Society of Cardiology/American College of Cardiology definition of a pathologic Q wave is:

- any Q-wave in leads V2 - V3 >= 0.02 s or QS complex in leads V2 and V3
- Q-wave >= 0.03 s and > 0.1 mV deep or QS complex in leads I, II, aVL, aVF, or V4 - V6 in any two leads of a contiguous lead grouping (I, aVL,V6; V4 - V6; II, III, and aVF)
- R-wave >= 0.04 s in V1 - V2 and R/S >= 1 with a concordant positive T-wave in the absence of a conduction defect

Question 54 of 328

A 45-year-old woman presents to the emergency department after a road traffic accident where she sustains multiple injuries including an open fracture of her left tibia and fibula. The following day she has an open reduction and internal fixation of the left tibia and fibula and remains in hospital for physiotherapy. She is quite immobile during this period and then develops subsequent painful swelling and erythema of the left calf. Subsequent ultrasonography confirms a left-sided above knee deep vein thrombosis.

Before treatment starts, she develops sudden onset weakness in her right leg and right arm, dysarthric speech and a reduction in conscious level. Subsequent CT scanning confirms the presence of a left-sided infarct in the middle cerebral artery territory. Doppler investigation of the carotids shows a 20% stenosis on the left side and 10% on the right side. The 24- hour tape shows average heart rate 52bpm with 1.5s pauses maximum, sinus bradycardia

Which of the following features from further investigations would best explain this woman's presentation?

A. Anti phospholipid antibody positive
B. Protein C deficiency
C. Patent foramen ovale (PFO)
D. Hypercholesterolaemia
E. Dilated cardiomyopathy on ECHO

C. Patent foramen ovale (PFO)

This unfortunate lady has developed a thrombus as a result of her recent operation and subsequent immobility. Part of the thrombus has embolised into her left middle cerebral artery.

One would normally expect the source of the embolus to be from the carotids or from the heart. However, the minimal carotid stenosis and lack of history of atrial fibrillation make this less likely. The finding of a

PFO on an ECHO would explain how a thrombus from the leg would reach the brain rather than the lungs.

PFOs are extremely common and have been found in 25-30% of people at autopsy. PFOs have been linked to an increased risk of stroke. There is also some evidence that subclinical DVTs in the presence of a PFO may be one cause for cryptogenic stroke http://content.onlinejacc.org/article.aspx?articleid=1120253

The evidence is however limited that PFO closure will reduce the risk of stroke.

The other options except E are all risk factors for stroke but cannot explain the mechanism of embolism with near-normal carotids and sinus rhythm. E is not associated with an increased risk of embolic stroke.

Question 55 of 328

A 52-year-old man of Afro-Caribbean descent is reviewed after having ambulatory blood pressure monitoring (ABPM). This had been ordered after a works medical recorded a blood pressure of 156/86 mmHg. He smokes 20 cigarettes/day and has a family history of ischaemic heart disease. The results show the following:

Average daytime blood pressure: 142/88 mmHg QRISK 10 year cardiovascular risk: 23%

Urine dipstick: NAD

ECG: sinus rhythm, rate 78/min

Na +	141 mmol/l
K +	4.6 mmol/l
Urea	4.5 mmol/l
Creatinine	82 µmol/l
Total cholesterol	5.4 mmol/l
HDL cholesterol	0.9 mmol/l
Fasting glucose	5.3 mmol/l

What is the most appropriate course of action?

A. Start treatment with a calcium channel blocker
B. Diagnose stage 1 hypertension and advise about lifestylechanges
C. Start treatment with an ACE inhibitor
D. Start treatment with a thiazide-like diuretic
E. Repeat the ABPM

A. Start treatment with a calcium channel blocker

Stage 1 hypertension is defined by an ABPM reading of >= 135/85 mmHg, with stage 2 hypertension having a cut-off of >= 150/95 mmHg.

This patient therefore has stage 1 hypertension. We should therefore treat if < 80 years of age AND any of the following apply; target organ damage, established cardiovascular disease, renal disease, diabetes or a 10-year cardiovascular risk equivalent to 20% or greater, as is present in this case.

ACE inhibitors are usually the treatment of choice for patients < 55-years-old but as this patient is of Afro-Caribbean descent a calcium channel blocker should be used instead.

Question 56 of 328

A patient with a severe rheumatic heart disease is about to attend a gastroscopy with oesophageal dilatation. He has no current active gastrointestinal infection.

What endocarditis prophylaxis is recommended?

A. Ciprofloxacin PO 30 min pre-procedure
B. None
C. IV ampicillin at time of surgery
D. IV cefazolin at time of surgery
E. Erythromycin PO 30 min pre-procedure

B. None

Prophylaxis is only indicated when one of the following are met:

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Cardiac transplantation with the subsequent development of cardiac valvulopathy
Congenital heart disease but only if it involves:Unrepaired cyanotic defects, including palliative shunts and conduitsCompletely repaired defects with prosthetic material or devices whether placed by surgery or catheter intervention, during the first 6 months after the procedure (after which the prosthetic material is likely to have been endothelialised) Repaired defects with residual defects at or adjacent to the site of a prosthetic patch or device (which inhibit endothelialisation

Congenital heart disease but only if it involves:

- Unrepaired cyanotic defects, including palliative shunts and conduits Completely repaired defects with prosthetic material or devices whether placed by surgery or catheter intervention, during the first 6 months after the procedure

(after which the prosthetic material is likely to have been endothelialised)

- Repaired defects with residual defects at or adjacent to the site of a prosthetic patch or device (which inhibit endothelialisation)

Active or not active gastrointestinal infection does not alter your management of prophylaxis, but would be advisable to defer the procedure if possible.

Question 57 of 328

A 56-year-old gentleman was admitted to the Emergency Department with a three-hour history of severe central chest pain. The pain came on suddenly whilst he was walking. The pain has remained severe in intensity since onset. He also felt short of breath at rest with associated clamminess. There was no history of trauma. His past medical history comprised of hypertension, hypercholesterolaemia and gout. He was prescribed amlodipine 5mg OD, ramipril 7.5mg OD, atorvastatin 20mg OD, allopurinol 100mg and orlistat 120mg TDS. He smoked 20 cigarettes per day and consumed 30 units of alcohol per week.

On examination, he appeared pale and clammy. His blood pressure was 196/78 mmHg in his right arm and 152/65 mmHg in his left arm. His heart rate was 92bpm. His oxygen saturations were 96% on air. Examination of his cardiovascular system revealed the presence of a prominent early diastolic murmur in the aortic area. Examination of his respiratory system revealed tachypnoea but no added sounds on auscultation. Examination of his gastrointestinal and neurological systems was unremarkable.

He was admitted to the resuscitation bay and commenced on 15 litres of oxygen per minute. He was administered IV diamorphine 2.5mg OD. Investigations conducted revealed the following results:

ECG: normal sinus rhythm 96 bpm, ST elevation in leads II, III and aVF Chest x-ray: normal appearances of heart and lung

What is the best immediate management step?

A. Commence thrombolysis
B. Transfer for immediate percutaneous coronary intervention
C. Commence aspirin 300mg OD and clopidogrel 300mg OD
D. Conduct myocardial perfusion scan
E. Commence IV labetalol infusion

E. Commence IV labetalol infusion

This patient has had an aortic dissection involving the ascending aorta and arch of the aorta, as manifested by the presence of severe chest pain, aortic regurgitation, unequal blood pressures and evidence of an inferior myocardial infarction on ECG. In this situation, thrombolysis is absolutely contraindicated as the myocardial infarction is due to dissection of the vessels and not due to an atherosclerotic thrombotic occlusion. Options 2 and 3 are therefore also not suitable. This gentleman requires urgent intravenous beta blockade for aggressive blood pressure control and to act as a negative inotrope. He will also require an urgent cardiothoracic surgical opinion and further imaging to confirm the diagnosis.

Question 58 of 328

A 75-year-old female is admitted to hospital with community-acquired pneumonia. She is currently being treated with intravenous benzylpenicillin and oral clarithromycin. On the third day of admission, she complains of a sensation of fullness on the lateral aspect of her right leg.

Her past medical history includes osteoarthritis, temporal arteritis (now off steroids) and a uterine prolapse.

Bloods performed the day before show:

Hb	131 g/l
Platelets	520 * 10 /l9
WBC	14.2 * 10 /l9
Na +	141 mmol/l
K +	4.1 mmol/l
Urea	6.2 mmol/l
Creatinine	86 µmol/l
CRP	78 mg/L

A doppler ultrasound scan is performed that shows a superficial vein thrombosis in the right leg.

What is the most appropriate management?

A. Treatment dose low molecular weight heparin (LMWH) and warfarin until warfarin therapeutic then anticoagulate for three months
B. Prophylactic dose low molecular weight heparin (LMWH) for 30days.
C. Treatment dose low molecular weight heparin (LMWH) for 30days.
D. Non-steroidal anti-inflammatory drugs for 8-12 days.
E. Low molecular weight heparin (LMWH) and warfarin untilwarfarin therapeutic then anticoagulate for six months.

B. Prophylactic dose low molecular weight heparin (LMWH) for 30days.

Superficial vein thrombosis (also referred to as thrombophlebitis) is a common condition and in the majority of cases is self-limiting. Patients presenting with a superficial vein thrombosis are at increased risk of a venous thromboembolic event and up to 20% of patients will already have a deep vein thrombosis (DVT) on presentation. Patients are more likely to have thrombus extension into the deep venous system if they have more than 5cm of thrombus within 10cm of the saphenofemoral junction (i.e. within the proximal long saphenous vein).

The evidence for how superficial vein thrombosis should be managed comes from a Cochrane review and is used to support the Scottish intercollegiate guidelines network (SIGN) guidelines on the prevention and management of venous thromboembolism (guide 122). The guidelines recommend that all patients with clinical signs of a superficial vein thrombosis should have an ultrasound scan to exclude a DVT.

Patients with a confirmed diagnosis of a superficial vein thrombosis should be considered for treatment with anti-embolism stockings and prophylactic doses of low molecular weight heparin (LMWH) for 30 days or fondaparinux for 45 days. In cases where LMWH is contraindicated, 8- 12 days of oral non-steroidal anti-inflammatory drugs should be offered as this has been shown to reduce the risk of thrombus extension.

Question 59 of 328

A 76-year-old man presents to the emergency department with complaints of shortness of breath on exertion, difficulty walking up stairs, and significant weight gain over the last 2 weeks. His daughter who is with him expresses concerns about him and says that he is needing to lay upright in his armchair in order to get any sleep.

His medical history includes 2 previous non-ST-segment elevation myocardial infarctions for which he was treated with coronary stenting and hypertension. Physical examination shows a heart rate of 111 beats per minute and blood pressure of 113/76 mmHg. He is visibly short of breath at rest and is using accessory muscles. His JVP is 7cm above the angle of Louis, his apical impulse is laterally displaced, and heart sounds are audible with a holosystolic murmur heard loudest at the apex. Auscultation of his chest reveals audible crepitations bi-basally and he has 2+ peripheral oedema extending to his mid-thighs. An ECG shows Q-waves in his inferior leads, and his bloods show elevated troponins.

Which of the following is the most appropriate next step in the management of this patient?

A. Obtain an urgent echocardiogram
B. Prescribe oral furosemide and discharge from the emergencydepartment with a view to follow up with his GP
C. Load him with aspirin and clopidogrel
D. Commence bisoprolol to control his heart rate
E. Administer a bolus of intravenous furosemide and then start himon an infusion

E. Administer a bolus of intravenous furosemide and then start himon an infusion

The most appropriate medication in patients with acute heart failure and a preserved ejection fraction who have signs of volume overload is addition/up-titration of a loop diuretic

This patient presents with acute decompensated congestive heart failure. He has evidence of significant volume overload on exam, with an elevated JVP and signs of pulmonary and peripheral oedema. The aetiology of his heart failure is likely to be ischaemic cardiomyopathy related to his history of myocardial infarctions and manifests with a displaced apical impulse and a holosystolic murmur heard loudest at the apical region, suggestive of significant ventricular dilatation. His symptoms are severe and he requires inpatient hospitalisation and treatment with intravenous loop diuretics to improve his symptoms and to optimise his volume status.

An echocardiogram would be useful in the evaluation of this patient but is not the most appropriate next step as he is currently significantly symptomatic and needs intravenous loop diuretics to improve his volume status.

Although this patient does need to be treated with loop diuretics, he is in significant distress and likely needs to be admitted as an inpatient and should be treated more aggressively with intravenous loop diuretics.

This patient does have a history of ischaemic heart disease and is at risk of having further ischemic events. However, the findings on his ECG represent an old inferior infarct, and there a no features to suggest an acute event. In addition, he may have elevated troponins simply as a result of having ischaemic cardiomyopathy. He does not necessarily need to be loaded on dual antiplatelet therapy at this moment, but he should have his troponins trended to ensure there is no significant rise in their values.

Starting a beta-blocker in acute decompensated heart failure is contraindicated.

Question 60 of 328

An 89-year-old gentleman presented to the general medical clinic with complaints of palpitations. He was diagnosed with atrial fibrillation (AF) three months ago and started on bisoprolol. This was part of a plan to rate control, rather than rhythm control, his AF. The bisoprolol has been up-titrated as his symptoms did not come under control with his dose. Palpitations occur almost every day but are not associated with any other symptoms. He also has a history of ischaemic heart disease with a myocardial infarction five years ago and type 2 diabetes mellitus. He currently takes bisoprolol, metformin, aspirin and simvastatin. He has declined anticoagulation with warfarin or NOAC despite the risk as his wife died from an intracranial bleed whilst taking warfarin.

On examination, his heart rate is 94/min and irregular. His chest is clear on auscultation and there is no peripheral oedema.

How should he be further managed?

A. Amiodarone
B. Dronedarone
C. Amlodipine
D. Diltiazem
E. Left atrial ablation

D. Diltiazem

The correct answer is diltiazem. This is a gentleman with symptomatic, but not decompensating, permanent AF which is not responding to firstline treatment with a beta-blocker (bisoprolol). NICE advises that first line treatment for a rate-control strategy in AF should be either a betablocker or a rate-limiting calcium channel blocker, but digoxin can be considered for non-paroxysmal AF in patients who are not very active. If the first-line treatment fails, either with continuing symptoms or poor response of ventricular rate then a combination therapy with any of the following two can be used: beta-blocker, diltiazem, digoxin. Amiodarone, dronedarone and left atrial ablation are all strategies for cardioversion. Amlodipine is a calcium channel blocker but is used in hypertension rather than in AF as it is not rate-limiting, and would therefore not help.

Question 61 of 328

A 65-year-old Caucasian man attends the dermatology clinic with a 3- week history of a new rash. He complains of a discolouration of his forearms and hands that initially appeared whilst on holiday in the south of France. It is mildly itchy but not painful. There is no history of a change in diet or detergents and he has no known allergies. His past medical history includes hypertension, type 2 diabetes, ischaemic heart disease and atrial fibrillation.

On examination, there is a purplish discolouration of his hands up to his elbows bilaterally. His face and scalp are mildly erythematous. There is no blistering or crusting.

Which of the following is most likely to be responsible for this patient's presentation?

A. Aspirin
B. Digoxin
C. Indapamide
D. Metformin
E. Ramipril

C. Indapamide

Thiazides may cause photosensitivity

This patient has drug-induced photosensitivity, a skin reaction secondary to UV radiation causing expected burns or dermatitis in patients taking photosensitising medications. Drugs which cause phototoxicity include: antibiotics (tetracyclines, sulfonamides, fluoroquinolones), NSAIDs, diuretics, sulfonylureas, antipsychotics as well as amiodarone, quinine and hydroxychloroquine. The clinical features of photosensitivity can vary according to the medication taken as well as the type of reaction. Some reactions may be phototoxic whilst others are photoallergic.

A phototoxic reaction results from direct damage mediated by UV activation of the photosensitising agent. These reactions can appear within minutes to hours after exposure and appears as a sunburn reaction with reddening and swelling. Rarely, the skin may change pigmentation (e.g. blue-green discoloration seen with amiodarone). In severe reactions, blisters and vesicles may be seen. Other symptoms may include itch, as seen in this scenario. Thiazides typically cause a phototoxic reaction. In contrast, a photoallergic reaction is a cellmediated response. These are less common and present as an eczematous, itchy skin reaction within 24-72 hours after exposure to sunlight. Unlike phototoxic reactions, photoallergic reactions are capable of spreading to areas that have not been exposed to sunlight. The treatment of drug-induced photosensitivity is to avoid the trigger, if possible. If the medication is essential to be taken then protective measures should be taken including sunscreen or protective clothing.

In toxic doses, digoxin is capable of causing side effects including arrhythmias, dizziness, yellow or green visual changes and skin reactions. However, they do not commonly cause photosensitivity. If there are any concerns regarding digoxin toxicity, a digoxin level can be taken with the therapeutic window ranging between 0.7ng/mL and 2.0ng/mL.

Aspirin is a common cause of acute or chronic urticaria. However, it does not cause photosensitivity.

Metformin and ramipril do not commonly cause a rash or skin discolouration. In rare cases, patients may have an allergic reaction to these medications which results in the eruption of urticaria and, in extreme cases, lip and tongue swelling and airway compromise. However, they do not cause photosensitivity.

Question 62 of 328

An 89-year-old lady presents acutely short of breath and distressed. She has a background of previous myocardial infarction (MI) and hypertension. She is now coughing up white sputum. Examination reveals bilateral course crepitations throughout the lung fields. She has a raised jugular venous pressure and peripheral oedema. Observations are a respiratory rate of 35/min, oxygen saturations of 92% on 15 litres of oxygen per minute, blood pressure 135/90 mmHg, heart rate 100/min. Chest X-ray reveals widespread interstitial shadowing. Intravenous furosemide has been given but the patient fails to improve.

Which of the following would be useful in treating this patient?

A. Intravenous antibiotics
B. Oral furosemide
C. Bilevel positive airway pressure
D. Continuous positive airway pressure
E. Chest physiotherapy

D. Continuous positive airway pressure

Acute heart failure not responding to treatment - consider CPAP

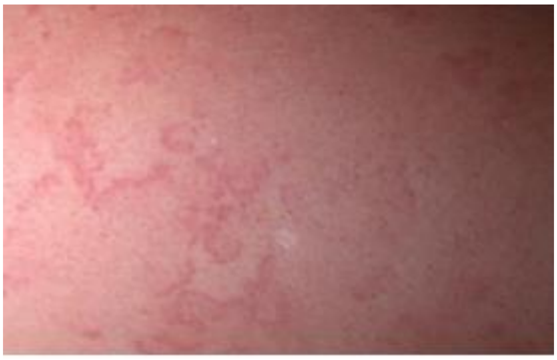
The patient is suffering from severe pulmonary oedema with bilateral course crackles and cough productive of white sputum. The patient has signs of right sided heart failure with raised JVP and peripheral oedema. They also have a history of MI and hypertension that are two risk factors for heart failure.

NICE guidance on Acute Heart Failure 2014 states that a patient who has failed medical management of pulmonary oedema with severe dyspnoea should be considered for CPAP. BIPAP is not used in acute pulmonary oedema.

Question 63 of 328

A 10-year-old girl is reviewed. Her mother describes her as being 'generally unwell'. For the past week she has been having joint pains and fever. Her mother also describes episodes of her making jerky, irregular movements. She recently went on holiday to the Lake District and had a severe sore throat around 4 weeks ago.

On examination her temperature is 37.9ºC, pulse 90/min, blood pressure 100/62 mmHg. Auscultation of the heart is unremarkable. A rash is noted on her torso:



What does the rash most likely represent?

A. Erythema marginatum
B. Erythema multiforme
C. Erythema chronicum migrans
D. Janeway lesions
E. Erythema toxicum

A. Erythema marginatum

The underlying diagnosis is rheumatic fever. This is supported by the recent sore throat, chorea (jerk, irregular movements) and polyarthralgia.

Erythema toxicum is a non-specific rash seen in newborns

Question 64 of 328

A 22-year-old man is brought to the emergency department after being granted asylum in the UK. Immigration officials had been concerned about the patient's well-being immediately on his arrival in the country. The patient reported feeling progressively more unwell over the previous 3 months after he had fled from his village in Syria. The primary symptoms reported by the patient were fevers, severe night sweats and profound fatigue. In addition, the patient had found that his exercise tolerance has greatly reduced in the previous four weeks and he became markedly breathless on minimal exertion.

The patient explained that he had experienced a prolonged period of inadequate food and shelter due to the war in his home country and while travelling across Europe. The patient had previously lived in a small village in Syria and had worked as a sheep farmer. Prior to fleeing his home the patient had regularly consumed food products made with unpasteurised sheep's milk. The patient had previously been in good physical health and had suffered no significant medical problems during his life.

On general examination, the patient appeared unwell and diaphoretic. The patient's sweat was noted to have an unusually unpleasant odour. Examination of the cardiovascular system identified multiple splinter haemorrhages under the patient's fingernails and toenails. Jugular venous pressure was elevated by 3-4 cm and pitting oedema was present to the patient's knees. A harsh systolic murmur was heard over the aortic area on auscultation. Bilateral basal crackles were heard on auscultation of the patient's lungs. The patient's spleen was palpable on examination of the abdominal system. No palpable lymphadenopathy was identified.

Please see the below table for results of initial investigations.

Haemoglobin	123 g / dL
Mean cell volume	80.3 fl
Lymphocytes	4.9 x 10>3 / microlitre (reference 1.5-4.0)
Platelets	109 x 10>3 / microlitre
Urea	8.9 mmol / L
Creatinine	126 micromols / L
Sodium	137 mmol / L
Potassium	4.1 mmol / L
Erythrocyte sedimentation rate	102 mm / h (reference 0-35)
C-reactive protein	99 mg / L (reference < 7)
Urinalysis	Positive for blood +++
Chest x-ray	Upper lobe blood diversion; generalised patchy airspace shadowing; bilateral shallow pleural effusions
ECG	Sinus rhythm; borderline right bundle branch block
Focused bedside transthoracic echocardiogram	0.6 cm vegetation on aortic valve; evidence of moderate-severe aortic stenosis; ejection fraction 30 %

Which of the following organisms is the most likely cause of the patient's presentation?

A. Clostridium burnetti
B. Bartonella quintana
C. Haemophilus parainfluenzae
D. Kingella kingae
E. Brucella melitensis

E. Brucella melitensis

The patient presents with clear symptoms, signs and investigation results consistent with aortic valve endocarditis and secondary congestive cardiac failure. It is likely that the patient's prolonged exposure to inadequate living conditions has weakened his immune system allowing the development of an opportunistic infection.

Of the available options, *Brucella melitensis* is the most likely to be the causative microorganism. Endocarditis - most commonly of the aortic valve - is a rare complication of Brucella; however, it is responsible for the majority of mortality from this disease. Of the different *Brucella* species known to cause endocarditis *Brucella melitensis* is known to be associated with the most severe complications.

Brucellosis is the most likely diagnosis in this patient due to his history of consumption of unpasteurised milk products and close contact with livestock from an endemic region. The clinical sign of malodorous sweat is considered to be nearly pathognomonic for Brucellosis. In addition, the patient's blood results are typical for the condition featuring lymphocytosis and thrombocytopenia.

The patient requires blood cultures and serological testing to confirm the diagnosis. Given the severity of the patient's condition, he would require treatment with empirical antibiotics with consideration of aortic valve replacement at an appropriate point in the future.

The other available answers are all organisms known to be rare causes of endocarditis that usually will not be identified without specialist microbiological investigations. There is no information in the case presentation that makes any of these microorganisms a more likely causative agent of endocarditis than *Brucella melitensis*.

Question 65 of 328

A 64-year-old hypertensive male presents to the emergency department with a history of sudden onset tearing chest pain. He is a chronic smoker with a 25 pack year history. He takes valsartan 160mg daily and amlodipine 5mg daily.

On examination, he is distressed and in severe pain. Blood pressure is 200/120 mmHg. The peripheral pulses are weak and his heart rate is 125 bpm.

Sublingual nitrates and oral aspirin are given to him in the emergency department and his twelve-lead ECG is performed which reveals tachycardia, left ventricular strain and deep S waves in lead V1-V3 and tall R waves in V4-V6.

Chest x-ray shows widening of the mediastinum with an irregular aortic contour.

Contrast-enhanced CT scan of the chest reveals an aortic intimal flap distal to left subclavian artery.

Which of the following is the most appropriate treatment option for this patient?

A. Blood pressure control with IV beta-blockers
B. Percutaneous stent insertion
C. Surgical repair

D. Blood pressure control with IV hydralazine
E. Continuous infusion of isosorbide dinitrate

A. Blood pressure control with IV beta-blockers

The diagnosis in this question is aortic dissection type B (distal to the left subclavian artery), the management of which is blood pressure control. The most appropriate drugs used are IV beta-blockers.

Aortic dissections can be classified according to the anatomic site of the dissection. Type A involves the aortic arch and the aortic valve while type B involves the descending thoracic aorta distal to the left subclavian artery. (Stanford Classification)

Stanford types A and B are further sub-classified according to the De Bakey classification.

Stanford Type A constitutes De Bakey I (extending to the abdominal aorta) and De Bakey II (localised to the ascending aorta). Stanford type B is synonymous with De Bakey type III.

The importance of these classifications is the difference in treatment. Universally, blood pressure control in mandatory with a target reduction in systolic BP to 120mmHg. Type A dissection should undergo surgery (aortic arch replacement) if the patient is fit enough since medical management alone carries a high risk of mortality (50% within 2 weeks). Type B dissections carry a better prognosis with 89% survival at one month and should thus initially be managed medically, with surgical interventions only if complications develop.

Indications for endovascular stenting include:

- Rapidly expanding dissections (>1cm per year)
- Critical diameter (>5.5cm)
- Refractory pain Malperfusion syndrome
- Blunt chest trauma
- Penetrating aortic ulcers

Question 66 of 328

A 32-year-old woman with pyrexia of unknown origin is admitted to the medical assessment unit.

Examination reveals a pale patient with a new cardiac murmur, evidence of splinter haemorrhages and splenomegaly. She looks unwell.

She has no past medical history, takes no regular medication and has no allergies.

The patient has high inflammatory markers and positive blood cultures which are growing Gram-positive cocci in clusters.

What is the single most appropriate antibiotic treatment?

A. IV amoxicillin
B. IV flucloxacillin
C. IV gentamicin
D. IV vancomycin
E. Oral doxycycline

B. IV flucloxacillin

IV flucloxacillin is the treatment of choice for native valve endocarditis caused by staphylococci

The most likely diagnosis here is infective endocarditis given the widespread clinical signs and the positive blood culture is most likely a *Staphylococcus aureus*, which is often described as Gram-positive cocci in clusters before full identification is completed.

The most appropriate antibiotic, therefore, is **IV flucloxacillin** which will adequately treat *S aureus*. This is the recommended treatment for any native valve staphylococcal endocarditis and is the correct answer in this case.

IV amoxicillin is incorrect. Although it is the recommended empirical antibiotic for endocarditis, it is incorrect to use if there is a known staphylococcal organism in the blood culture.

IV gentamicin is often added to amoxicillin in native valve endocarditis but it is unnecessary as the organism has been identified in a blood culture.

You may see a patient with a prosthetic valve where you would need to consider using **IV vancomycin** to cover an MRSA, however, in this case, the patient has no medical history so this is not correct.

Oral doxycycline would treat *S aureus* but is inappropriate as IV antibiotics are always required in infective endocarditis.

Question 67 of 328

A 55-year-old obese man with a history of hypertension, diabetes and angina develops central crushing chest pain whilst gardening alone. He is short of breath and clammy. He takes two puffs of his glyceryl trinitrate spray but has only mild relief from this.

He calls an ambulance, but before the ambulance arrives he suffers a cardiac arrest. The ambulance crew commence cardiopulmonary resuscitation (CPR). Heart monitoring shows him to be in ventricular tachycardia and after a DC shock and a further round of CPR, he recovers cardiac output.

He is taken to the local hospital intensive care unit where he remains unconscious. The doctors explain to his family that because of the time between his cardiac arrest and CPR commencing, his brain function may not recover well.

What is the most reliable indicator of this patient's prognosis at 72 hours post-arrest?

A. Electroencephalogram
B. Glasgow coma scale motor score
C. Pupillary reflex
D. Somatosensory evoked potential
E. Gag reflex

C. Pupillary reflex

Ability to predict poor outcome (death or severe disability) in a comatosed patient followings cardiac arrest is important for decision making regarding withdrawal of treatments as well as communicating with families.

No clinical neurological signs have been shown to correlate reliably with poor outcomes when measured less than 24 hours after cardiac arrest.

Work by Rittenberger and colleagues (2010) looked at patients who suffered ventricular tachycardia or ventricular fibrillation cardiac arrests. They found that GCS motor score did not correlate with cardiac arrest outcome when measured at 24 or 72 hours. However, lack of pupillary light or corneal reflex at 72 hours was a reliable predictor of death.

Vestibulo-ocular reflexes are also used but are less reliable. No biochemical, imaging or neurophysiological studies are currently recommended for the assessment of prognosis.

Question 68 of 328

A 74-year-old gentleman presents with oedema. He also states that his urine has been frothy over the last few weeks. He has no past medical history and is on no regular medications.

On examination he has pitting oedema up to the mid thighs. His JVP is 8cm from the sternal angle, and rises with inspiration. His pulse is irregularly irregular, and ECG shows fast atrial fibrillation with a rate of 145 bpm. He is otherwise systemically well with a BP of 135/85mm Hg. On neurological exam you note weakness and a sensory deficit in the distribution of the right ulnar nerve and left posterior tibial nerve.

You administer a loading dose of 1mg IV digoxin over 2 hours. Shortly after this the patient deteriorates and loses consciousness. A repeat ECG shows ventricular tachycardia, which then develops into ventricular fibrillation. Unfortunately the patient did not survive resuscitation attempts.

What is the most likely underlying disease?

A. Hypertrophic obstructive cardiomyopathy
B. AL amyloidosis
C. Brugada disease
D. AA amyloidosis
E. Cryoglobulinaemia

B. AL amyloidosis

Digoxin administration is not recommended in cardiac amyloidosis owing to a higher risk of digoxin toxicity, as the drug binds avidly to amyloid fibrils

The presence of Kussmauls sign (JVP which rises on inspiration) and significantly raised JVP is suggestive of constrictive pericarditis or restrictive cardiomyopathy. Together with the presence of nephrotic syndrome, and mononeuritis multiplex, one must consider amyloidosis.

AA amyloidosis occurs due to chronic inflammation e.g. rheumatoid arthritis. There is no evidence of a past medical history that would predispose to AA amyloidosis. Furthermore, cardiac manifestations are very rare in AA amyloidosis. This is in contrast to AL amyloidosis, which occurs due to light chain disease, where cardiac manifestations are very common.

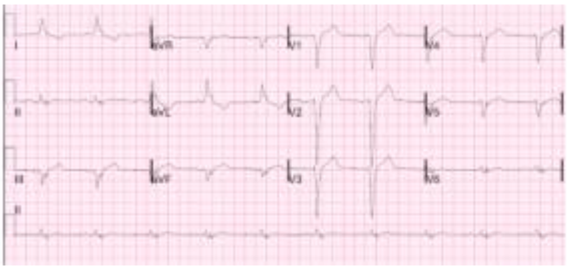
Digoxin administration is not recommended in cardiac amyloidosis owing to a higher risk of digoxin toxicity, as the drug binds avidly to amyloid fibrils. In this case, administration of digoxin has led to cardiac arrhythmia due to the enhanced effects of digoxin on an amyloid heart

Question 69 of 328

A 49-year-old man presents to the emergency department of a tertiary centre with a 4-hour history of central chest pain. There is no radiation of pain, but he reports to be feeling breathless and light-headed. Other than a recent viral upper respiratory tract infection, he has been well in himself recently. His past medical history includes hypertension, hyperlipidaemia and a post-operative deep vein thrombosis 2 years ago. Current medications include ramipril, amlodipine and atorvastatin and he denies any allergies.

On examination, he appears clammy to touch. His chest is clear on auscultation, although he is mildly tachypnoeic with saturations of 94%. Heart sounds are normal and his peripheral pulses are intact. He has a soft and non-tender abdomen.

An ECG is recorded, as shown below:



Given the likely diagnosis, what is the most appropriate next step in the management of this patient?

A. Discharge with NSAIDs
B. Fibrinolysis
C. Insulin and dextrose infusion
D. Percutaneous coronary intervention
E. Rivaroxaban

D. Percutaneous coronary intervention

This patient's ECG shows a left bundle branch block (LBBB) with broadened QRS complexes (> 120ms), a dominant S wave in V1 (creating 'W' impression) and broad monophasic R waves in leads I, aVL, V5 and V6 (creating 'M' impression). In patients with an ECG showing LBBB, it is important to establish whether or not this is a new finding as a new presentation of LBBB is concerning for myocardial ischaemia. In combination with a history of chest pain, shortness of breath, and being clammy to touch, it is likely that this patient is having a myocardial infarction. For patients presenting to the hospital within 12 hours of a STEMI with the availability of primary percutaneous coronary intervention (PCI) within 2 hours, PCI is the most appropriate and definitive management of this patient where the obstructed artery can be stented. As this patient has presented within 4 hours to a tertiary centre, it is likely that PCI can be achieved and is, therefore, the correct answer.

It would be inappropriate to discharge this patient with analgesia as a new finding of LBBB and a clinical history of chest pain is highly suggestive of myocardial ischaemia and needs urgent treatment.

Fibrinolysis is an alternative option for managing acute coronary syndrome. However, if PCI is available, it should be prioritised as the most appropriate treatment.

Insulin and dextrose are used in the management of hyperkalaemia. ECG changes in hyperkalaemia commonly include peaked T waves. However, in severe hyperkalaemia, ECG changes can include bundle branch blocks including LBBB. This is much rarer than myocardial ischaemia and given the history of chest pain, shortness of breath and sweating, an acute coronary syndrome is the more likely cause for which PCI is indicated.

Rivaroxaban is used in the treatment of a pulmonary embolism (PE). Although this patient has a higher risk of venous thromboembolism with a previous DVT, it is very unlikely for a PE to cause LBBB

Question 70 of 328

An 84-year-old gentleman is admitted to hospital with a short history of episodes of loss of consciousness. The patient has no clear recollection of the events, but his family informs you that they have not identified any specific pattern to them. Most of them have been unwitnessed, with the exception of the last one, where according to his wife he became pale, his eyes rolled backwards and fell on the chair. Some minor flickering was noted. Once he regained consciousness he was briefly confused and anxious, but soon realised where he was. Cardiovascular examination was unremarkable, with no postural hypotension but a blood pressure of 103/55 mmHg, and no focal neurology was isolated. His bloods were unremarkable.

His ECG was that of sinus rhythm: 67/min with Right Bundle Branch Block (RBBB). You see from a previous echocardiogram in his notes, that he has a degree of heart failure with an ejection fraction of 45%. A 72 hour holter monitor revealed no significant pauses.

Which action would you take next?

A. Arrange MRI head
B. Arrange EEG
C. CRT-D placement
D. Arrange insertion of Reveal Device
E. Arrange performance of Carotid sinus and Tilt-test

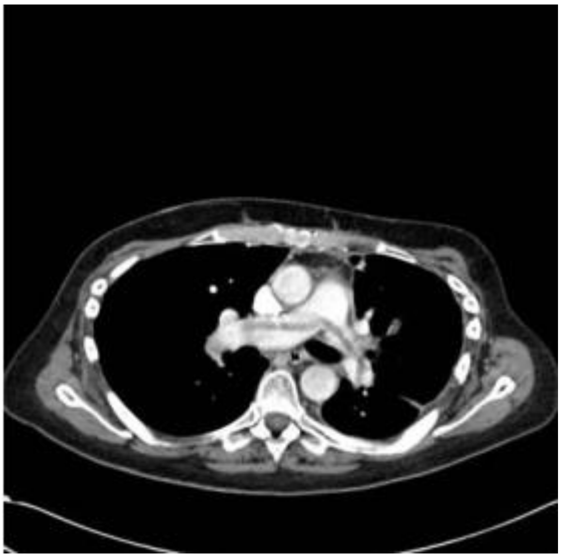
E. Arrange performance of Carotid sinus and Tilt-test

In patient with BBB and unexplained syncope but an ejection fraction >35% proceed with further testing (e.g. carotid sinus massage, electrophysiological studies) prior to initiation of management

As per the ESC Guidelines on Cardiac Pacing and Cardiac Resynchronization therapy (2013) it is important to exclude any other probable causes of collapse/syncope prior to installing any device. It is important to note that 'Less than half of the patients with BBB and syncope have a final diagnosis of cardiac syncope, albeit the probability is different among different type of BBB'. Given his symptomatology and the examination findings alongside the 72-hour holter monitor this is unlikely to be purely cardiogenic therefore further investigation is needed. With his age and presentation, autonomic dysfunction could be the cause, therefore carotid sinus and tilt-test may provide the answer. An MRI head and an EEG remain plausible options, but given the lack of solid seizure-like activity, can be arranged later on, provided that no answer is given by other tests.

Question 71 of 328

A 72-year-old man is admitted to hospital with shortness-of-breath. On examination his pulse is 96/min, BP 100/64 mmHg, respiratory rate 20/min, temperature 37.5ºC, oxygen saturations 96% on room air. A 12- lead ECG shows sinus rhythm, at a rate of 94/min with no diagnostic ST-T changes. The troponin I level is < 0.05 µg/L. A CT chest (with contrast) is ordered:



What is the most likely diagnosis?

A. Superior vena cava obstruction
B. Aortic dissection (Stanford type A)
C. Infective endocarditis
D. Aortic dissection (Stanford type B)
E. Pulmonary embolism

E. Pulmonary embolism

The CT shows a large saddle embolus where the pulmonary trunk splits to form the right and left pulmonary arteries.

Most image-based questions can be answered without looking at the image. If we therefore concentrate on the history a few clues point towards a pulmonary embolism (PE). The first is tachypnoea. Around 95% of patients with a PE have a respiratory rate > 16/min. Tachypnoea is not as common in any of the other diagnoses. A low-grade temperature is also an under appreciated sign of pulmonary embolism. This could of course be consistent with infective endocarditis but there are no other features to support this diagnosis.

Question 72 of 328

A 19-year-old woman is being reviewed in the cardiology clinic for recurrent syncopal attacks in the last 2 years. The attacks mainly occur during or after strenuous exercise.

Her vital signs are a temperature of 37 ºC, blood pressure 105/65 mmHg, pulse 83 beats/minute, and oxygen saturation 98% on room air. Cardiac examination is unremarkable. She has thickened skin over her palms and soles. An electrocardiogram (ECG) shows deep t-wave inversions in V1 to V3.

What is the most appropriate anti-arrhythmic drug for this patient?

A. Bisoprolol
B. Digoxin
C. Magnesium sulphate
D. Metoprolol
E. Sotalol

E. Sotalol

Arrhythmogenic right ventricular cardiomyopathy - T wave inversion in V1-3

Syncopal attacks precipitated by exercise and deep T-wave inversions from V1 to V3 point towards arrhythmogenic right ventricular cardiomyopathy (ARVC). ARVC, as described in this scenario, can occur with hereditary Naxos disease in which woolly hair and palmoplantar skin thickening can be seen. **Sotalol** is the most effective anti-arrhythmic drug for patients with ARVC. Sotalol is superior to amiodarone in preventing and treating ventricular arrhythmias in ARVC.

Bisoprolol is incorrect because the anti-arrhythmic properties of bisoprolol are not equivalent to sotalol in preventing arrhythmias in ARVC. Bisoprolol is a widely used rate-controlling agent and less frequently used as an anti-arrhythmic.

Digoxin is unlikely to benefit this patient with ARVC. Digoxin is used as an anti-arrhythmic in patients with concomitant heart failure.

Magnesium sulphate has no role in treating ARVC. It is an antiarrhythmic of choice in torsades de pointes.

The patient in this scenario has features similar to hypertrophic cardiomyopathy (HCM), in which **metoprolol** is the first-line drug of choice. The skin keratosis described in this scenario makes Naxos disease and ARVC more likely.

Question 73 of 328

A 72-year-old male presents with a five hour history of left sided chest pain, radiating to his left arm. He also complains of sweatiness in both his hands and has vomited three times in the last 2 hours. ECG demonstrates ST depression in II, III and aVF, troponin is 0.78 (normal range <0.03). On examination, he is alert but extremely clammy. You note his pulse at the radial artery is 35/ minute and regular. His BP on the cardiac monitor is 120/67. An NSTEMI is diagnosed and the patient is taken to the catheter laboratory for reperfusion therapy.

Which coronary artery is most likely to be occluded?

A. Left anterior descending artery
B. Left circumflex artery
C. Obtuse marginal branch artery 1
D. Obtuse marginal branch artery 2
E. Right coronary artery

E. Right coronary artery

The sino-atrial node (SAN) is supplied by the right coronary artery in 60- 80% of patients, with the left circumflex supplying the remainder of the population. The OM1 and OM2 arteries are branches of the left circumflex artery, classically supplying the apex of the heart.

Question 74 of 328

A 17-year-old man from Romania is seen on the acute medical take. He is usually fit and well but for the past week has had a sore throat and fevers. He was unsure of his vaccination status and a throat swab taken from pustular exudate on his tonsils grew *Corynebacterium diphtheriae* for which he has started erythromycin. His maternal grandfather is known to have glucose-6-phosphate deficiency but he has never received testing.

He presents today with one day of shortness of breath. He is experiencing fevers and having difficulty swallowing. On examination, he is tachypnoeic with a respiratory rate of 34 breaths per minute. He had bibasal crepitations and a JVP can be seen at 4cm above the angle of Louis. He is coughing white frothy material and saturating at 90%.

Na +	137 mmol/l
K +	4.2 mmol/l
Urea	6.4 mmol/l
Creatinine	60 µmol/l
Troponin	29,000 ng/ml (normal range <20)
Hb	110 g/l
Platelets	300 * 10 /l9
WBC	9.6 * 10 /l9
Neutrophils	4.3 * 10 /l9
Lymphocytes	8.2 * 10 /l9
Throat swab	Corynebacterium diphtheriae resistant to erythromycin, sensitive to penicillin

What complication has arisen?

A. Acute haemolytic crisis
B. Myocarditis
C. Diphtheria pneumonitis
D. Interstitial lung disease
E. Lemierre's Syndrome

B. Myocarditis

Myocarditis can be a secondary complication of diphtheria

The picture shows a large troponin rise with the rapid onset of acute heart failure. Myocarditis is a rare recognised complication of diphtheria and is due to exotoxin produced. The organisms resistance to the macrolide antibiotic has undoubtedly allowed it to persist despite medical therapy. Diphtheria pneumonitis, Lemierre's syndrome and interstitial lung disease could all conceivably present with bibasal crepitations but no troponin rise. An acute haemolytic crisis would usually have a very low haemoglobin and signs of jaundice that are not present here.

Question 75 of 328

A 23-year-old gentleman presents with sudden shortness of breath, lethargy and fevers. He is currently homeless and has been brought in by a friend. He has vomited three times since arrival but has no diarrhoea.

He is usually well and has a metal plate in his right wrist for a fracture sustained in an assault a few weeks prior. He does not take any regular medications and is not registered with a local GP. He denies any alcohol or substance use.

He is currently taking rifampicin and isoniazid for pulmonary tuberculosis diagnosed 4 months ago and is compliant with his directly observed therapy.

On examination, he has a pan-systolic murmur over the left sternal edge. He has bilateral lung crepitations to the midzones with dullness to percussion at the base. His heart rate is 96/min, temperature is 37.8ºC and he is saturating at 94% with 4 litres oxygen by nasal cannulae. He has a bounding JVP that reaches the ear lobe with cannon V-waves seen. Tracking marks can be seen in the arms and there are injection sites in his groin. He has poor dentition with tenderness under the left jaw. His right wrist is tender over the plate and there is no redness and a mildly reduced range of motion.

Hb	96 g/l	Na	139 mmol/l
Platelets	156 * 10 /l	K	4.2 mmol/l
WBC	14.2 * 10 /l	Urea	5.6 mmol/l
Neuts	12.0 * 10 /l	Creatinine	96 µmol/l
CRP	156 mg/l		

Chest x-ray	bilateral alveolar shadowing, small right sided effusion
ECG	T wave inversion in V1-V4
Blood cultures	Staph aureus

What is the underlying cause of this presentation?

A. Poor dental hygiene
B. Intravenous drug use
C. Infected orthopaedic plate
D. Tuberculosis
E. Prolonged vomiting

B. Intravenous drug use

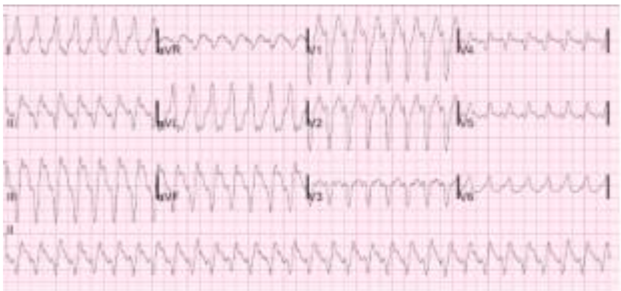
Tricuspid valve endocarditis can cause tricuspid regurgitation, which may manifest with a new pan-systolic murmur, large V waves and features of pulmonary emboli

This gentleman has infective endocarditis. The cannon V waves and pan systolic murmur narrow this down to the tricuspid valve being affected which is very common in intravenous drug users as this is the first valve reached from venous blood. The tracking marks are a clue even though the patient denies this. Tuberculosis does not cause murmurs and usually only affects the pericardium of the heart. Poor dental hygiene can cause a *strep* endocarditis that is less florid and more insidious. An infected orthopaedic plate is a rare cause of endocarditis. Prolonged vomiting would not cause this. The lack of pitting oedema suggests this is a rapid onset right sided heart failure.

Question 76 of 328

A 68-year-old man attends the emergency department with palpitations and dizziness. This had a sudden onset approximately one hour ago. He denies chest pain. His observations are as follows: heart rate 170 beats per minute, BP 100/70 mmHg, respiratory rate 18 breaths per minute, and temperature 37.2 ºC.

An ECG is performed in the department:



What is the most likely diagnosis?

A. Atrial fibrillation with aberrant conduction
B. Monomorphic ventricular tachycardia (VT)
C. Polymorphic ventricular tachycardia (VT)
D. Supraventricular tachycardia with aberrant conduction
E. Ventricular flutter

B. Monomorphic ventricular tachycardia (VT)

The ECG demonstrates a broad-complex tachycardia. It can be difficult to distinguish between ventricular tachycardia and supraventricular tachycardia with aberrant conduction (e.g. LBBB). Therefore it is always safest to assume that the arrhythmia is ventricular in origin until proven otherwise. Electrocardiographic features that increase the likelihood of VT include:

- Absence of typical RBBB or LBBB morphology
- Extreme axis deviation ('northwest axis'): QRS positive in aVR and negative in I and aVF
- Very broad complexes > 160ms
- AV dissociation Capture beats Fusion beats
- Positive concordance throughout the precordial leads
- Negative concordance throughout the precordial leads
- RSR' complexes with an R>R'

Monomorphic ventricular tachycardia is the correct option. The ECG demonstrates RSR' complexes with an R>R' which is the most specific finding in favour of VT. Since the morphology of the QRS waves is similar beat to beat then the diagnosis is monomorphic VT rather than polymorphic VT.

Atrial fibrillation with aberrant conduction is incorrect. The presence of P waves (seen best in lead II) and the regular rhythm make this an unlikely diagnosis.

Polymorphic ventricular tachycardia is incorrect. This would also present with a broad complex tachycardia with similar criteria as discussed above. However, in this condition, the morphology of the ventricular complex would vary from beat to beat.

Supraventricular tachycardia with aberrant conduction is incorrect. Although this is a possibility, the extremely broad QRS duration and the presence of RSR' complexes with R>R' favour the diagnosis of monomorphic ventricular tachycardia.

Ventricular flutter is incorrect. This condition is an extreme form of ventricular tachycardia (VT) with loss of organised electrical activity. The ECG would demonstrate a continuous sine wave with no identifiable P waves, QRS complexes, or T waves.

Question 77 of 328

A 65-year-old with exertional dyspnoea over the past 3 months is referred to the pulmonary hypertension team. An initial echocardiogram demonstrated 65% ejection fraction, preserved left ventricular function with a pulmonary arterial pressure of 72 mmHg. She undergoes a right and left heart catheter, revealing the following saturations:

Right atrium high	60%
Right atrium mid	89%

Right atrium low	70%
Right ventricle high	70%
Right ventricle mid	73%
Right ventricle low	72%
Pulmonary artery	71%
Capillary wedge	96%

What is the most likely diagnosis?

A. Aortic stenosis
B. Atrial septal primum defect
C. Atrial septal secundum defect
D. Pulmonary stenosis
E. Mitral stenosis

C. Atrial septal secundum defect

The key to questions regarding saturations and cardiac catheters is to spot the 'step-up' in oxygen saturation. It is present between the high and mid right atrium, demonstrating the presence of a left-to-right shunt. Primum ASD defects typically occur lowering in the septum than secundum defects, which typically can be found in the mid-atrial region.

Question 78 of 328

A 30-year-old man presents with a fever. He complains that he has had a fever, headache and lethargy for three weeks. On examination, his temperature is 38.5C. You notice a healed human bite mark on his right forearm, he tells you he was bitten in a pub brawl about a couple months ago. Diastolic and systolic murmurs are heard on auscultation. A transoesophageal echo demonstrates an oscillating mass on a bicuspid aortic valve, with aortic regurgitation. Three blood cultures are taken before administration of empirical antibiotics, two grow small colonies of tiny pleomorphic gram-negative bacilli.

What is the likely causative organism?

A. Eikenella corrodens
B. Escherichia coli
C. Phoenicoparrus andinus
D. Staphylococcus aureus
E. Streptococcus viridans

A. Eikenella corrodens

This patient fits the Duke criteria for infective endocarditis as there is: echocardiographic evidence of an intra-cardiac mass associated with a valve, a fever of >38 and two blood cultures of an endocarditis causing microorganism. Additionally, this patients bicuspid aortic valve is a risk factor for developing endocarditis.

Eikenella corrodens is a gram-negative bacilli, which is a commensal of the human mouth. It is a member of the HACEK group, an acronym for a group of organisms that can cause gram-negative endocarditis (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species.) The human bite injury and gram-negative culture make *Eikenella corrodens* the most likely causative organism.

Streptococcus viridans and *Staphylococcus aureus* are commoner causes of infective endocarditis, which are easily cultured and are gram-positive.

Escherichia coli could cause endocarditis and is a gram-negative bacilli, but is not the most likely in this case.

Phoenicoparrus andinus is the binomial nomenclature for the rare Andean Flamingo, which are not known to cause infective endocarditis.

Question 79 of 328

A 30-year-old pregnant woman (24 weeks) is admitted to the acute medical unit with sudden onset shortness of breath and pleuritic chest pain. She has no past medical history other than eczema and this is her first pregnancy.

On examination, auscultation of her chest reveals only a mild wheeze with oxygen saturations of 94% on room air and a respiratory rate of 25/min. Her heart sounds are normal, with a heart rate of 97bpm and blood pressure is 105/60 mmHg. An ECG shows sinus rhythm.

The FY1 doctor on the ward has requested a D-dimer to try and 'speed up the diagnosis', which comes back positive.

What is the next appropriate investigation?

A. Ventilation-Perfusion (V/Q) scan
B. Chest x-ray
C. Peak flow measurement
D. CT Pulmonary Angiogram (CTPA)
E. Ultrasound doppler of the lower legs

B. Chest x-ray

It is likely that this woman has had a pulmonary embolism given the acute nature of the shortness of breath and pleuritic chest pain, together with tachycardia and reduced oxygen saturations.

The correct way to investigate a pregnant woman with a possible pulmonary embolism is to first perform a chest x-ray. This is vital to ensure other diagnoses such as pneumonia and pneumothorax are identified

Ultrasound doppler of the lower legs is the next step as this can demonstrate a venous thromboembolism of the lower limb vasculature without radiation. If a thrombus is found, appropriate management with low molecular weight heparin can be initiated.

If the chest x-ray and the ultrasound doppler are normal, a ventilationperfusion scan should be performed. The presence of a normal chest xray can essentially function as the ventilation part of the V/Q scan. This allows for a half-dose radiation V/Q scan.

The radiation dose to the foetus of a V/Q scan is slightly higher than that of a CTPA, however both are well below the threshold of specific harm to the foetus. Please note that a CTPA should only be used in the presence of lung disease including asthma or an abnormal chest x-ray, as the radiation dose to the proliferating maternal breasts may be significant in the development of carcinogenesis later in life.

A d-dimer is not appropriate as it may be raised in pregnancy and may lead to further inappropriate tests based on the positive result alone.

Question 80 of 328

A 23-year-old Afro-Caribbean female presents with a four-month history of fatigue, transient fever lasting hours, 12kg weight loss and nonspecific bilateral headaches. She has presented to the Emergency Department four times in the past 3 months with non-specific abdominal pains that are worse after eating and also blue-lighted into her local hyperacute stroke unit as a thrombolysis patient after sudden onset loss of monocular blindness in her left eye, which resolved before any treatment was given. She has no other past medical history, does not smoke and drinks minimally.

On examination, cranial nerve examination and fundoscopy are both unremarkable. Upper and lower limb neurology are intact with downgoing plantars. Her heart sounds demonstrates a gallop rhythm, an early diastolic murmur and a mild radial-radial delay. Chest auscultation is clear. She appears very warm and measures 38.4ºC in your clinic with facial flushing. Blood tests are as follows:

Hb	94 g/l
Platelets	245 * 10 /l
WBC	18.4 * 10 /l
Eosinophil	0.1 * 10 /l
ESR	121 mm/hr
Na	141 mmol/l
K	4.0 mmol/l
Urea	5.2 mmol/l
Creatinine	68 µmol/l
CRP	56 mg/l

Complement levels were reported as normal and an antibody screen including ANCA and ANA was negative. Urine dip is negative. Chest Xray demonstrates focal consolidation. Her heart rate is 95 and regular, her blood pressure is 185/110 mmHg.

What is the unifying diagnosis?

A. Systemic lupus erythematosus
B. Polyarteritis nodosa
C. Poorly controlled primary hypertension
D. Ascending aortic aneurysm
E. Takayasu arteritis

E. Takayasu arteritis

A systemic condition is clearly present in this patient: there is a combination of fever, weight loss, pyrexia, ischaemic abdominal pain, transiently ischaemic cerebral occlusion, raised inflammatory markers and hypertension associated with radial-radial delay. The key differentials are between PAN and Takayasu arteries, which are medium-sized and large vessel vasculitis respectively. Ischaemic colitis is a common presentation in PAN but almost always associated with one of positive ANCA, eosinophilia, peripheral neuropathy and hepatitis B. In addition, the involvement of temporal arteries and it appears the ascending aorta to produce radial-radial delay suggests Takayasu arteritis to be the most likely diagnosis. Immediate CT or MRI imaging is necessary with acute immunosuppression with high-dose steroids, followed by maintenance immunosuppression with azathioprine, methotrexate or cyclophosphamide.

Question 81 of 328

A 73-year-old man was admitted as an emergency suffering from severe, central and crushing chest pain. ECG revealed evidence of anterior ST elevation MI and primary percutaneous coronary intervention was performed with the deployment of two drug-eluting stents to the left anterior descending artery. The patient had no previous coronary artery disease or significant family history. He is an ex-smoker and drinks approximately 10 units of alcohol per week.

Post-procedure the patient was well and mobilised on the ward without further chest pain or shortness of breath. Clinical examination was unremarkable.

The patient was commenced on aspirin, clopidogrel, ramipril, bisoprolol and atorvastatin therapy. Further investigations performed following intervention are summarised as below.

Haemoglobin	13.9 d / dL
White cell count	8.6 * 10 /l
Platelets	199 * 10 /l
Urea	7.2 mmol / L
Creatinine	110 micromol / L
Sodium	137 mmol / L
Potassium	4.3 mmol / L
Total cholesterol	5.4 mmol / L
LDL cholesterol	3.1 mmol / L
HDL cholesterol	1.2 mmol / L
Triglycerides	2.5 mmol / L

Transthoracic echocardiogram: no valvular abnormality; mild anterior dyskinesia with overall normal left ventricular systolic function; ejection fraction 55-60 %

Primary PCI report: total occlusion of mid-LAD, two DES deployed with good angiographic result; 50 % mid-vessel occlusion of the right coronary artery; circumflex unobstructed.

Prior to discharge, the patient asks to speak to you about any other possible strategies to reduce his risk of suffering a further heart attack.

Which of the following interventions is recommended for this patient by NICE guidance on secondary prevention of myocardial infarction?

A. Percutaneous coronary intervention to right coronary artery
B. Mediterranean-style diet
C. Abstinence from alcohol
D. Omega-3 fatty acid supplements
E. Aldosterone antagonist (for example, eplerenone)

B. Mediterranean-style diet

NICE recommends several lifestyle changes after a myocardial infarction. These include smoking cessation, a Mediterranean-style diet, achievement of a healthy weight, limitation of alcohol consumption to recommended healthy limits and 20-30 minutes of physical activity daily. NICE does not recommend routinely eating oily fish or the consumption of omega-3 supplements, although it is noted that there is no evidence of harm from these interventions.

Aldosterone antagonists are recommended for use in patients with symptoms and signs of heart failure or with evidence of systolic impairment on echocardiography. There is no evidence that percutaneous treatment of mild asymptomatic coronary artery disease (such as in this patient) reduces the future risk of myocardial infarction.

Question 82 of 328

A 69-year-old man with a background of ischaemic heart disease attends his routine cardiology appointment. He reports a 2-month history of progressively worsening shortness of breath and is only able to walk 100 yards before needing to stop for rest. He has occasional exertional chest pain which resolves with sublingual glyceryl trinitrate. He is currently taking aspirin, atorvastatin, lansoprazole, bisoprolol, ramipril, spironolactone and sublingual glyceryl trinitrate as required.

On examination, his heart rate is 80bpm and regular with a blood pressure of 130/75mmHg. His chest is clear with good air entry bilaterally and saturations of 94% on room air. He has a soft and nontender abdomen with no palpable organomegaly. There is pitting oedema to his knees.

ECG: Sinus rhythm, Q waves and T wave inversion in V1-V4, QRS duration 110ms.

Echocardiogram: Left ventricular ejection fraction 33%, pulmonary arterial pressure 20mmHg.

What is the most appropriate step in the management of this patient?

A. Cardiac resynchronisation therapy
B. Digoxin
C. Furosemide
D. Ivabradine
E. Nicorandil

D. Ivabradine

Ivabradine should be considered in heart failure if the patient has sinus rhythm > 75/min and a LVEF < 35% and have not responded to to ACE-inhibitor, beta-blocker and aldosterone antagonist therapy

Ivabradine is a 3rd line agent in the treatment of heart failure. It works by selectively inhibiting the 'funny current' I*f*, also known as the pacemaker current found in the sinoatrial node. The drug acts to lower the heart rate and therefore the oxygen demand needed to supply to the myocardium. Criteria for prescribing ivabradine include a heart rate > 75bpm and an ejection fraction of < 35%.

Cardiac resynchronisation therapy (CRT) is another 3rd line treatment agent for heart failure. It is indicated for patients with left ventricular dysfunction and consequently a reduced LV stroke volume which is complicated by a dyssynchronous ventricular contraction secondary to a conduction delay (usually LBBB). It involves inserting electrodes into the walls of the ventricle to coordinate their contraction and ensure a synchronised contraction of the left ventricle to increase the ejection fraction. An indication for its use is a reduced ejection fraction (< 35%) and widened QRS complexes (>120ms) on the ECG.

Digoxin can be used as a 3rd line agent in the treatment of heart failure. It is strongly indicated in patients with co-existing atrial fibrillation.

Furosemide can provide symptomatic relief from fluid overload in heart failure. However, it does not improve mortality and is therefore not the next recommended treatment option.

Nicorandil is a potassium channel agonist that causes vasodilatation and is therefore used in the treatment of stable angina. Due to the effects of vasodilation on blood pressure and ejection fraction, its use is contraindicated in those with left ventricular dysfunction.

Question 83 of 328

A 29-year-old man is admitted to the cardiology ward following a collapse whilst playing football. He has no recollection of events other than running on the pitch and waking up in the ambulance. In the last 2- 3 months, he has been complaining of intermittent palpitations but put this down to work-related stress. There is no history of chest pain and he has no past medical history of note.

His observations are recorded within normal limits. On auscultation, chest sounds are clear and heart sounds are normal. He has a soft and non-tender abdomen and his neurological examination is unremarkable.

A bedside echocardiogram demonstrates a hypokinetic right ventricle.

Given the likely diagnosis, what is the most characteristic finding on this patient's ECG?

A. Left ventricular hypertrophy
B. Positive deflection at the J point
C. Right bundle brach block
D. Slurred upstroke in QRS
E. Small positive deflection at the end of QRS complex

E. Small positive deflection at the end of QRS complex

The most characteristic ECG finding in arrhythmogenic right ventricular dysplasia (ARVD) is the epsilon wave (a small positive deflection at the end of the QRS complex)

This patient has arrhythmogenic right ventricular dysplasia (ARVD), a type of inherited cardiovascular disease. ARVD can present as palpitations, syncope, or sudden cardiac death similar to hypertrophic obstructive cardiomyopathy (HOCM). Over time, the right ventricular myocardium is replaced by fibrofatty tissue and patients develop signs of right ventricular failure. This patient's echocardiogram finding of a hypokinetic right ventricular wall is suggestive of the diagnosis. The most characteristic ECG finding in ARVD is an **epsilon wave**. An epsilon wave is a positive deflection following the end of the QRS complex caused by post-excitation of right ventricular myocytes.

Left ventricular hypertrophy is a common ECG finding of HOCM. HOCM is the most common cause of sudden cardiac death and can also present with palpitations and syncope, as seen in this patient. However, this patient's echocardiogram findings are in keeping with ARVD, of which the epsilon wave is the most characteristic ECG finding.

An **Osborn wave (or J wave) is a positive deflection at the J point**. There are multiple causes, of which the most common is hypothermia. Other causes of J waves include left ventricular hypertrophy and Brugada syndrome. However, an Osborn wave is not associated with ARVD.

There are multiple causes of **right bundle branch block**, including right ventricular hypertrophy. In ARVD, rather than hypertrophy of the right ventricle, the myocardium is replaced by fatty tissue. Right bundle branch block is not a sign of ARVD. Instead, the left bundle branch block is more likely to feature on an ECG of a patient with ARVD.

A **delta wave** is a slurred upstroke in the QRS complex that is commonly associated with pre-excitatory activity, such as that seen in WolffParkinson White syndrome. It is not associated with ARVD.

Question 84 of 328

A medical opinion was sought from the obstetrics team regarding a 38- year-old 28 weeks pregnant lady. A routine blood pressure check revealed a blood pressure of 158/98 mmHg. Other than suffering from hyperemesis gravidarum, her pregnancy had proceeded without complication. She specifically denied the presence of headaches, vomiting, change in vision, abdominal pain, seizures or bleeding per vagina. She had noticed no change in the frequency of foetal movements, and her 20-week antenatal scan revealed the presence of a healthy foetus with a rate of growth within the expected range. Her past medical history was unremarkable; she was a non-smoker and did not consume alcohol. Her blood pressure at the booking antenatal appointment was 148/88 mmHg. Her sister suffered from pre-eclampsia during her pregnancy necessitating delivery by caesarean section.

Examination revealed the presence of a well 28-week old pregnant lady. Her blood pressure was indeed 158/98 mmHg, her heart rate was 86 bpm and temperature 36.5ºC. Examination of the cardiovascular system revealed normal heart sounds, a JVP of 3cm and the absence of pedal oedema. Examination of the respiratory system was unremarkable. Examination of the gastrointestinal system revealed the presence of a symphysiofundal height appropriate for the stage of gestation with easily obtainable foetal heart sounds on hand held Doppler examination. Examination of the neurological system was unremarkable with normal reflexes, cranial nerve function and peripheral motor and sensory function. Urinalysis revealed no abnormality.

What is the next best management step?

A. Commence ramipril
B. Commence labetalol
C. Commence indapamide
D. Commence magnesium sulphate
E. Transfer to high dependency unit to observe for signs of preeclampsia

B. Commence labetalol

This lady has pre-existing hypertension; her blood pressure at the antenatal booking clinic was elevated and continues to be elevated throughout (as opposed to gestational hypertension in which hypertension develops after 20 weeks). If untreated hypertension is associated with adverse maternal and foetal outcomes including intrauterine growth restriction, placental abruption, cerebrovascular accidents and prematurity. There are no clinical features of preeclampsia, including notably the presence of proteinuria and peripheral oedema, and there is, therefore, no indication for admission to a high dependency unit or to commence magnesium sulphate. Of the remaining options, labetalol is the safest antihypertensive to use in pregnancy; methyldopa is an alternative. The usual first line ACE inhibitors are absolutely contraindicated in pregnancy.

Question 85 of 328

A 38-year-old female of Asian descent, with no significant past medical history, presents after a syncopal event while pruning hedges. She has had a 6-month history of fever, arthralgia and for the past few weeks has had multiple episodes of vertigo and one syncopal event. She denies headaches or visual complaints. Her examination reveals a diminished radial pulse in the left arm and a systolic blood pressure difference in the upper extremities of 14 mmHg. A bruit is auscultated along the left upper extremity. Dopplers of the upper extremities indicate a stenotic area along the subclavian that is later confirmed by Magnetic Resonance Angiography (MRA). She is diagnosed with subclavian steal syndrome. Laboratory tests reveal a normocytic normochromic anaemia, elevated CRP and ESR, negative ANA and ANCA, and all other laboratory tests are within normal range.

Of the following, What is the most likely diagnosis?

A. Fibromuscular dysplasia
B. Ehlers-Danlos syndrome
C. Takayasu arteritis
D. Giant cell arteritis
E. Wegener's granulomatosis

C. Takayasu arteritis

This patient likely has Takayasu arteritis which is essentially a chronic vasculitis primarily of the aorta and its branches. These patients can present in a variety of different ways depending on the vessels affected, however, they all typically have a prodrome of systemic symptoms including fatigue, weight loss and low-grade fevers prior to developing any vascular complaints. From a pathology standpoint biopsies of vessels are very similar to giant cell and are typically not performed.

There are 6 criteria for the diagnosis of Takayasu. Presence of 3 of the 6 has 90% sensitivity and specificity for diagnosis:

1. Age onset <=40 years

2. Claudication of the extremities

3. Decreased pulsation of one or both brachial arteries

4. Difference of at least 10 mm Hg in systolic blood pressure

between the arms

5. Bruit over one or both subclavian arteries or the abdominal aorta

6. Arteriographic narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities, not due to arteriosclerosis, fibromuscular dysplasia, or other causes

Fibromuscular dysplasia typically affects the renal arteries leading to renal artery stenosis and hypertension, and it not accompanied by other systemic manifestations like fever and malaise. Ehlers-Danlos syndrome is a genetic defect in type III collagen and can lead to aneurysms along with hyperelasticity of the skin and hypermobile joints, but other systemic manifestations are typically not present. Giant cell arteritis is most similar to Takayasu in pathology, however typically affects older patients and usually presents with headaches and tenderness over the temporal artery. Lastly, Wegener's is actually a small vessel vasculitis and its most common presenting symptoms include persistent rhinorrhoea, purulent/bloody nasal discharge, oral and/or nasal ulcers, polyarthralgias, myalgias, or sinus pain. Most with Wegener's are ANCA positive.

Question 86 of 328

A 72-year-old woman with a 30 year history of type 2 diabetes mellitus comes for review. She was diagnosed with chronic kidney disease (secondary to diabetes) 8 years ago and has seen declining renal function since. Her current medication includes ramipril 10mg od, amlodipine 10mg od, simvastatin 40mg on and Novomix 30 insulin bd.

Her most recent renal function tests show the following:

Na +	139 mmol/l
K +	5.3 mmol/l
Urea	10.2 mmol/l
Creatinine	123 µmol/l
eGFR	40 ml/min/1.73m²

Blood pressure in clinic is 156/88 mmHg and this is confirmed on a second reading.

What should be done regarding her blood pressure medication?

- A. Add bisoprolol
- B. Add indapamide
- C. Add doxazosin
- D. Add spironolactone
- E. Add an angiotensin II receptor blocker

B. Add indapamide

Poorly controlled hypertension, already taking an ACE inhibitor and a calcium channel blocker - add a thiazide-like diuretic

Tight blood pressure remains a key management aim in patients with diabetic nephropathy. ACE inhibitors are clearly the most evidence based management in this arena but her blood pressure is persistently high. If we look at the NICE guidelines the next step would be the addition of a thiazide based diuretic (e.g. indapamide) and there is no reason not to follow these recommendations in this situation.

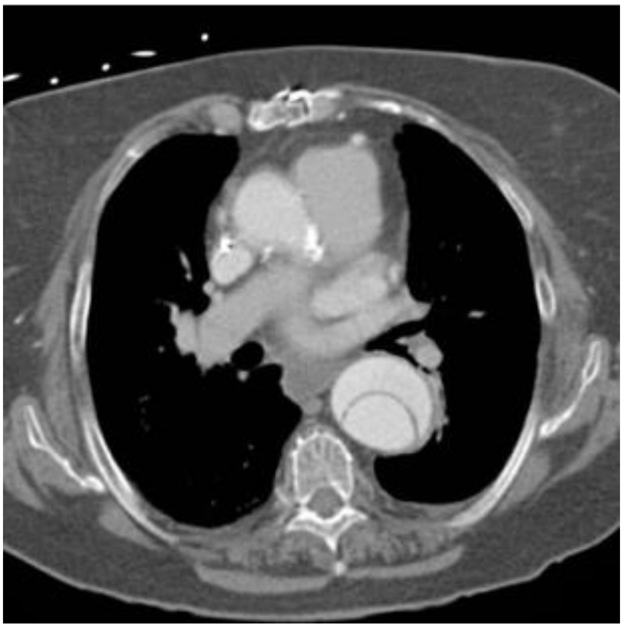
If the eGFR is less than 30 ml/min/1.73m² then thiazides should be avoided as the BNF states:

Thiazides and related diuretics are ineffective if eGFR is less than 30 mL/minute/1.73 m2 and should be avoided; metolazone remains effective but with a risk of excessive diuresis

Spironolactone and angiotensin II receptor blockers may risk precipitating hyperkalaemia.

Question 87 of 328

A 74-year-old man with a history of depression, chronic obstructive pulmonary disease and hypertension is admitted to hospital with severe central chest pain. He has no history of ischaemic heart disease or similar chest pains in the past. On admission blood pressure is 160/98 mmHg, pulse 110/min, respiratory rate 18/min and oxygen saturations are 93% on room air. A CT chest (with contrast) is shown below:



What is the most appropriate management?

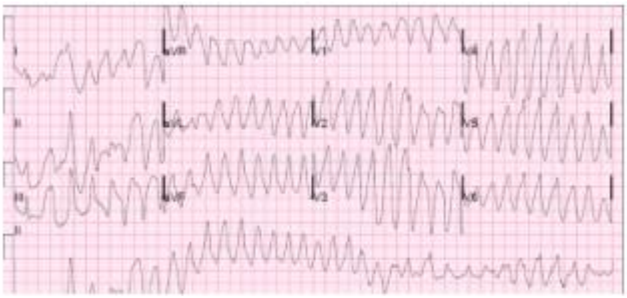
- A. Chest drain
- B. Cardiothoracic surgery
- C. Intravenous labetalol
- D. Thrombolysis with tenecteplase
- E. Low-molecular weight heparin

C. Intravenous labetalol

Dissection of the descending aorta can be seen. As this is a Stanford type B dissection it is treated conservatively with intravenous beta-blockers to lower blood pressure and help prevent any extension.

Question 88 of 328

A 44-year-old woman presents to the emergency department with dyspnoea. She has been feeling intermittently dizzy and short-of-breath for the past 2 weeks. On examination her pulse is 180/min, blood pressure 100/66 mmHg, oxygen saturations 98% on room air. Her chest is clear and she appears well perfused. An ECG is obtained:



What is the most appropriate treatment? ,

- A. Intravenous amiodarone
- B. Intravenous adenosine
- C. Intravenous magnesium
- D. Intravenous labetalol
- E. Unsynchronised DC shock

C. Intravenous magnesium

IV magnesium sulfate is used to treat torsades de pointes

The ECG shows an irregular wide-complex tachycardia, a form of polymorphic ventricular tachycardia or more specifically torsades de pointes. This patient had an underlying long QT interval secondary to a combination of medications. The acute treatment for this is intravenous magnesium.

Precipitating medications should, of course, be reviewed and electrolyte abnormalities corrected.

If the patient was in shock or periarrest then the ALS tachycardia should be followed, i.e. SYNCHRONISED DC shocks. There are, however, no 'adverse' signs in this patient.

The ALS periarrest guidelines state the following:

Treat torsade de pointes VT immediately by stopping all drugs known to prolong the QT interval. Do not give amiodarone for definite torsade de pointes. Correct electrolyte abnormalities, especially hypokalaemia. Give magnesium sulfate 2 g IV over 10 min (= 8 mmol, 4 mL of 50% magnesium sulfate).

Question 89 of 328

A 67-year-old woman is complaining of a six-hour history of chest pain and dizziness in the high-dependency unit. She underwent a mitral valve replacement five days ago and had some temporary trans-venous pacing wires removed earlier today.

On examination, she has oxygen saturations of 93% on 2 litres via nasal cannula, has a heart rate of 110/min, a blood pressure of 76/43mmHg, has a temperature of 37.9ºC, and is responsive to voice. She feels cool peripherally. An ECG is performed at the bedside which shows sinus rhythm with QRS complexes of alternating amplitude.

Blood tests from this morning show the following:

Hb	89 g/L	(115 - 160)
Platelets	121 * 10 /L 9	(150 - 400)
WBC	13.1 * 10 /L 9	(4.0 - 11.0)
Na +	143 mmol/L	(135 - 145)
K +	3.1 mmol/L	(3.5 - 5.0)
Urea	18.2 mmol/L	(2.0 - 7.0)
Creatinine	151 µmol/L	(55 - 120)
CRP	282 mg/L	(< 5)
Magnesium	0.83 mmol/L	(0.85 - 1.10)

What is the most appropriate management given the likely diagnosis?

A. Electrolyte replacement
B. Emergency percutaneous coronary intervention
C. Pericardiocentesis
D. Prolonged course of antibiotics
E. Urgent temporary pacing wire insertion

C. Pericardiocentesis

Electrical alternans is suggestive of cardiac tamponade

This woman has clinical signs of cardiac tamponade which is confirmed by electrical alternans on ECG. Electrical alternans occurs due to the movement or 'swinging' of the heart within the pericardium as a result of the fluid present. This results in a variable amplitude of the QRS complex depending on the hearts proximity to the ECG leads. In this case, this was likely precipitated by a traumatic removal of trans-venous pacing wires causing bleeding into the pericardial space. As a result, she requires an urgent echocardiogram to confirm the diagnosis and subsequent **pericardiocentesis** or re-sternotomy to drain the blood. It is worth noting that her acute kidney injury is the result of poor cardiac output as a result of her tamponade.

Although there are electrolyte abnormalities on this patient's blood tests that should be replaced, this is not likely to be the cause of her acute presentation. An arrhythmia post-operatively could cause a reduction in cardiac output however the ECG performed here demonstrates sinus rhythm and therefore **electrolyte replacement** would not reverse her current condition.

An acute coronary syndrome must be considered in cardiac postoperative patients complaining of chest pain however the electrical alternans on ECG with no remarkable ST changes to speak of is more consistent with a diagnosis of cardiac tamponade. Therefore, **emergency percutaneous coronary intervention** is not the most appropriate option here.

A **prolonged course of antibiotics** may be employed if a diagnosis of infective endocarditis is suspected however this is not the case here for a variety of reasons. Firstly, infective endocarditis post-operatively is unlikely to present within 5 days. Furthermore, the electrical alternans on ECG is indicative of cardiac tamponade rather than infective endocarditis. Finally, although the patient has a fever and a raised CRP, these are common findings post-operatively due to the systemic inflammatory response to surgery and are not specific for infective endocarditis.

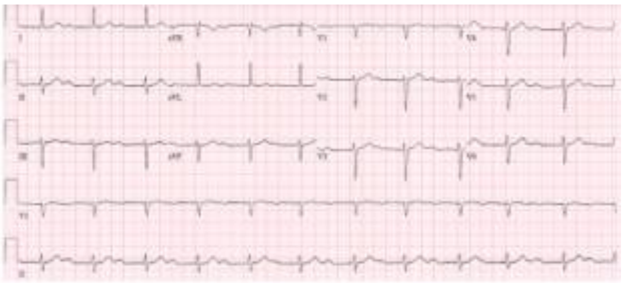
Arrhythmias are common in the post-operative period for patients who have undergone cardiac surgery, particularly valve surgery, however, this patient is in sinus rhythm at an acceptable rate. Therefore, as this patient's pathology is mechanical rather than electrical, **urgent temporary pacing wire insertion** will not help with her current issue.

Question 90 of 328

A 58-year-old man is referred to the cardiology clinic for a review. He complains of a 4-week history of intermittent palpitations and chest discomfort for approximately 1-2 minutes. He works as a stockbroker and has been recently promoted. There is no past medical history of note and he is an active tennis player on the weekends. He takes no regular medications and drinks 1 bottle of wine per week.

On examination, he has a heart rate of 65 beats/min and is regular with a blood pressure of 131/68mmHg. He has normal heart sounds and equal air entry on auscultation. His calves are soft with no pitting oedema.

An ECG is taken, as shown below:



What is the recommended management for this patient?

A. Catheter ablation of accessory pathway
B. Oral aspirin
C. Oral bisoprolol
D. Reassurance and discharge
E. Referral for pacemaker insertion

D. Reassurance and discharge

Reassurance and discharge is correct. This patient's ECG shows firstdegree heart block with a prolonged PR interval. First-degree heart block is not of any clinical concern and does not warrant further management. Taking a closer look at this patient's presentation, it seems that his chest discomfort and palpitations have coincided with a new job promotion and could be related to stress or anxiety. This history is atypical for cardiac ischaemia and there are minimal risk factors present to suggest that this patient's presentation was related to sinister cardiac pathology.

Catheter ablation of accessory pathway is incorrect. An accessory pathway (e.g. Bundle of Kent) is capable of creating a re-entry circuit that predisposes the patient to tachyarrhythmias. An example of a re-entry tachycardia associated with an accessory pathway is Wolff-ParkinsonWhite (WPW) syndrome. ECG features of WPW include PR-interval shortening, QRS prolongation and the classic 'delta wave' (the slow, slurred uprising of the QRS complex). These features are not seen on this patient's ECG. Catheter ablation is also used in the treatment of atrial fibrillation, but this patient has a regular rhythm with visible p waves, making atrial fibrillation very unlikely.

Oral aspirin is incorrect. This is used in the management of ischaemic heart disease that appears as the presence of Q waves, ST-segment elevation or depression or T wave inversion. None of these symptoms are seen, making ischaemic heart disease unlikely and, therefore, the use of aspirin incorrect.

Oral bisoprolol is incorrect. This is used in the management of ectopic burden and tachyarrhythmias. However, it is not used in the management of first-degree heart block.

Referral for pacemaker insertion is incorrect. Indications for pacemaker insertion include complete heart block, second-degree mobitz type 2 heart block, ventricular pauses >3 seconds and previous asystole. This patient has first-degree heart block which is not an indication to be referred for permanent pacemaker insertion.

Question 91 of 328

An 83-year-old male presents with ischaemic sounding chest pain that has persisted for the past one hour. A 12-lead ECG is performed and shows deep T wave inversion in leads V1 and V2.

Which is the most likely implicated coronary artery?

A. Left circumflex artery
B. Left main stem artery
C. Proximal left anterior descending artery
D. Right coronary artery
E. Distal left anterior descending artery

C. Proximal left anterior descending artery

Ischaemic changes in leads V1-V4 - left anterior descending

Wellens' syndrome is an ECG manifestation of critical proximal left anterior descending (LAD) coronary artery stenosis in patients with unstable angina. It is characterized by symmetrical, often deep (>2 mm), T wave inversions in the anterior precordial leads.

Question 92 of 328

A 22-year-old woman presents to the emergency department with a 1- day history of abdominal pain and vomiting. She denies fever or diarrhoea and disclosed that she went out to a party the night before and consumed 7 glasses of wine. She reports that there is a heart condition that runs in her family, but she cannot remember the name of the condition.

Her observations are within normal limits. On examination, there is central and epigastric tenderness but no guarding or peritonism. Her respiratory and cardiovascular examinations were unremarkable.

Venous blood gas:

pH	7.35	(7.35 - 7.45)
Na +	138 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Bicarbonate	22 mmol/L	(22 - 29)
Lactate	3.5 mmol/L	(< 1.6)
Glucose	6.2 mmol/L	(4 - 8)

ECG: Sinus rhythm, normal axis, QRS duration 110ms, QTc 550ms.

What drug is it most important to avoid?

A. Codeine
B. Cyclizine
C. Hyoscine butylbromide
D. Omeprazole
E. Ondansetron

E. Ondansetron

5HT-3 receptor antagonists shouldn't be used as antiemetics in patients with long-QT syndrome

This patient has a prolonged QTc interval of 550ms. A normal QTc interval for women should lie between 350-460ms. Patients with a prolonged QTc interval are at particular risk of developing critical arrhythmias such as Torsades de pointes (a polymorphic ventricular tachycardia). It is therefore extremely important to avoid drugs that may prolong the QTc interval further. **Ondansetron** is a type of 5HT-3 receptor antagonist that is associated with QTc interval prolongation and should therefore be avoided.

Codeine is a weak opioid analgesic with common side effects of nausea, drowsiness and constipation. It does not prolong the QTc interval.

Cyclizine is a H1-receptor antagonist. Side effects of cyclizine include urinary retention, dry mouth, and blurred vision. Prolongation of the QTc interval is not a common feature of this medication.

Hyoscine butylbromide is used in the treatment of gastric spasm. It is an anticholinergic agent and is, therefore, contraindicated in myasthenia gravis, urinary retention and gastrointestinal obstruction. It does not prolong the QTc interval.

Omeprazole is a proton-pump inhibitor used in the treatment of gastritis and gastro-oesophageal bleeding. Complications include electrolyte disturbances (e.g. hypomagnesaemia) and increased risk of *Clostridium dificile* infections but not prolongation of the QTc interval.

Question 93 of 328

A 64-year-old man presents to his general practitioner (GP) with several months of chest pain that occurs only on exertion. When he pauses to rest, the pain dissipates within a few minutes. He has a past medical history of high cholesterol, for which he takes atorvastatin. The GP commences him on bisoprolol.

Several weeks later, the patient re-attends, stating that the symptoms are still not under control.

What should be added next?

A. Amlodipine
B. Isosorbide mononitrate
C. Ivabradine
D. Nicorandil
E. Verapamil

A. Amlodipine

If angina is not controlled with a beta-blocker, a longer-acting dihydropyridine calcium channel blocker should be added

This patient is experiencing stable angina - the chest pain is occurring on exertion, but not at rest. NICE recommend the use of a beta-blocker or calcium channel blocker (CCB) first-line. As this patient has been commenced on bisoprolol already, the next step is to add a CCB. A dihydropyridine CCB should be used, to avoid reducing the heart rate further, and so **amlodipine** is the most appropriate option here.

Isosorbide mononitrate would be appropriate to use as a third agent, if the combination of a beta-blocker and CCB was not adequate. However, at this stage, a CCB should be added.

Similarly, **ivabradine**, which modulates the 'funny current', would be appropriate as a third agent instead of isosorbide mononitrate. A CCB should be added first, as this patient is only on bisoprolol.

Nicorandil is another alternative agent to be added third, instead of isosorbide mononitrate or ivabradine. It would not be appropriate to add currently, as the patient is only on bisoprolol.

Verapamil is a non-dihydropyridine CCB. As such, it is negatively chronotropic and so should not be used alongside a beta-blocker; this may precipitate complete heart block. It would have been suitable as a first-line alternative to the beta-blocker.

Question 94 of 328

A 64-year-old man presents to his general practitioner 4 weeks after a permanent pacemaker (PPM) insertion. This was inserted for symptomatic first-degree heart block. He reports that since this was inserted, he has actually felt worse and his exercise tolerance has become more limited.

An ECG is performed and shows a paced rhythm on VVI at 70/min. Each pacing spike is followed by a QRS complex and there are no pacing spikes in between beats. He has regular p waves at a rate of 35/min which are not related to the QRS complexes.

What is the most appropriate intervention?

A. Convert to a dual chamber pacemaker
B. Increase the pacing output
C. Increase the pacing sensitivity
D. Reduce the pacing output
E. Reduce the pacing sensitivity

A. Convert to a dual chamber pacemaker

A VVI pacemaker will pace and sense the right ventricle. In the presence or organised atrial activity, a VVI pacemaker may pace the ventricles out of sync with the atria resulting in pacemaker syndrome.

This man currently has single-chamber pacing to the ventricles as identified by his mode (VVI). Although this guarantees a ventricular rate, this is at the expense of atrioventricular concordance. For some people, cardiac output may actually fall because of this reduced diastolic function (known as pacemaker syndrome). Hence the worsening of this man's symptoms. One way to correct this would be to **convert to a dual-chamber pacemaker** and establish DDD pacing. This would pace both the atria and ventricles and ensure atrioventricular concordance. Atrial pacing would be possible given that the patient has p waves and therefore is not in atrial fibrillation.

Increasing the pacing output is a useful intervention when there is insufficient capture (the pacing spikes are not at a sufficient voltage to elicit a corresponding QRS complex). As this man's ECG shows good capture, this is not the most appropriate intervention.

An **increase of pacing sensitivity** increases the voltage required to inhibit the pacemaker. This would be a helpful intervention if the pacemaker was being inappropriately inhibited (potentially by noise). As the pacemaker is currently delivering regular pacing spikes at an appropriate rate, over-inhibition is not the cause of this man's symptoms and so this intervention would not be appropriate.

A **reduction in the pacing output** can be helpful to preserve the pacemaker's battery life and therefore the lowest output required to safely and reliably achieve capture should be used at all times, however this will not help with this patient's complaint.

Reducing the pacing sensitivity reduces the voltage required to inhibit the pacemaker. This could be employed if the patient's native rhythm was faster than the rate of the pacemaker but was still not inhibiting the pacemaker from firing. This is particularly important to avoid R on T pacing. As the pacing spikes here are immediately followed by QRS complexes, this man is reliant on his pacemaker's rate and there is no evidence that native QRS complexes are not able to inhibit the pacemaker. Therefore this intervention is not indicated.

Question 95 of 328

A 58-year-old female reports having symptomatic episodes of palpitations for the last six months. She is normally fit and drinks the occasional small glass of red wine when she goes out for a meal. The last episode was four days ago when she was cooking in her kitchen. She describes that she felt light headed with central chest discomfort that eased after twenty minutes. In clinic, her observations are all stable and an initial twelve lead electrocardiogram shows sinus rhythm.

What would be the investigation of choice?

A. 24 hour ambulatory electrocardiogram
B. Electrocardiogram treadmill test
C. 24 hour blood pressure
D. 72 hour ambulatory electrocardiogram
E. Event recorder electrocardiogram

E. Event recorder electrocardiogram

Atrial fibrillation is a common arrhythmia that may be persistent or paroxysmal. It is more common in women compared to men.

All patients with suspected atrial fibrillation should have a manual pulse check followed by a twelve-lead electrocardiogram. Those who have episodes less than 24 hours apart should have a 24-hour ambulatory electrocardiogram. In patients who experience episodes more than 24 hours apart, an event recorder electrocardiogram would be the most suitable investigation of choice.

24-hour blood pressure monitoring would be considered in a patient with suspected hypertension.

Electrocardiogram treadmill test is useful for revealing abnormal heart rhythms induced by exercise and ischaemic changes suggestive of coronary heart disease.

A 72-hour ambulatory electrocardiogram is used in much the same way as a 24 and 48-hour test. However, current NICE guidelines suggest for atrial fibrillation of episodes more than 24 hours apart an event recorder device is most useful.

Question 96 of 328

A 24-year-old man presents to the emergency department with one hour of palpitations and dizziness. He has no significant past medical history and is on no regular medications. He works as an accountant. There is no history of illicit drug use.

His observations are heart rate 180 beats per minute, blood pressure 88/59 mmHg, respiratory rate 22/minute, oxygen saturations 96% on air and temperature 36.4ºC.

Clinical examination is unremarkable except for a regular bounding tachycardia.

An ECG demonstrates ventricular tachycardia with positive concordance throughout the chest leads and similar morphology throughout.

As he is haemodynamically unstable, emergency electrical cardioversion is undertaken in the emergency department resuscitation area, which is successful.

Post cardioversion, his observations are heart rate 84 beats per minute, blood pressure 120/84 mmHg, respiratory rate 18/minute, oxygen saturations 96% on air and temperature 36.6ºC.

A repeat ECG demonstrates sinus rhythm and T wave inversion in leads V1-V3 with no other significant abnormalities.

Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	188 * 10 /L	(150 - 400)
WBC	7.2 * 10 /L	(4.0 - 11.0)
Na	141 mmol/L	(135 - 145)
K	4.4 mmol/L	(3.5 - 5.0)
Urea	5.6 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Adjusted calcium	2.41 mmol/L	(2.2 - 2.6)
Magnesium	0.92 mmol/L	(0.85 - 1.10)
Troponin	17 ng/L	(<14)

A CT pulmonary angiogram excludes a pulmonary embolism.

What is the likely diagnosis?

A. Arrhythmogenic right ventricular cardiomyopathy
B. Brugada syndrome
C. Catecholaminergic Polymorphic Ventricular Tachycardia
D. Right ventricular outflow tract ventricular tachycardia
E. Romano-Ward syndrome

A. Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy - T wave inversion in V1-3

Arrhythmogenic right ventricular cardiomyopathy (AVRC) is the correct answer. AVRC is a condition inherited with an autosomal dominant pattern, which is characterised by replacement of the normal right ventricular myocardium with fibrofatty tissue. It typically presents in the 2nd-4th decade of life with palpitations, syncope or sudden cardiac death and is a cause of monomorphic ventricular tachycardia. The resting ECG is typically abnormal and may demonstrate T wave inversion in V1- V3. The mildly elevated troponin in this case is simply secondary to ventricular tachycardia. Imaging will demonstrate structural and functional abnormalities of the right ventricle.

Brugada syndrome is incorrect. This is also an inherited cause of sudden cardiac death (autosomal dominant) but it traditionally causes a polymorphic ventricular tachycardia and the resting ECG is characterized by 'coved' ST segment elevation >2mm in >1 of V1-V3 followed by a negative T wave.

Catecholaminergic Polymorphic Ventricular Tachycardia is incorrect. This is an inherited cause of arrhythmia and sudden cardiac death characterized by palpitations, syncope of cardiac arrest precipitated by exercise or emotions. It is typically associated with polymorphic ventricular tachycardia as suggested by the name. Usually, the resting ECG is normal.

Right ventricular outflow tract ventricular tachycardia (RVOT-VT) is incorrect. Idiopathic RVOT-VT is not an inherited condition and the resting ECG is normal.

Romano-Ward syndrome is incorrect. This is a cause of congenital long QT syndrome, which can cause a polymorphic ventricular tachycardia. We are told there are no abnormalities on the resting

ECG apart from T wave inversion. Therefore, we can assume the QT interval is normal.

Question 97 of 328

An 82-year-old man presents with loss of consciousness. His wife states that he complained of feeling dizzy, before going pale in colour and falling to the ground. He was unconscious for approximately one minute. On regaining consciousness he was not confused and recovered within minutes. He denies any chest pain, shortness of breath or palpitations. He states that over the past few months he has had several episodes of light headedness however he has never lost consciousness before.

A 7 day holter was performed:

Heart rate	3 episodes of bradycardia of 20-30 bpm which correlated withepisodes of pre-syncope
Other events	Absence of P waves for 3.5 seconds

How will you manage this patient?

A. VVI pacemaker
B. Biventricular pacemaker
C. AAIR pacemaker
D. Reassurance
E. Bisoprolol

C. AAIR pacemaker

In pure sinus node dysfunction without AF or evidence of AV block, an AAIR or DDDR pacemaker can be used. Most cardiologists would choose a DDDR pacemaker since many of these patients go onto develop AV block

The 7 day holter confirms symptomatic sinus bradycardia and an episode of sinus arrest (absence of P wave for > 3 seconds). This confirms the diagnosis of sick sinus syndrome Sick sinus syndrome can be difficult to manage, as it can present with bradyarrhythmias, tachyarrhythmias, or a mixture of both. Bradyarrhythmias can be well controlled with pacemakers, while tachyarrhythmias respond well to rate limiting drugs such as calcium channel blockers, digoxin and beta blockers. However drugs to control tachyarrhythmia may exacerbate bradyarrhythmias. Therefore, a pacemaker is often implanted before drug therapy is begun for the tachyarrhythmia.

This patient has been having symptomatic bradycardia episodes secondary to sinoatrial node disease. Therefore an AAIR pacemaker is indicated. AAI pacemakers both sense and pace the atria. They are useful for isolated sinoatrial node disease. These are not suitable in patients with atrial fibrillation.

VVI pacemakers will both sense and pace the ventricle. VVI or VVR pacemakers are useful for pure sustained slow atrial fibrillation.

Biventricular pacemakers are used in heart failure with left bundle branch block.

Bisoprolol is a rate limiting drug which would worsen the bradycardia and the patients symptoms.

Question 98 of 328

A 45-year-old male patient presents with a worsening shortness of breath to the medical assessment unit. His has an accompanying letter from his GP stating that his past medical history is significant only for a deteriorating renal function that is secondary to polycystic kidney disease.

On examination there is no evidence of fluid overload, with the lung fields remaining clear and the JVP not elevated. You do however discern a late systolic murmur heard best at the cardiac apex which is immediately preceded by a 'click'.

Observations

- heart rate 82bpm
- blood pressure 106/86mmHg
- Respiratory rate 16 per minute
- temperature 36.5
- oxygen saturation 97% on room air

What is the most likely diagnosis?

A. Mitral valve prolapse
B. Mitral stenosis
C. Pulmonary stenosis
D. Mitral regurgitation
E. Aortic stenosis

A. Mitral valve prolapse

Adult polycystic kidney disease can be associated with extra-renal complications. Up to 85% of patients with autosomal dominant polycystic kidney disease (ADPKD) will exhibit liver cysts by the age of 30. Other complications include intra-cranial aneurysm and heart valve disease. Affected heart valves can occur in up to 25% of ADPKD patients and of them the majority have mitral valve prolapse. The majority of patients with mitral valve prolapse with be asymptomatic but when symptoms are present mitral valve prolapse has to be considered and investigated with an echocardiogram.

The 'click' coupled with the knowledge of the underlying ADPKD makes the murmur heard in this patient that of a mitral valve prolapse. The prolapse can worsen and cause a secondary mitral regurgitation leading to symptoms such as shortness of breath. The narrow pulse pressure present also suggests an element of left ventricular dysfunction

Question 99 of 328

A 64-year-old caucasian male presented to heart failure clinic with shortness of breath on exertion. He has a history of heart failure, initially diagnosed three years previously.

His current medications included ramipril, aspirin, bisoprolol, simvastatin and spironolactone. He is concerned that despite all of these medications his breathlessness is worsening. In addition to this he is now using four pillows to sleep at night.

On examination he is comfortable at rest with fine crackles at both lung bases and pitting oedema reaching up to both knees. His observations reveal a respiratory rate of 16 breaths per minute, oxygen saturation 96% in room air, blood pressure 110/85 mmHg, heart rate 70 beats per minute, temperature 37.2ºC.

His ECG revealed a normal sinus rhythm with narrow QRS complexes. A recent echocardiogram completed two weeks previously demonstrated an ejection fraction of 30%. His current medications were reviewed and he was found to be on the maximum dose for each of these.

His baseline U&E results are as follows:

Na +	136 mmol/L	(135 - 145)
K +	4.5 mmol/L	(3.5 - 5.0)
Bicarbonate	26 mmol/L	(22 - 29)
Urea	6.7 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)

What is the optimum treatment option for this patient?

A. Cardiac Resynchronisation Therapy
B. Digoxin
C. Hydralazine combined with a nitrate
D. Ivabradine
E. Sacubitril-Valsartan (after stopping ACE inhibitor)

E. Sacubitril-Valsartan (after stopping ACE inhibitor)

Sacubitril-valsartan is considered in heart failure patients with a LVEF < 35% who are still symptomatic on ACE-inhibitors & betablockers

This patient has heart failure, he is symptomatic despite maximum medical therapy with an ACE inhibitor, beta blocker and aldosterone antagonist. His heart rate is 70 bpm, therefore ivabradine cannot be used at this time. After a period of ACE inhibitor washout sacubitril-valsartan is the optimal therapeutic option.

Digoxin has been found to not have any improvement in long-term outcome and therefore is not the correct answer in this case.

Hydralazine with a nitrate is indicated in the afro-caribbean population; we are told this patient is caucasian, hence this answer is incorrect.

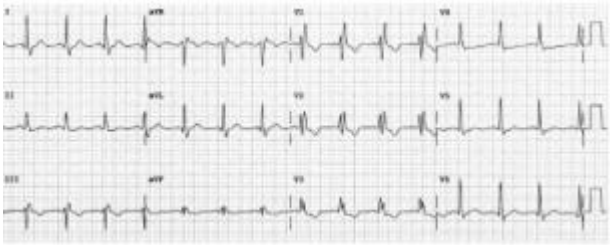
Ivabradine is contraindicated as the patients heart rate if 70 bpm, the guidelines state it should be > 75 bpm for ivabradine to be prescribed.

Question 100 of 328

A 50-year-old man is brought into the emergency department following a collapse whilst gardening. He denies any presyncopal symptoms but now describes shortness of breath. His past medical history includes prostate cancer and hypertension.

On examination, there is good air entry bilaterally. His peripheral pulses are present bilaterally with a capillary refill time of < 2 seconds. There is no postural drop in blood pressure and his neurological examination is unremarkable.

An ECG is taken, as shown below:



What is the most likely cause of this patient's presentation?

A. Aortic stenosis
B. Hypercalcaemia
C. Hypokalaemia
D. Left ventricular hypertrophy
E. Pulmonary embolism

E. Pulmonary embolism

This patient's ECG demonstrates right bundle branch block (RBBB) with an RSR pattern in leads V1-V3 (creating an 'M-shaped' QRS complex), with wide slurred S waves in the leads I, aVL, V5-V6 (creating a 'Wshaped' QRS complex). A widened QRS interval (i.e. > 120ms) is also a feature of RBBB. There are multiple causes of RBBB and in some cases, it may be found incidentally as a normal variant. However, pathological causes commonly include increased right heart strain (e.g. right ventricular hypertrophy, cor pulmonale or pulmonary embolism). Given the history of malignancy, collapse and shortness of breath, a pulmonary embolism is the most likely cause of this patient's presentation to the hospital and ECG findings of RBBB.

Whilst aortic stenosis can cause the symptoms of collapse and breathlessness, it is not common for aortic stenosis to cause RBBB. Rather, aortic stenosis may be responsible for the appearance of left bundle branch block (LBBB) or left ventricular hypertrophy on an ECG.

The most common ECG finding in hypercalcaemia is QT interval shortening. In severe hypercalcaemia (> 3.4mmol/L) J waves may be seen. Although hypercalcaemia is more likely to be present in a patient with a diagnosis of malignancy, it would not be responsible for this patient's RBBB and is unlikely to be the underlying diagnosis.

Hypokalaemia causes the following ECG changes: prolonged PR interval, widespread ST depression and T wave flattening or inversion and prominent U waves (most clearly in leads V2-V3). It does not cause RBBB and is, therefore, incorrect.

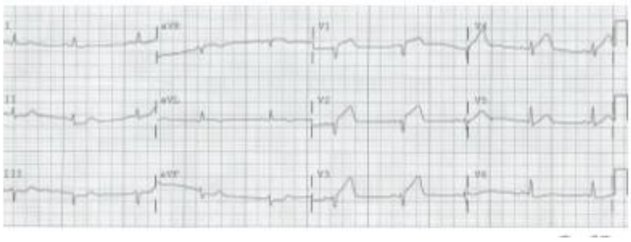
Left ventricular hypertrophy (LVH) has numerous causes, most commonly hypertension. There are lots of specific voltage criteria to be met to accurately diagnose LVH on an ECG including:

- R wave in V4, V5 or V6 > 26mm
- R wave in V5 or V6 plus S wave in V1 > 35 mm
- Largest R wave plus largest S wave in precordial leads > 45 mm

Additional features include left axis deviation and left atrial enlargement. Although this patient has hypertension, there are no features of LVH on his ECG and it is unlikely to cause his episode of syncope, making it the incorrect answer.

Question 101 of 328

You review a 60-year-old man in resus who has been admitted with a 30-minute history of cardiac-sounding chest pain. His ECG is shown below:



Where is the lesion most likely to be?

A. Right coronary
B. Left main stem
C. Posterior intraventricular artery
D. Left anterior descending
E. Left circumflex

D. Left anterior descending

Ischaemic changes in leads V1-V4 - left anterior descending

ST elevation can be seen in V2-V4 which is highly suggestive of a left anterior descending lesion. A left main stem occlusion would result in more widespread changes.

Question 102 of 328

A 53-year-old woman has been admitted to the hospital with progressively worsening dyspnoea. She denies a cough but describes orthopnoea and the feeling of palpitations.

Observations are shown below:

Heart rate	112 bpm
Blood pressure	86/42 mmHg
Respiratory rate	28 /min
Oxygen saturations	99%
Temperature	36.8 ºC

On examination, she is overweight and appears dyspnoeic. Her airway is self-maintained and her chest appears clear on auscultations. Heart sounds are difficult to auscultate, her JVP is raised and her capillary refill time is normal. There is no evidence of pedal oedema.

Given the likely diagnosis, what might you see on the ECG?

A. Deep lateral Q waves with left ventricular hypertrophy
B. Electrical alternans
C. Global ST elevation
D. S1 Q3 T3
E. Trifascicular block

B. Electrical alternans

Electrical alternans is suggestive of cardiac tamponade

A history of dyspnoea, orthopnoea, and palpitations, associated with hypotension and tachycardia are classical symptoms of many cardiorespiratory illnesses. However, quiet or absent heart sounds with a raised JVP should raise concerns for cardiac tamponade. This can be confirmed with the ECG findings of sinus tachycardia, low QRS voltage, or electrical alternans.

Electrical alternans is a diagnostic feature of large pericardial effusion and cardiac tamponade. The alternate QRS amplitudes are due to the 'swinging' effect of the heart whilst contracting which subsequently gives rise to increased and decreased electrical impedance.

Deep lateral Q waves with left ventricular hypertrophy is a classical ECG finding of hypertrophic cardiomyopathy (HOCM). HOCM is the most common cause of sudden death in young people and is due to left ventricular hypertrophy without an identifiable cause. Patients can display all of the above symptoms. Dyspnoea is common due to left ventricular stiffness, resistance, and impaired filling. Patients may have a jerky pulse and may also present in arrhythmia, most commonly, atrial fibrillation. However, compared to the above scenario, patients have audible heart sounds, and may have a loud S1 and sometimes a 4th heart sound. There may be an ejection systolic murmur radiating to the apex which changes in intensity with a change in posture.

Pericarditis is associated with **global ST elevation**. Patients typically present with many of the above symptoms. Pericarditis is a common cause of pericardial effusion due to the accumulation of fluid in the pericardial sac due to inflammation. The distinguishing feature between pericarditis and pericardial effusion is the presence or absence of heart sounds, with pericarditis having audible heart sounds.

Symptoms of dyspnoea, palpitations, and orthopnoea, along with hypotension and tachycardia are common signs and symptoms associated with a pulmonary embolism (PE). The most common ECG finding in PE is sinus tachycardia, however, patients may have evidence of right axis deviation, atrial arrhythmia, right bundle branch block, P pulmonale, and **S1 Q3 T3**. S1 Q3 T3 is the presence of deep S waves in lead I along with Q waves and T wave inversion in lead 3.

Trifascicular block is the combination of third-degree atrioventricular block, right bundle branch block, and either left anterior fascicular block or left posterior fascicular block. These patients generally required pacemaker insertion. The most common causes are structural heart disease, particular fibrosis of the myocardium, and ischaemic heart disease. It may also occur in anterior myocardial infarction and aortic stenosis. Many of the pathological causes of trifascicular block may cause the symptoms described in the above scenario, however, heart sounds would still be audible. Trifascicular block is not associated with pericardial effusion.

Question 103 of 328

A 78-year-old woman attends the cardiology outpatient department after being referred by her general practitioner with angina. The patient reports consistent chest tightness after walking around 200 metres on flat ground but denies any episodes of pain at rest. Her symptoms have been stable at the current level for at least six months. Her GP has previously attempted treatment with both metoprolol and amlodipine but both were stopped after the patient reported dizziness and was found to be hypotensive.

The patient was formerly a heavy smoker but had stopped 15 years previously after suffering a non-ST elevation myocardial infarction (managed with medical therapy only). The patient had been diagnosed with type 2 diabetes mellitus 10 years previously and was known to have chronic kidney disease.

The patients current medications included aspirin 75 mg daily, simvastatin 20 mg daily, ramipril 1.25 mg daily and gliclazide 60 mg twice daily. She sometimes used a nitrate spray to relieve episodes of angina but found that it normally made her very dizzy.

Clinical examination was unremarkable except for a blood pressure of 98 / 65 mmHg.

Please see below for results of recent investigations.

Transthoracic echocardiogram: normal valvular function; moderately impaired left ventricular; ejection fraction 35 %.

Electrocardiogram: sinus rhythm at 85 beats per minute; normal axis; normal QRS complex, normal ST segments and T waves.

Urea	15.6 mmol / L
Creatinine	234 micromol / L
Sodium	135 mmol / L
Potassium	4.9 mmol / L

Cardiac stress MRI: evidence of mild myocardial ischaemia in left anterior descending territory, estimated < 10 % myocardium ischaemic.

What is the correct next line therapy for the patients angina?

A. Percutaneous coronary intervention
B. Nicorandil
C. Ranolazine
D. Ivabradine
E. Long-acting isosorbide mononitrate

D. Ivabradine

The patient has stable angina and has been intolerant of first line medical therapy. Due to her co-morbidities several of the second-line medical therapy options are contra-indicated. Ranolazine acts a late inward calcium channel antagonist but is contra-indicated in severe renal disease. Both nicorandil and ISMN are contra-indicated in this patient due to her history of hypotension.

Therefore, ivabradine is the most appropriate option. The drug acts as an If channel antagonist to reduce heart rate and is appropriate in this patient without a history of bradycardia. It should not be used in patients with moderate to severe angina as it has been shown to increase the incidence of cardiovascular events in these patients.

Revascularisation techniques such as PCI have not been show to reduce mortality or rate of MI in stable coronary artery disease. Therefore, medical therapy options should be exhausted before consideration of invasive treatment (particularly in this patient with renal failure making contrast administration very undesirable).

Question 104 of 328

A 43 year old man has been referred to endocrinology clinic for blood pressure investigation and management. Over the past year the patient has had a persistently raised blood pressure between 170/100mmHg and 180/110mmHg. Despite starting the patient on ramipril 5mg once daily four weeks ago the patient's blood pressure on this visit remained raised at 164/93mmHg.

During the history taking part of the consultation the patient mentions that he has been troubled with headaches for the past year, and has noticed that his stool frequency has increased and his stools have become looser. He tells you that he's rather embarrassed to admit that he's been having flushing episodes, and feels that his clothes are much looser than they were 1 year ago.

On discussing his family history he mentions that both his mother and his father had to have cancerous lumps removed in their middle ages. His mother had a breast lump removed, and his father had some form of pancreatic mass removed.

On examination the patient is tall with a wide arm span. Examination of the cardiovascular system reveals only a minor tachycardia of 95bpm and a quiet systolic flow murmur not radiating to the carotids. Abdominal examination reveals no palpable masses, and examination of his lungs is completely normal.

The GP had previously arranged a 24h urinary catecholamine test; results are as follows:

Total urine catecholamines 210mcg/24hr. This is raised.

As a follow up to this test the GP had arranged a CT of the patient's abdomen and pelvis which is reported as normal apart from a few incidental simple renal cysts.

Urinalysis in clinic today shows:

Leucocytes	-
Blood	-
Glucose	+
Ketones	-

Which test is most likely to elucidate the cause of the patient's hypertension?

A. Pentagastrin stimulation test
B. 24h urinary HIAA
C. MRI renal angiography
D. GH, IGF-1 and 'gut hormones'
E. MIBG (metaiodobenzylguanidine) scan

E. MIBG (metaiodobenzylguanidine) scan

This question tests the candidates knowledge of causes of secondary hypertension. The commonly listed causes of secondary hypertensions are listed below

Endocrine	Adrenal	Renal
Cushing's Syndrome	Conn's Syndrome	Diabetic nephropathy
Acromegaly	Adrenal hyperplasia	Chronic glomerulonephritis/tubul nephritis
Thyroid disease	Phaeochromocytoma	Adult polycystic kidney d
Hyperparathyroidism	-	Renovascular disease

The best way of narrowing down to the correct answer in this question is to actually look at what the answers are suggesting

Pentagastrin stimulation test	**Test for medullary carcinoma of the thyroid (associated with MEN2 - multiple endocrine neoplasia)**
24h Urinary HIAA	Screening for carcinoid
MRI renal angiography	Test for renal artery stenosis
GH, IGF-1 and 'gut hormones'	Test for pancreatic malignancy associated with MEN1

MIBG scan	Test for phaeochromocytoma

While this patient might well have MEN2 (as suggested by the patients body habitus and features consistent with phaeochromocytoma), medullary thyroid cancer would be unlikely to cause his blood pressure issues. Therefore the pentagastrin stimulation test, where one injects the patient with pentagastrin and looks for an abnormally high release of calcitonin as a response, is not a suitable first test. It may well be considered if the patient is diagnosed with a phaeochromocytoma to rule out medullary thyroid cancer as part of MEN 2.

The patient does have a few features consistent with carcinoid syndrome, for example the episodic flushing and increased stool frequency. However carcinoid syndrome doesn't present with these symptoms until it has metastasised to the liver, and this patient has had a normal CT scan of his abdomen making this a less likely diagnosis.

MRI renal angiography is used to diagnose renal artery stenosis; this patient has far too many other endocrine features for this to be renal artery stenosis. In addition the fact his blood pressure has not got worse with angiotensin converting enzyme inhibitors makes the diagnosis less likely.

Testing for gut hormones would be done in a patient in whom you were considering a diagnosis of pancreatic neoplasm as part of MEN1.

This leaves the MIBG (metaiodobenzylguanidine) scan. The patient has raised levels of total urinary catecholamines, suggesting a diagnosis of phaeochromocytoma, however, his CT scan show's no evidence. As you may be aware there is a rule of 10 that is commonly used to describe phaeochromocytoma, in that:

10% are malignant

10% are bilateral

10% are familial

10% are in children

The other sites that phaeochromocytomas can present include: Anywhere alone the sympathetic chain which runs alongside the spinal cord, the distal aorta, ureters and urinary bladder.

The MIBG scan uses radioactive iodine as a tracer for phaeochromocytoma tumour cells, which is detected through the use of a gamma camera., making it the next test that should be used in diagnosing this patient's phaeochromocytoma, i.e. the cause of his hypertension.

Question 105 of 328

An 84-year-old male was admitted to the coronary care unit (CCU) after being admitted as a primary percutaneous coronary intervention (PPCI) call for sudden onset chest pain and ST elevation on anterior leads of his ECG. Angiography demonstrated a mid-left anterior descending artery acute occlusion likely secondary to plaque rupture that was stented with a drug-eluting stent. Two hours after being admitted to CCU, he complained of nausea and vomited twice, which settled after being prescribed cyclizine by a passing medical senior house officer. Thirty minutes afterwards, you are asked to see the patient as the patient has become increasingly short of breath. He complains of no new chest pain, nausea, vomiting, sweating or palpitations. Interrogation of his cardiac telemetry reveals a new sinus tachycardia only without other arrhythmias. On examination, the patient is in respiratory distress, with bibasal inspiratory crackles and raised jugular venous pulse.

His observations are as follows: blood pressure is 186/80 mmHg, heart rate 120 beats per minute and regular, Sats 92% on 3 litres, respiratory rate 33/min.

A repeat 12-lead ECG reveals no new ST elevation changes or other ischaemic changes. A portable chest radiograph demonstrates bibasal alveolar oedema and bilateral small pleural effusions.

What is the cause of the patient's deterioration?

A. In-stent thrombosis
B. Pulmonary embolus
C. New independent cardiac ischaemic occlusion
D. Cyclizine induced heart failure
E. Cardiac tamponade secondary to cardiac instrumentation

D. Cyclizine induced heart failure

This patient has entered acute pulmonary oedema, associated with systemic hypertension and tachycardia following administration of cyclizine in the context of an acute STEMI, typical of cyclizine-induced heart failure. Cyclizine is a H1 receptor antagonist and anticholinergic, resulting in systemic hypertension and inducing tachycardia. It can aggravate a fragile myocardium into acute failure and is hence not recommended by NICE in patients with ACS or severe heart failure1. In this patient, the lack of chest pain or ST elevation on ECG makes acute in-stent thrombosis or a further ACS episode unlikely. The patient is hypertensive instead of hypotensive, with no mention of low voltage on ECG, making cardiac tamponade an unlikely cause.

Question 106 of 328

A 63-year-old patient is called to his GP for a health check. He has a past medical history of asthma and a family history of hypertension and bowel cancer. He has a 10 pack-year history of smoking but quit with the help of the practice nurse 2 years ago. He drinks 24 units of alcohol per week, and his body mass index is 25 kg/m². He does not take any regular medication. His blood pressure is 155/95 mmHg. He is sent for ambulatory blood pressure monitoring (ABPM), which shows an average blood pressure of 145/90 mmHg. His 10-year cardiovascular risk is 8%.

Examination, including fundoscopy, is unremarkable. Bloods show:

Hb	132 g/l
Platelets	330 * 10 /l
WBC	7.3 * 10 /l
Na	142 mmol/l
K	3.9 mmol/l
Urea	5 mmol/l
Creatinine	80 µmol/l
eGFR	91 ml/min
Fasting plasma glucose	5mmol/L
Serum total cholesterol	4mmol/L
HDL cholesterol	1.8mmol/L
Urinary albumin:creatinine ratio	1.1 mg/mmol
Urine dip	negative for haematuria

An ECG shows sinus rhythm.

What is the first step in the management of this man's blood pressure?

A. Lisinopril

B. Lifestyle advice

C. Amlodipine

D. Spironolactone

E. Atenolol

B. Lifestyle advice

This patient has a persistently raised blood pressure. During ABPM, two measurements are taken every hour during waking hours and at least 14 measurements are used to confirm the average blood pressure. This man's average blood pressure is >135/85 mmHg on ABPM; he has stage 1 hypertension, which warrants intervention. Given that his 10-year cardiovascular risk is low, and there is no evidence of end-organ damage, the most appropriate option at this stage is lifestyle advice.

The patient should be advised regarding diet and exercise. He has already given up smoking, but he should cut down on caffeine, salt and alcohol. Relaxation therapies have been shown to produce a small reduction in blood pressure, but these are not routinely offered in primary care. Drug treatment should be initiated if the average blood pressure is >150/95 mmHg, if he has a 10-year cardiovascular risk >10%, or if he develops end-organ damage. The first drug of choice in a patient over 55 years would be a calcium-channel blocker, such as amlodipine.

Question 107 of 328

A 23-year-old rugby player has a blackout whilst playing a match. No head injury is noted. There was no warning and he recovered quickly within seconds. This has never happened before. There was no chest pain. His father died in his sleep aged 49 and was known to have Brugada syndrome. At presentation several hours later the patient's electrocardiogram (ECG) and routine blood profile including FBC, U&E, and glucose are normal. He is sent to cardiology clinic for further investigation. A diagnosis of Brugada syndrome is suspected.

Which agent may they elect to use there to provoke the down-going ST elevation in leads V1-V3 characteristically seen in the ECG of a patient with Brugada Syndrome?

A. S Digoxin

B. Sotalol

C. Nifedipine

D. Adenosine

E. Flecanide

E. Flecanide

Exertional syncope in a young person with a family history of sudden cardiac death or with an abnormal ECG at presentation should trigger alarm bells in your head this person may be at risk of sudden cardiac death (which you should note is a preventable death if the condition is recognised in time and an implantable cardioverter defibrillator (ICD) is put in.)

The condition alluded to here is Brugada Syndrome. This is an autosomal dominant condition resulting in loss of function of the cardiac sodium channel. The characteristic ECG change is down-going ST elevation in V1 to V3. However, this may not be present, especially so long after the syncope episode. The way to bring out the ECG change in cardiology clinic safely is to give a sodium channel blocker (usually flecainide), providing additional sodium channel blockade to that already pathologically present. Once a diagnosis is made, the life-saving treatment is an ICD device. Genetic family counselling and testing will be of additional importance (testing for a mutation in the SCN5A gene).

The substantial majority of the approximately 100,000 sudden cardiac deaths each year in the UK are caused by coronary heart disease. However, most sudden deaths in people under 30 years old are caused by inherited cardiomyopathies and arrhythmias. A sensible list of differentials to consider in a young-person sudden cardiac death case are hypertrophic obstructive cardiomyopathy (HOCM), long-QT syndrome, Brugada, and arrhythmogenic right ventricular cardiomyopathy (ARVC). These will each be covered elsewhere using different questions as triggers.

\

Question 108 of 328

A 65-year-old lady with a history of diabetes and newly diagnosed atrial fibrillation (AF) was admitted to hospital with a moderate-large sized embolic stroke. Her blood pressure on admission was 165/90 mmHg with a heart rate of 95 beats per minute.

An MRI brain was performed 24 hours after admission which showed a moderate to large area of infarction involving the anterior 2/3 of the left middle cerebral artery territory without haemorrhagic transformation.

With regards to management of her AF and stroke prevention, the most appropriate decision would be to commence which of the following?

A. An adjusted dose intravenous heparin infusion

B. Therapeutic dose low molecular weight heparin (LMWH) andtransition to oral anticoagulation in 10-14 days

C. Aspirin and wait 10-14 days before commencing formalanticoagulation

D. Warfarin with LMWH bridging therapy

E. OR calculate the CHADS-vasc score and make a decision

C. Aspirin and wait 10-14 days before commencing formalanticoagulation

Moderate-large areas of cerebral infarction are subject to the risk of haemorrhagic transformation within the acute period - usually defined as 10-14 days. With this in mind, patients with AF should be cautiously commenced on therapeutic dose formal anticoagulation 10-14 days after stroke onset in the absence of spontaneous haemorrhagic transformation.

The use of aspirin and/or low dose heparin/LMWH for venous thromboembolism (VTE) prophylaxis can be considered within 24 hours of symptom onset.

CHADS2 or CHADS-Vasc scores are used to estimate the risk of embolic stroke in patients with atrial fibrillation and assist with deciding on whether or not to anti-coagulate a patient. This patient scores highly enough to be started on formal anticoagulation, but this is not the focus of the question in this case. The focus is on the timing of anticoagulation in this clinical setting.

Question 109 of 328

A 57-year-old man attends his GP surgery for review. For the past year, he has experienced exertional chest pain, which initially only came on whilst walking uphill, but has now started to affect him when walking on the flat. The pain is alleviated by the use of glyceryl trinitrate spray. He denies ever having had chest pain at rest and does not report any symptoms of postural hypotension. His other medications include aspirin, atorvastatin and atenolol, which has been maximally titrated.

What is the most appropriate next step in management for this patient?

A. Refer for assessment for percutaneous coronary intervention (PCI) or CABG
B. Start amlodipine
C. Start isosorbide mononitrate
D. Start ranolazine
E. Start verapamil

B. Start amlodipine

If angina is not controlled with a beta-blocker, a longer-acting dihydropyridine calcium channel blocker should be added

The correct answer is **start amlodipine**. This patient has a likely diagnosis of stable angina, as he suffers from exertional chest pain which is alleviated by the use of GTN spray. As he is currently taking a betablocker at the maximum permissible dose, the next most appropriate step in management is to add in a calcium channel blocker. In this scenario, dihydropyridine calcium channel blockers are preferred to nondihydropyridine calcium channel blockers, due to the increased risk of the latter causing complete heart block in combination with betablockers.

Refer for assessment for percutaneous coronary intervention (PCI) or CABG is incorrect. As the patient has stable angina, with no symptoms at rest, he does not warrant urgent referral for PCI. Non-urgent referral for PCI or CABG would be appropriate if his symptoms were not improved by the addition of amlodipine.

Start isosorbide mononitrate is incorrect. This would be an appropriate third-line management option for stable angina in this patient if amlodipine failed to alleviate his symptoms. However, it should only be started whilst awaiting assessment for revascularization with PCI or CABG.

Start ranolazine is incorrect. This would also be more appropriate as a third-line management option whilst awaiting specialist assessment for PCI or CABG.

Start verapamil is incorrect. Although it would be reasonable to start a calcium channel blocker in this patient, starting a non-dihydropyridine calcium channel blocker such as verapamil in a patient already on a betablocker would run the risk of precipitating complete heart block.

Question 110 of 328

A 63-year-old man presents for review at his GP surgery. He is known to have hypertension and was started on amlodipine five years ago. Due to persistent poor hypertensive control, he began taking enalapril two years ago but has continued to struggle to keep his blood pressure within the required range. He reports no symptoms of postural hypotension, and his latest ambulatory blood pressure readings show an average blood pressure of 161/93 mmHg.

His latest blood test results are shown below:

Na +	138 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Urea	4.5 mmol/L	(2.0 - 7.0)
Creatinine	84 µmol/L	(55 - 120)

What medication should be offered to this patient as the next step in managing his hypertension?

A. Bendroflumethiazide
B. Bisoprolol
C. Doxazosin
D. Indapamide
E. Spironolactone

D. Indapamide

orly controlled hypertension, already taking an ACE inhibitor and a calcium channel blocker - add a thiazide-like diuretic

The correct answer is **indapamide**. Current guidelines advise that in the absence of any clear contraindications, patients with poorly controlled hypertension already taking an ACE inhibitor and a calcium channel blocker should be offered a thiazide-like diuretic. Thiazide-like diuretics are sulfonamide-based diuretics that have similar pharmacological properties to thiazides but have been shown in recent trials to reduce systolic blood pressure more effectively than conventional thiazides, without a significant difference in side-effect profile. Indapamide is the only thiazide-like diuretic provided in the answer choices.

Bendroflumethiazide is incorrect as thiazide-like diuretics, rather than thiazide diuretics such as bendroflumethiazide now tend to be preferred as third-line antihypertensive therapy in most patients for the reasons outlined above.

Bisoprolol is incorrect. This would be an appropriate option for a patient with persistent hypertension already taking a calcium channel blocker, an ACE inhibitor and a thiazide-like diuretic with serum potassium > 4.5mmol/L.

Doxazosin is incorrect. Alpha blockade with doxazosin would be another option for a patient with persistent hypertension already taking a calcium channel blocker, an ACE inhibitor and a thiazide-like diuretic with serum potassium > 4.5mmol/L.

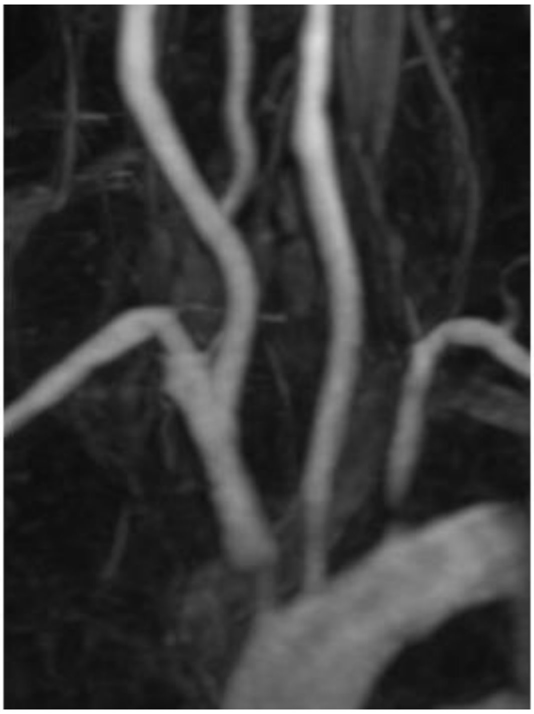
Spironolactone is incorrect. Aldosterone receptor antagonism with spironolactone may be offered to patients with persistent hypertension despite taking a calcium channel blocker, an ACE inhibitor and a thiazide-like diuretic with serum potassium < 4.5mmol/L, due to the propensity of spironolactone to cause hyperkalaemia.

Question 111 of 328

A 26-year-old woman is investigated for persistent malaise, fever, headaches and raised inflammatory markers. She was diagnosed with Raynaud's syndrome three years ago after complaining of cold hands. The most recent bloods in the referral letter show a CRP of 64 mg/l.

On examination blood pressure is 80/64 mmHg in the right arm and 72/54 mmHg in the left arm. The heart rate is 72/min and a diastolic murmur is noted on ascultation of the heart.

Magnetic resonance angiography is requested:



What is the most appropriate maangement?

A. Plasma exchange
B. Rituximab
C. Prednisolone
D. Cardiothoracic surgery referral
E. Intravenous immunoglobulin

C. Prednisolone

The magnetic resonance angiography (MRA) demonstrates stenoses of the supra-aortic arteries, especially the brachiocephalic trunk and the left subclavian artery with near-occlusion of the left vertebral artery. This findings are consistent with a diagnosis of Takayasu's arteritis.

Question 112 of 328

A 34-year-old gentleman with Marfan's syndrome and known mitral regurgitation presents to the emergency department with increasing shortness of breath for three days. He can currently walk 100 metres at a time before needing to stop. He feels restless at times and has noticed his heart is racing in his chest. There is no chest pain. He is under annual surveillance with echocardiography and is currently managed on furosemide and ramipril.

On examination, his pulse is irregularly irregular at 96 beats per minute. He is alert with a clear chest and no visible JVP. He has a soft S1 with a loud grade 4 pan-systolic murmur with radiation into the axilla. He is skinny but alert.

Na +	134 mmol/l
K +	4.2 mmol/l
Urea	4.3 mmol/l
Creatinine	89 µmol/l
ECG	no visible P-waves, irregular narrow complex rhythm at 84 per minute
CXR	cardiomegaly with no effusions or lung shadowing
BedsideECHO	No pericardial effusion, normal sized cardiac chambers, no regional wall motion abnormality

What is the most appropriate next action?

A. Increase furosemide
B. DC cardioversion
C. Bisoprolol
D. Refer to cardiothoracic surgery
E. Repeat Echocardiography

D. Refer to cardiothoracic surgery

New AF in mitral regurgitation -> refer for mitral valve replacement

This gentleman has mitral regurgitation and has developed atrial fibrillation which is a common complication following dilation of the mitral annulus. He is not in pulmonary oedema and there is no haemodynamic compromise so DC cardioversion would be inappropriate. He shows no signs of cardiac failure so diuresis with furosemide will not help. Although, he is in atrial fibrillation, his rate is slow and does not need reducing at present with a beta blocker. A repeat ECHO will be useful to confirm current heart structure. The development of atrial fibrillation is an indication to refer for mitral valve surgery as is an ejection fraction less than 60%, pulmonary hypertension or a dilated left ventricle.

Question 113 of 328

A 34-year-old male presents with increased shortness of breath on minimal exertion associated with reduced exercise tolerance. He was diagnosed with a 'heart condition' 4 years ago after three episodes of loss of consciousness. His only other past medical history is asthma, which is well controlled on a Seretide 250 inhaler. His last echocardiogram demonstrates asymmetric left ventricular and septal wall hypertrophy, associated with an increased left ventricular outflow tract gradient and systolic anterior wall motion. He was started on verapamil by his cardiologist 2 years ago but over the past 3 months, he reports a deterioration of his shortness of breath associated with increasing lower limb swelling.

Which treatment is most appropriate?

A. Propranolol
B. Disopyramide
C. Ramipril
D. DDDR pacemaker insertion
E. Cardiac myectomy

B. Disopyramide

The patient was diagnosed with echocardiogram findings associated with cardiogenic syncope in a young male, consistent with hypertrophic obstructive cardiomyopathy (HOCM). Medical treatment of HOCM consists of starting either a beta blocker, typically propranolol (but contraindicated in this case due to asthma) or a non-dihydropyridine calcium channel blocker, typically verapamil. In the case of persistent symptoms despite monotherapy, American Heart Association and European Society of Cardiology recommend consideration of disopyramide, a negative inotropic 1a anti-arrhythmic that demonstrated a significant decrease of LVOT gradients and mortality when compared to placebo. However, its significant cholinergic side effects and concerns of pro-arrhythmias, restricts its use to a second line agent. Surgical myectomy, DDDR pacemakers and alcohol ablation should be considered in patients who continue to be symptomatic despite 2 agents. ACEi should be avoided in HOCM patients with LVOT as reducing

afterload can worsen the LVOT gradient.

Question 114 of 328

A 43-year-old male presents with central chest pain that spread into his jaw and arm. He is nauseous and sweaty and arrives to the emergency department. He is immediately given aspirin and glyceryl trinitrate spray. On examination, he has normal heart sounds and a clear chest. However, he is pale and clammy

Hb	145 g/l
Platelets	400 * 10 /l9
WBC	8.6 * 10 /l9
Na +	135 mmol/l
K +	4.3 mmol/l
Urea	4.5 mmol/l
Creatinine	67 µmol/l
Troponin	957 ng/ml (normal range <20)
ECG	Biphasic T waves in V2-V3

What is the likely explanation of the ECG?

A. Normal variant
B. Brugada Syndrome
C. Wellens Syndrome
D. Hypertrophic cardiomyopathy
E. Takotsubo cardiomyopathy

C. Wellens Syndrome

Deeply inverted or biphasic T waves in V2-V3 suggests Wellen's syndrome and high risk of critical LAD stenosis

This gentleman has clear acute coronary syndrome. The ECG findings are unique to Wellens Syndrome in which there is a critical stenosis of the left anterior descending artery. These patients are at risk of imminent occlusion of this artery and should be admitted for coronary angiography and further intervention. Takotsubo cardiomyopathy has ST elevation in the apical leads (V5, V6). Hypertrophic cardiomyopathy typically has T wave inversion in the anteroseptal leads. Brugada has ST elevation and T wave inversion in V1-V2. Biphasic T-waves are not a normal variant.

Question 115 of 328

A 65-year-old man presents with loss of consciousness. He has a past medical history of two myocardial infarctions, one of which was four weeks ago. His wife states that he felt dizzy, complained of his vision going dark, and then fell to the floor.

An ECG shows ST elevation in V1-V4 without reciprocal depression.

What is the most likely diagnosis?

A. Thromboembolic stroke
B. Ventricular tachycardia
C. Anterior STEMI
D. Subarachnoid haemorrhage
E. Subdural haematomaubmit answer

B. Ventricular tachycardia

The presence of ST elevation without reciprocal depression shortly following a myocardial infarction is suggestive of a left ventricle aneurysm. Left ventricle aneurysms predispose to both ventricular arrhythmias and cardiac thrombo-embolisms.

The presence of ST elevation without reciprocal depression shortly following a myocardial infarction is very suggestive of a left ventricle aneurysm. Left ventricle aneurysms predispose to both ventricular arrhythmias and cardiac thromboembolisms, both of which are high up the differential in this case. The patient has presented with classic features of syncope, which makes an arrhythmia much more likely than an embolic stroke which rarely presents with syncope.

Subarachnoid haemorrhage can present with both loss of consciousness and ST elevation, and would be an important differential to consider, albeit less likely.

Question 116 of 328

A 36 year old woman presents to the medical assessment unit with a 2 day history of pleuritic right sided chest pain, and shortness of breath. She is 38 weeks pregnant with her first child, her pregnancy so far had been uncomplicated.

On examination, she is slightly tachypnoeic, with no added sounds on chest auscultation.

There is no clinical evidence of a deep vein thrombosis. Her oxygen saturations are 95% on room air, heart rate 98/min.

What is the next appropriate investigation?

A. CTPA
B. D Dimer
C. Chest x-ray
D. V/Q scan
E. Bilateral leg dopplers

C. Chest x-ray

Venous thromboembolic event (VTE) is an important cause of maternal death in the UK. Pregnant women are 10x more likely to have a VTE than non-pregnant women of the same age.

Where there is suspicion of a pulmonary embolism (PE) , a chest x-ray should be performed initially. If this does not explain the patient's symptoms, compression duplex dopplers should be performed. A diagnosis of deep vein thrombosis (DVT) can indirectly confirm a PE, reducing radiation doses for the mother.

If both tests are negative, and the clinical suspicion of PE remains high, further imaging should be organised; either CTPA or ventilationperfusion scan (V/Q scan). British thoracic society guidelines (BTS) recommend a CTPA in non-pregnant women.

The decision as to which scan to perform should be ideally taken with the input from the patient. V/Q scanning carries a slightly increased risk of childhood cancer compared with CTPA but carries a lower risk of maternal breast cancer. The ventilation component of the V/Q scan may be able to be omited, reducing the radiation dose.

A D Dimer would not assist in the diagnosis, as it may be raised anyway in pregnancy due to disturbances in the coagulation system.

Guidelines: RCOG- The acute management of thrombosis and embolism during pregnancy and the puerperium

Question 117 of 328

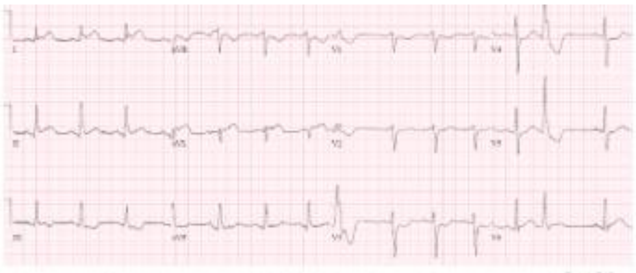
A 50-year-old woman with a past medical history of type 1 diabetes, angina, and hypertension presents with vomiting and epigastric discomfort that came on suddenly earlier this morning.

Her blood glucose level is 10.4 mmol/L and her urine dip is '+' for ketones.

Observations are as follows:

- Respiratory rate: 19/min
- Oxygen saturations: 96% on room air
- Heart rate 96bpm
- Blood pressure 105/67 mmHg

Her blood results are awaited, and her ECG is shown below.



© Image used on license from Dr Smith, University of Minnesota

What diagnostic option is most likely to confirm the diagnosis?

A. Abdominal x-ray
B. CT scan of the abdomen
C. Repeat ECG with posterior chest leads
D. Serum cortisol
E. Venous blood gas

C. Repeat ECG with posterior chest leads

The ECG here shows sinus rhythm with a rate of roughly 85bpm. There is ST elevation in leads I, aVL, and v6. There is ST depression in lead v3 and v4. Conduction appears to be normal. There are two premature ventricular complexes (PVCs).

The above findings can be explained by an acute coronary syndrome involving the posterior and lateral coronary territories. Posterior chest leads would help to confirm a posterior myocardial infarction, so **repeat ECG with posterior chest leads** is the correct answer.

A **venous blood gas** would be the option of choice if aiming to confirm diabetic ketoacidosis, but given the blood glucose is <11.0 mmol/L and ketonuria is less than 2+, this diagnosis is less likely.

CT scan of the abdomen would be correct if her symptoms were thought to be coming from an intraabdominal cause, but given the ECG evidence of an acute coronary syndrome which would explain her epigastric discomfort and vomiting, this seems less likely.

Serum cortisol would be useful in confirming a diagnosis of adrenal crisis, which could present as epigastric discomfort, hypotension and vomiting. The ECG findings make the diagnosis of acute coronary syndrome more likely.

Abdominal x-ray would be useful in looking for evidence to suggest bowel obstruction or perforation. Obstruction would not explain the territorial ST-segment changes and so is not correct in this instance.

Question 118 of 328

A 60-year-old woman has a heart rate of 180bpm on the medical admission unit. An ECG performed demonstrates a regular narrowcomplex tachycardia. The patient complains of palpitations but no chest pain and blood pressure remains 140/95. Initial vagal maneuvers are performed including carotid massage with no success. Intravenous adenosine 6mg is given followed by a further two doses of adenosine 12mg. Unfortunately, this failed to cardiovert or reveal an interpretable underlying rhythm.

What is the next management step?

A. Further adenosine
B. Synchronised DC cardioversion
C. Verapamil
D. Digoxin
E. Amiodarone

C. Verapamil

The resuscitation council recommends:

Adenosine 6mg for supraventricular tachycardias followed by a further two doses of adenosine 12mg if no response. If adenosine is contraindicated, or fails to terminate a regular narrow-complex tachycardia without demonstrating atrial flutter, consider giving a calcium-channel blocker, for example intravenous verapamil 2.5 - 5mg over 2 min.

The combination of vagal maneuvers and 6mg/12mg/12mg will terminate most regular narrow-complex tachycardias. Further adenosine is not thought to be of benefit.

Digoxin and amiodarone are used in the treatment of atrial fibrillation but not indicated in regular narrow-complex tachycardias. However, remember to consider alternative diagnoses such as atrial flutter/fibrillation, especially when the above rhythm fails to terminate after adenosine.

The patient is stable; with no adverse features to suggest DC cardioversion is indicated.

Question 119 of 328

A 82-year-old man who is resident in a nursing home and has diabetes, hypertension and bilateral below knee amputations for peripheral vascular disease presents with a two month history of gradual deterioration. He is generally tired and has little appetite. He has lost 6 pounds since the start of the year and is not keen to leave his room anymore. He has spiked temperatures on numerous occasions and been given several course of oral antibiotics by the GP for possible urinary and lower respiratory tract infections.

On visiting him, you note a new pan systolic murmur which radiates into the axilla. He has several splinter haemorrhages and a palpable spleen. There are small haemorrhages and infarctions seen on fundoscopy. He is admitted to the emergency department?

CRP	72 mg/L
ESR	64 mm/hr
Blood cultures	Viridans streptococci
Transthoracic ECHO	11mm vegetation on the anterior cusp of the mitral valve

What is the likeliest cause behind this presentation?

A. Poor dentition
B. Former intravenous drug use
C. Childhood rheumatic fever
D. Senile calcification
E. Repeat courses of antibiotics

A. Poor dentition

Patients with very poor dental hygiene may develop endocarditis secondary to Viridans streptococci e.g. *Streptococcus sanguinis*

This is a case of infective endocarditis which can be acute or chronic. The chronic endocarditis tends to present over months with gradual deterioration and is most often caused by *Viridans streptococci*. This is a common oral commensal and observation of the oral cavity will likely reveal poor dental disease. This is common in people who are cared for where dental hygiene needs can be missed or difficult to achieve. Intravenous drug use is a cause commonly of *Staphylococcus aureus* endocarditis which is acute and rapidly fatal. Childhood rheumatic fever and senile calcification are rarer causes of endocarditis. Repeat courses of antibiotics causes *Clostridium difficile* colitis not endocarditis.

Question 120 of 328

A 78-year-old lady presents with syncope. She states that she has had several episodes of light headedness over the past couple of months. There are no obvious precipitants of the dizzy spells. She has a past medical history of angina, COPD and hypertension. Her regular medicines include GTN, aspirin, ramipril and furosemide.

ECG results are as follows:

Rate	68 beats per minute
Rhythm	Sinus rhythm
PR interval	220 ms
QRS duration	130 ms
QRS morphology	Right bundle branch block
Cardiac axis	Left axis deviation

What investigation will you order?

A. 7-day ECG Holter monitor
B. Transthoracic echocardiogram
C. Transesophageal echocardiogram
D. Brain natriuretic peptide (BNP)
E. Tilt-table test

A. 7-day ECG Holter monitor

Patients who present with syncope and have an ECG showing incomplete trifascicular block need a Holter test to assess for episodes of complete heart block

The right bundle branch block (RBBB), left axis deviation (LAD) and prolonged PR interval are suggestive of incomplete trifascicular block.

These patients require a 7-day ECG Holter monitor to assess for episodes of complete (third degree) hear block. It is likely that a permanent cardiac pacemaker will be required to prevent further syncopal episodes.

A tilt-table test is useful for investigating vasovagal syncope.

The patient may also have underlying structural heart disease so a transthoracic echo would also be prudent to perform. However, the most immediate concern is of arrhythmia, making a 7 day holter the better answer.

Question 121 of 328

An 18-year-old man attends the clinic with blurred vision. This has progressively worsened over the past few years. He has a past medical history of recurrent deep vein thromboses and mild learning difficulty. On examination, you note an increased arm span to body height ratio, and the presence of scoliosis. Ophthalmological assessment reveals a downward lens dislocation.

What is the most likely diagnosis?

A. answerEctopia lentis syndrome
B. Ehlers danlos syndrome
C. Homocystinuria
D. Marfan's syndrome
E. Multiple endocrine neoplasia type 2B

C. Homocystinuria

Tall, long fingered, downward lens dislocation, learning difficulties,

DVT - homocystinuria

The patient has several clinical features of a Marfanoid body habitus. The differential for a Marfanoid body habitus is wide and includes Marfan's syndrome and homocystinuria.

Homocystinuria is correct. The patient has several clinical features associated with homocystinuria (e.g. Marfanoid body habitus, recurrent DVTs, learning disability and ectopia lentis). It is important to remember that the ectopia lentis in homocystinuria is inferonasal, in contrast to the superior-temporally dislocation associated with Marfan's syndrome.

Ectopia lentis syndrome is incorrect. Ectopia lentis syndrome is an inherited connective tissue condition that shares some of the features of Marfan's syndrome - particularly lens dislocation of the eye. However, patients with ectopia lentis syndrome do not have any vascular complications associated with Marfan's syndrome. Patients with ectopia lentis syndrome do not have any of the other features demonstrated in this case.

Ehlers danlos syndrome is incorrect. The Ehlers-Danlos syndromes (EDS) are generally characterised by joint hypermobility, joint instability and dislocations, scoliosis, and other joint deformities. In the rarer types of EDS, there is also a weakness of specific tissues that can lead, for example, to major gum and dental disease, eye disease, cardiac valve and aortic root disorders, and life-threatening abdominal organ, uterine, or blood vessel rupture. Thrombotic complications and lens dislocation are rare in this condition making it a less likely diagnosis.

Marfan's syndrome is incorrect. Although the patient has a Marfanoid body habitus, the presence of downward lens dislocation, learning difficulties, and recurrent DVTs favour the diagnosis of homocystinuria.

Multiple endocrine neoplasia type 2B is incorrect. This is a rare, genetic disorder that affects the endocrine glands and causes medullary thyroid cancer, pheochromocytoma, and parathyroid gland cancer. Although it can be associated with a Marfanoid body habitus, there are no other clinical features to suggest that this is the diagnosis.

Question 122 of 328

A 67-year-old with a history of ischaemic heart disease (primary percutaneous intervention for a STEMI three years ago) is admitted with a pyrexia of unknown origin. On examination his pulse is 96/min, temperature 38.2ºC and blood pressure 104/66 mmHg. A systolic murmur is noted but auscultation of the chest is unremarkable. His postmyocardial infarction echocardiogram three years ago showed no valvular disease. Chest x-ray is normal and urine dipstick shows blood ++. A petechial rash is noted on his hands and legs. A presumptive diagnosis of infective endocarditis is made and empirical treatment with IV amoxicillin and gentamicin given. Two days later blood cultures show a coagulase-negative staphylococcus.

What is the most appropriate action with respect to antibiotic therapy?

A. Switch to flucloxacillin
B. Switch to flucloxacillin + vancomycin + rifampicin
C. Make no changes to treatment
D. Switch to flucloxacillin + vancomycin
E. Switch to flucloxacillin + rifampicin

A. Switch to flucloxacillin

The BNF now recommend flucloxacillin monotherapy for native-valve endocarditis caused by staphylococci.

Question 123 of 328

A 49-year-old Afro-Carribean man is diagnosed with hypertension. He has no significant past medical history and remains asymptomatic. His 24 hour blood pressure monitoring shows an average of 165/97mm Hg.

Which of the following drugs should be used initially to lower his blood pressure?

A. Ramipril
B. Bisoprolol
C. Amlodipine
D. Indapamide
E. Furosemide

C. Amlodipine

Newly diagnosed patient of black African or African-Caribbean origin with hypertension - add a calcium channel blocker

This patient has stage two hypertension. Because he is of Afro-Caribbean origin, the first line drug is a calcium channel blocker, not an angiotensin converting enzyme inhibitor. Diuretics and beta-blockers are not first line management for hypertension.

Question 124 of 328

A 73-year-old man with a history of severe biventricular heart failure comes to the clinic for review. He can only walk around 100 metres to the bus stop and climbs the stairs once per day only. Medication includes ramipril 10mg, furosemide 80mg, bisoprolol 10mg, spironolactone 25mg, aspirin and atorvastatin. On examination his blood pressure is 123/82 mmHg, pulse is 85 beats per minute at rest. He has bilateral basal crackles on auscultation of the chest and mild pitting oedema of both ankles.

Investigations

Hb	122 g/l	Na +	134 mmol/l	Bilirubin	11 µmol/l
Platelets	190 * 10 /l 9	K +	5.0 mmol/l	ALP	105 u/l
WBC	7.4 * 10 /l 9	Urea	11.2 mmol/l	ALT	33 u/l
Neuts	4.5 * 10 /l 9	Creatinine	142 µmol/l	γGT	56 u/l
Lymphs	1.2 * 10 /l 9	Albumin	38 g/l		
Eosin	0.5 * 10 /l9				

Chest x-ray: Cardiomegaly, bilateral upper lobe diversion ECG: Left bundle branch block, ventricular rate 85 ECHO: Ejection fraction 31%

Which of the following is the most appropriate next step with regards to his heart failure medication?

A. Add digoxin
B. Add valsartan

C. Add ivabradine
D. Increase furosemide by 40mg per day
E. Increase spironolactone to 100mg per day

C. Add ivabradine

The correct answer is add ivabradine. This patient has uncontrolled symptoms of heart failure despite near maximal medical therapy. His heart rate is greater than 75 beats per minute at rest, according to NICE guidelines this means ivabradine is indicated as a potential intervention. The ivabradine outcome study in heart failure indicated an 18% relative risk reduction in cardiac events (mainly driven by heart failure admissions and heart failure deaths), for the intervention added in to standard of care versus standard of care alone.

A large meta-analysis of use of digoxin in heart failure suggested a 14% increase in mortality associated with its' use. This has led to a reduction in use of digoxin for heart failure in recent years. With respect to increasing spironolactone or adding valsartan, these options are likely to significantly increase risk of hyperkalaemia with limited benefit in improving symptoms. Although increasing furosemide may reduce symptoms of heart failure, it may also precipitate a large rise in serum creatinine.

Question 125 of 328

A 77-year-old female has been admitted electively for investigation of raised pulmonary arterial pressures (50 mmHg) detected on a transthoracic echocardiogram, which had otherwise demonstrated normal left ventricular function and chamber sizes. No valve abnormalities were identified. Her right heart catheter saturations are shown as below:

SVC	76%
IVC	74%
Right atrium (high)	73.5%
Right atrium (mid)	73%
Right atrium (low)	72.7%
Right ventricle	72%
Pulmonary artery	70.8%
Pulmonary capillary wedge	95%

What is the most likely diagnosis?

A. Normal study
B. Patent ductus arteriosus
C. Anomalous pulmonary venous drainage to SVC
D. Patent foramen ovale
E. Tricuspid regurgitation

C. Anomalous pulmonary venous drainage to SVC

This is a very subtle question. When interpreting right heart catheter data, remember the saturation should decrease gradually as the venous blood reaches the pulmonary capillary wedge saturation, which should be equal to arterial blood. The second consideration for normal venous return is that oxygenation in the superior vena cava should always be lower than the inferior vena cava, due to the high oxygen demands from the brain. There are no sudden increases in oxygen saturations in this study, suggestive of a left to right shunt but the SVC saturations is markedly higher than the IVC, allowing a diagnosis of anomalous pulmonary venous drainage of more highly oxygenated blood into the SVC.

Question 126 of 328

A 72-year-old gentleman is admitted with syncope and palpitations. He is known to have atrial fibrillation and is on flecainide and warfarin. His past medical history also includes benign prostatic hypertrophy and essential thrombocytosis.

His other medications include tiotropium 18 micrograms OD, tamsulosin 400 micrograms OD, ramipril 2.5mg and simvastatin 40mg. He has recently stopped a tablet due to shortness of breath but cannot remember what it was.

On arrival, he is tachycardic with a heart rate of 215 /min. He is alert. He denies chest pain but is aware of some shortness of breath. He is attached to a 3-lead cardiac monitor which shows a narrow complex tachycardia of 210-220 beats per minute. It is difficult to tell on the monitor however it appears regular. A 12-lead ECG confirms a regular narrow complex tachycardia with a ventricular rate of 215/min.

What is the most likely diagnosis?

A. Atrial fibrillation
B. Atrial flutter with 1:1 conduction
C. Atrial flutter with variable conduction
D. Atrio-ventricular re-entry tachycardia (AVRT)
E. Atrio-ventricular nodal re-entry tachycardia (AVNRT)

B. Atrial flutter with 1:1 conduction

Flecainide is a pure sodium channel blocker which prolongs the cardiac action potential to slow conduction. It is recognised to increase the risk of AF transforming into flutter. Flutter with 1:1 conduction would result in a ventricular rate of 300 /min which is impossible to conduct via the AV node. However, because flecainide slows the rate of cardiac conduction it means that if a patient develops atrial flutter the atrial rate will not be 300 /min, but more likely around 200 /min which then could conduct via the AV node at a 1:1 ratio. For this reason, patients should always be co-prescribed a beta blocker to reduce risk if this happens, and you wonder if this was the tablet that had recently been stopped.

The key to this question is recognising the increased risk of atrial fibrillation transforming into atrial flutter in patients on flecainide. The regular rhythm on ECG makes atrial fibrillation and atrial flutter with variable conduction less likely. He has no specific risk factors for AVRT or AVNRT, however, his flecainide use increases the chance of atrial flutter and therefore this is the correct answer.

Question 127 of 328

An 87-year-old gentleman is reviewed in the cardiology clinic. He has unstable angina with multiple confluent lesions in all three main coronary vessels and in major tributaries on angiography. The lesions are not amenable to stenting or bypass. On assessment in the clinic, the blood pressure is 104/43mmHg, heart rate is 57bpm. His ECG confirms atrial fibrillation but no new ischaemic changes. There is no clinical sign of heart failure. He is currently taking aspirin, bisoprolol, ramipril, isosorbide mononitrate, nicorandil and simvastatin. His main symptom is chest pain on minimal exertion.

Which of the following is the most appropriate drug to control this patients angina?

A. Diltiazem
B. Digoxin
C. Ivabradine
D. Omega 3
E. Ranolazine

E. Ranolazine

National guidelines were published by the Scottish Intercollegiate Guideline Network (SIGN) on the management of stable angina in 2007 with updates by NICE in 2011. Stable angina is defined as chest pain of cardiac aetiology which is precipitated by exertion with a demonstrable flow limiting lesion on angiography. Many patients who experience angina will ultimately go on to have revascularisation procedures to improve or restore coronary flow which will improve their symptoms of angina, however while waiting for interventional procedures optimisation of drug therapy is the aim. Drug therapy also is considered first-line treatment for non-critical lesions.

First line therapy in the treatment of angina is beta-blockade. Betablockers reduce myocardial oxygen consumption by acting as a negative inotrope and also by reducing heart rate. Some patients are unable to take beta-blockers such as asthmatics, or find that side effects such as tiredness, eczema or sexual dysfunction mean they are not tolerable. In these instances, use of calcium channel blockers such as diltiazem are recommended as first-line treatment. Since both of these classes of drug cause a reduction in heart rate and blood pressure their use must be monitored carefully, especially in the elderly. Concomitant use of betablockers and calcium channel blockers should be avoided where possible due to the risk of high degree conduction block and cardiac arrest.

Long-acting nitrates, such as isosorbide mononitrate or dinitrate are considered second-line therapy in stable angina. They can be used as monotherapy or as an adjunct to beta-blocker or calcium channel blocker therapy. They work by causing vasodilatation; both drugs possess a nitric oxide moiety which causes endothelial relaxation in blood vessels. This causes coronary vasodilation and improved blood flow to the myocardium with improved symptoms. A consequence of vasodilatation is hypotension and this should be considered when prescribing this drug to patients.

Another second-line option drug for stable angina in those patients who cannot tolerate nitrates or they are ineffective is nicorandil. This drug has a similar ultimate effect in that it causes dilatation of peripheral and coronary vessels to reduce symptoms of angina. It works by activating potassium channels on endovascular smooth muscle cells reducing intracellular calcium and hence relaxing the blood vessel. It too can cause profound hypotension and severe headaches.

Ivabradine is a drug which can be used for both angina and heart failure. It works by reducing heart rate to reduce myocardial oxygen demand and improve diastolic function. In this case, the heart rate is adequately controlled so reduction is not necessary. Ivabradine also works by inhibiting the hearts natural pacemaker potential in the sinoatrial node, hence it only works when the patient is in sinus rhythm, unlike here.

Ranolazine is a viable option in the management of angina where other avenues have been exhausted. It works by inhibiting the delayed sodium influx channel in the myocardium, reducing the intracellular calcium concentrations in the heart muscle. This, in turn, leads to a negative inotropic effect and reduction in symptoms of angina. Ranolazine does not cause a profound hypotensive effect and is the best choice in this scenario.

Digoxin is not commented upon as a specific treatment for heart failure In NICE guidance although it does have a modest positive inotropic effect. The relative bradycardia of the patient in the vignette makes this an unwise choice here.

Omega 3 and other fatty fish oils are not recommended to be prescribed to heart failure patients in NICE guidance due to lack of evidence of any effectiveness.

Question 128 of 328

A 32-year-old primigravida at 37 weeks attends the antenatal unit complaining of abdominal pain which is worse on the right side. She has also been vomiting. Her blood pressure is 148/97 mmHg. She denies any abnormal discharge and reports that fetal movements are still present. Her blood results are shown below.

Hb	93 g/l
Platelets	89 * 10 /l9
WBC	9.0 * 10 /l9
Urate	0.49 mmol/l
Bilirubin	32 µmol/l
ALP	203 u/l
ALT	190 u/l
AST	233 u/l

You are phoned for advice on the results. What is the most likely diagnosis?

A. HELLP syndrome
B. Obstetric cholestasis
C. Acute fatty liver
D. Hyperemesis gravidarum
E. Gout

A. HELLP syndrome

The most likely diagnosis here is HELLP syndrome (haemolysis, elevated liver enzymes and low platelets), a serious manifestation of preeclampsia. The clinical features of hypertension, vomiting and abdominal pain support the diagnosis but are not pre-requisites. The abdominal pain here may be a sign of liver inflammation and resulting stretch of the liver capsule.

Obstetric cholestasis is associated with intense pruritus and the most sensitive marker is a rise in serum bile acids. Acute fatty liver is another serious condition, which also has associations with pre-eclampsia. It would typically cause greater elevations in liver enzymes and a deep jaundice. Hyperuricaemia may be a useful marker of pre-eclampsia and does not necessarily indicate an attack of gout. Urate is thought to rise due to diminished kidney function and reduced clearance. Hyperemesis gravidarum should be a diagnosis of exclusion and would be unlikely to present for the first time this late into pregnancy

Question 129 of 328

A 76-year-old female presents to the clinic for evaluation in the company of her daughter. She has a history of ischaemic cardiomyopathy with a recent echocardiogram showing an ejection fraction of 30%, increased filling pressures, moderate aortic stenosis, moderate mitral regurgitation, and pulmonary arterial systolic pressures of 32 mmHg. At present, she can walk approximately 100 yards before she gets significantly short of breath, and this has been the case since her last hospitalisation 4 months ago. Otherwise, she feels reasonably well and has no new complaints today. She monitors her weight regularly at home and says that these have been stable.

Her medications include aspirin, amlodipine, metoprolol, lisinopril, furosemide, gabapentin, as required paracetamol, and timolol and brinzolamide eye drops. Physical examination shows a heart rate of 63 beats per minute and blood pressure of 129/76 mmHg. Her JVP is about 4cm above the angle of Louis, her apical impulse is laterally displaced, and heart sounds are audible with a holosystolic murmur heard loudest at the apex. Auscultation of her chest is clear and she has trace peripheral oedema.

What is the next best step in the management of this patient?

A. Discontinue amlodipine
B. Add spironolactone
C. Undertaken ECG to assess her QRS interval
D. Up-titrate the dose of furosemide
E. Go down on the dose of her metoprolol

B. Add spironolactone

Patients with heart failure and an ejection fraction < 35% who are euvolaemic and are already taking an ACE-inhibitor and a betablocker should have an aldosterone antagonist added to their regimen as a next step

This patient has congestive heart failure related to her history of ischaemic cardiomyopathy. She seems to be doing relatively well, and her symptoms are stable. In addition, she has been monitoring her weight at home which has also been stable, and she does not have signs of volume overload on physical exam. Her heart rate and blood pressure are also in acceptable limits. Of note, her recent echocardiogram shows an ejection fraction of 30%. She, therefore, qualifies for the addition of an aldosterone antagonist to her drug regimen. Individuals with congestive heart failure who already on an ACE-inhibitor and betablocker, and to have an ejection fraction of less than 35% who are started on an aldosterone antagonist have been shown to have low mortality compared to those who do not have an aldosterone antagonist added to their medications.

Her blood pressure is acceptable at the moment and so she does not need to discontinue amlodipine.

Cardiac resynchronization therapy is indicated in heart failure patients with NYHA functional class III and IV patients who remain symptomatic despite stable, optimal heart failure medical therapy and who have an LVEF ≤ 35% and a prolonged QRS duration on an ECG. This patient is not yet on optimal medical therapy and should be started on an aldosterone antagonist before she can be considered for this approach.

She does not have signs of volume overload and therefore does not require changes to the dose of her furosemide today.

Her heart rate is in acceptable limits today and she does not have symptoms to suggest that the dose of her beta-blocker needs to be decreased.

Question 130 of 328

An 84-year-old presents to the emergency department with and acute deterioration in shortness of breath on a background of 9 months of progressively reduced exercise tolerance. Her past medical history includes hypertension, previous myocardial infarctions 7 months ago, chronic kidney disease and COPD. She has a 50 pack year smoking history giving up 2 years ago. Her exercise tolerance is 150 yards, limited by shortness of breath.

On examination, an ejection systolic murmur can be heard in the aortic area with bibasal crackles on chest auscultation. An admission chest xray is consistent with pulmonary oedema and intravenous diuresis is commenced. A transthoracic echocardiogram demonstrates ejection fraction of 33% with impaired left ventricular function, no vegetations, a bicuspid heavily calcified aortic valve with an area of 0.7cm2 and a peak gradient of 32mmHg. Angiography demonstrates non-flow limiting stenosis of 65% in the left anterior descending artery but no lesions requiring revascularisation. Lung function testing following successful diuresis reveals forced vital capacity at 55% of predicted and forced expiratory volume in 1 second at 48% of predicted.

The patient is keen for a definitive intervention if appropriate.

What is the appropriate next action?

A. answerNo action
B. Balloon aortic valvuloplasty
C. Aortic valve replacement
D. Transcatheter aortic valve implantation
E. Coronary artery bypass graft and aortic valve replacement

D. Transcatheter aortic valve implantation

The patient has presented with pulmonary oedema on a background of severe aortic stenosis, secondary to calcifications and a bicuspid valve. Interestingly, this is a patient who presents with low-gradient low-area aortic stenosis not uncommonly encountered in more elderly patients. In the context of poor LV function, the aortic valve gradient may be normal or only mildly raised in the presence of a severely narrowed aortic valve area.

A second consideration is the suitability of this patient for surgery. She has underlying lung disease secondary to COPD and functional impairment on pulmonary testing, renal impairment and recent myocardial infarction. She is a high-risk surgical candidate and unlikely suitable for aortic valve replacement. Inaction is not an option, the patient has presented with pulmonary oedema and underlying exerciseinduced dyspnoea. Balloon aortic valvuloplasty is a palliative procedure prone to restenosis for patients unsuitable for other interventions. She does not require a CABG for her coronary artery disease, which worryingly seems inconsistent with the degree of left ventricular impairment, suggesting aortic stenosis to likely be responsible for the majority of symptoms. A transcatheter aortic valve implant (TAVI) is the appropriate management in this situation. The catheter-delivered device produces similar one-year survival as aortic valve replacement but a higher risk of stroke, TIAs and vascular complications. Compared to medical management alone, one-year survival is reduced with TAVI from 50.7% to 30.7%

Question 131 of 328

A 53-year-old gentleman is reviewed in clinic due to abnormal blood tests. He has a past medical history of hypertension, type two diabetes, obesity, and depression. He started taking atorvastatin two months ago due to a routine assessment of QRISK and elevated cholesterol levels. He had a blood test as requested at three months following the start of treatment.

These shows that his alanine aminotransferase have increased from 28iU/L to 94iU/L. Other blood tests have remained within normal ranges apart from cholesterol which as improved from 5.4mmol/L to 4.9mmol/L.

How should his atorvastatin treatment be managed?

A. Stop atorvastatin and repeat LFT within 4-6 weeks
B. Continue atorvastatin and repeat LFT within 4-6 weeks
C. Change atorvastatin to simvastatin
D. Investigate for elevated creatinine kinase
E. Stop atorvastatin and arrange for an urgent abdominalultrasound

B. Continue atorvastatin and repeat LFT within 4-6 weeks

The correct answer is to continue atorvastatin and repeat LFT within 4-6 weeks. This patient has developed elevated transaminases following starting a statin, but these are within three times the upper range of normal. Please note that this is three times the maximum normal range, not three times above the patient's baseline result. Therefore it is acceptable to continue atorvastatin but monitor liver function with a repeat test in 4-6 weeks. If the level had been greater than three times the normal upper range then stopping the atorvastatin and repeating LFT would have been appropriate. There is no need to arrange for an ultrasound at the moment as there is a clear explanation, and there is no evidence of new muscle pain to justify testing for creatinine kinase. Changing statin can play a role if the statin is not tolerated, but that is not the case so far.

Question 132 of 328

A 28 year-old man with a background of asthma presents to the emergency department with palpitations.

He reports a 2 day history of coryzal symptoms and wheeze. He has been using his salbutamol inhaler several times per day due to these symptoms.

On examination the patient appears alert and comfortable but complains of a fluttering sensation in his chest. The pulse rate is 180bpm and the blood pressure is 135/90mmHg. Oxygen saturations are 96% on room air.

There is equal bilateral air entry with mild polyphonic wheeze throughout on chest auscultation.

A 12-lead ECG reveals a narrow-complex regular tachycardia at 180bpm with pseudo r' waves after each QRS complex in lead V1.

What is the most appropriate initial management?

A. Adenosine 6mg IV
B. Metoprolol 5mg IV
C. Synchronised DC shock
D. Vagal manoeuvres
E. Amiodarone 300mg IV

D. Vagal manoeuvres

The first-line management of SVT is vagal manoeuvres: e.g. Valsalva manoeuvre or carotid sinus massage

This scenario describes a supraventricular tachycardia, most likely to be atrioventricular nodal reentrant tachycardia (AVNRT). AV nodal reentrant tachycardia is the most common regular supraventricular tachycardia.

Often a retrograde p-wave is visible in continuity with the QRS complex, appearing as a 'pseudo r'' wave in lead V1 or a 'pseudo s'' wave in the inferior leads.

According to the Resuscitation council guidelines, a regular narrowcomplex tachycardia in the absence of adverse features (shock, syncope, myocardial ischaemia or heart failure) should be treated initial with vagal manoeuvres. Adenosine and metoprolol may worsen bronchospasm so would not be appropriate in this setting. IV Verapamil or synchronised DC cardioversion could be tried if vagal manoeuvres are unsuccessful.

Question 133 of 328

A 45-year-old male is referred to the rapid access chest pain clinic with symptoms typical of angina. He is a non-smoker and has no past medical history. The pain is located in the centre of his chest and made worse by exertion.

According to the NICE guidelines, which is the most appropriate investigation?

A. Treadmill ECG
B. Trans-thoracic echocardiogram
C. CT-coronary angiography
D. Nuclear perfusion stress test
E. Diagnostic coronary angiography

C. CT-coronary angiography

The correct answer is **CT-coronary angiography**. According to the NICE guidelines (CG95), a CT coronary angiogram should be offered as the first-line investigation for patients with typical or atypical angina symptoms and who are in the intermediate risk group (10-29% 10-year risk of developing cardiovascular disease). This patient fits into this category due to his age, sex, and lack of other risk factors. The CT coronary angiogram will help visualise the coronary arteries and identify any significant stenosis.

Treadmill ECG was once a common initial test for angina but it has now been superseded by more accurate tests such as CT coronary angiography. Treadmill ECG can have false positives and negatives, hence it is not recommended as a first-line investigation by NICE.

A **Trans-thoracic echocardiogram** is useful in assessing cardiac function but it does not directly visualise the coronary arteries so it would not be appropriate in this case. It may be used in conjunction with other tests if there are signs of heart failure or valvular heart disease.

Nuclear perfusion stress test involves injecting a radioactive tracer and then imaging the heart under stress and at rest. While this test can identify areas of myocardium that are under-perfused due to significant stenosis, it exposes patients to radiation, is more expensive than CT angiography and does not directly image the coronaries. Hence, it is usually reserved for cases where other investigations are contraindicated or inconclusive.

Finally, **Diagnostic coronary angiography**, while considered the gold standard for diagnosing coronary artery disease, is invasive and carries risks such as bleeding, stroke or kidney damage from contrast dye. As per NICE guidelines, it should only be used when non-invasive tests are inconclusive or contraindicated or when immediate revascularisation is being considered.

Question 134 of 328

A 68-year-old male is admitted with confusion and an ataxic gait. His past medical history includes heart failure and atrial fibrillation. His drug history includes dabigatran, bisoprolol and ramipril.

Investigation results are as follows:

Hb	110 g/l	Na +	139 mmol/l
Platelets	140 * 10 /l 9	K +	3.8 mmol/l
WBC	10.2 * 10 /l 9	Urea	6.5 mmol/l
Neuts	8.2 * 10 /l 9	Creatinine	42 µmol/l
Lymphs	1.4 * 10 /l 9	CRP	12 mg/l
PT ratio	1.6 * 10 /l 9	aPTT	50 seconds
CT head	Large acute right-sided subdural haematoma with ventricular effacement and midline shift		

How will you manage this patient?

A. Platelet transfusion
B. Fresh frozen plasma
C. Red cell transfusion
D. Tranexamic acid
E. Idarucizumab

E. Idarucizumab

Bleeding on dabigatran? Can use idarucizumab to reverse

Dabigatran is an oral anticoagulant acting by direct inhibition of thrombin. In active bleeding, or life-threatening haemorrhage, idarucizumab should be used. This is a specific antidote which reverses the effect of dabigatran.

The PT ratio and INR is not a reliable marker following dabigatran ingestion, and should not be used to monitor the anticoagulant effects. The aPTT and, if available, the thrombin time (TT) should be used to measure the anticoagulant effect of dabigatran,

If idarucizumab is unavailable, and particularly if there is evidence of acquired coagulopathy, consider administration of red cell concentrate, fresh frozen plasma, and/or platelet transfusion.

Question 135 of 328

An 18-year-old male presents with shortness of breath. He states that it has gradually worsened over the past year. He denies cough, wheeze or chest pain. He has no past medical history of note. On examination you note a loud second heart sound. An ECG shows right bundle branch block (RBBB) with left axis deviation (LAD).

What is the most likely diagnosis?

A. Coronary sinus atrial septal defect

B. Ventricular septal defect

C. Idiopathic pulmonary hypertension

D. Chronic pulmonary emboli

E. Ostium primum atrial septal defect

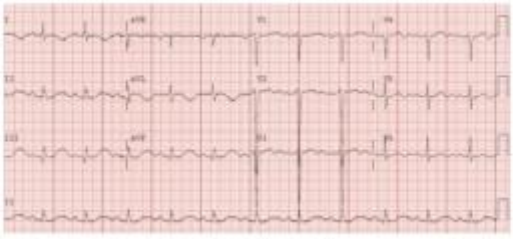
Both primum and secondum atrial septal defects result in RBBB. The axis can be of use in distinguishing between ostium primum ASDs (usually have a LAD) and ostium secondums (usually have RAD).

The patient has presented with features of pulmonary hypertension, namely the progressive shortness of breath and loud second heart sound. The ECG is very suggestive of an atrial septal defect (ASD). Atrial septal defects result in RBBB. The axis can be of use in distinguishing between ostium primum ASDs (usually have a LAD) and ostium secondums (usually have RAD). The ECG features in this case are therefore more suggestive of an ostium primum.

Furthermore, although ostium secondums are more common overall, they do not usually present as early as this. In contrast, ostium primum defects are usually much lower down in the septum and often involve the atrioventricular valves which accelerates the pathogenesis resulting in presentation at a younger age.

Question 136 of 328

A 23-year-old man with known ulcerative colitis presents for the fourth time in 6 months with a severe flare. On examination, he has a distended and generally tender abdomen. He was treated with intravenous hydrocortisone, standard 0.9% saline intravenous fluids and thromboprophylaxis. Although an abdominal film demonstrated dilated large bowel loops, no operation was deemed necessary after surgical review. The same treatment was continued for 3 days. On day 3 of his admission, he reports chest pain with palpations. A 12 lead ECG was taken:



© Image used on license from Dr Smith, University of Minnesota

What is the most likely underlying diagnosis?

A. Hyperkalaemia
B. Hypokalaemia
C. Hypocalcaemia
D. Intravascular depletion → sinus tachycardia
E. Atrial fibrillation

B. Hypokalaemia

Hypokalaemia is a common consequence following extensive GI losses, in addition to bicarbonate and chloride losses. In this case, lack of potassium replacement resulted in tachyarrhythmia with U waves (see extra complex after the T wave). The patient may well be intravenously dry as well but while this may result in tachycardia, it does not explain U waves.

Question 137 of 328

A 78-year-old woman presents to the emergency department with complaints of palpitations. Her episodes of palpitations occur roughly once a month and are not associated with any chest pain or shortness of breath. She has a past medical history of ischaemic heart disease, type 2 diabetes, depression, hypertension and migraines. She takes aspirin, metformin, simvastatin and uses paracetamol when she needs them for headaches. She lives alone with a twice daily package of care.

An ECG demonstrates an irregularly irregular rhythm with no p-waves. She is offered bisoprolol to control her symptoms but does not want to take it regularly. She asks if she could take the bisoprolol only when she has palpitations as they occur so rarely.

What would make a 'pill-in-thepocket'□ strategy inappropriate for her?

A. Hypertension
B. History of ischaemic heart disease
C. Age
D. Living alone
E. Palpitations too frequent

B. History of ischaemic heart disease

The correct answer is a history of ischaemic heart disease. This patient has paroxysmal AF. NICE recommends that when people have infrequent paroxysms and few symptoms a 'pill-in-the-pocket' strategy can be offered. This means giving rate-control medications for as needed use, rather than regular use. It can be considered in those with paroxysmal AF who:

- Have no history of left ventricular dysfunction, valvular or ischaemic heart disease
- Have infrequent episodes
- Systolic blood pressure >100mmHg and heart rate >70bpm
- Are able to understand when to take the tablet

This patient could not be offered this strategy as she has a history of ischaemic heart disease.

Question 138 of 328

A 73-year-old gentleman was shown to have left ventricular dysfunction and hypertrophy on an echocardiogram post acute myocardial infarction (MI). Prior to discharge, he was started on ramipril 2.5mg, bisoprolol 2.5mg, atorvastatin 10mg and aspirin 75mg. His medical history included osteoporosis for which he took Calcichew D3 forte and alendronic acid. He did not smoke or drink alcohol. On admission his kidney function showed the following:

Sodium	136 mmol/L
Potassium	3.7 mmol/L
Urea	7.0 mmol/L
Creatinine	120 micromol/L
eGFR	64 ml/min/1.73m²

His GP checked his bloods again ten days after the initiation of his new medication to titrate the dose of ramipril as requested on the discharge letter from the cardiology team. The results are below:

Sodium	134 mmol/L
Potassium	4.2 mmol/L
Urea	8.0 mmol/L
Creatinine	156 micromol/L
eGFR	50 ml/min/1.73m²

How would you manage this gentleman's deteriorating renal function?

A. Continue the ramipril and repeat the bloods in one week
B. Decrease the dose of ramipril to 1.25mg daily
C. Stop the ramipril
D. Switch the ramipril to losartan
E. Request a renal ultrasound scan

A. Continue the ramipril and repeat the bloods in one week

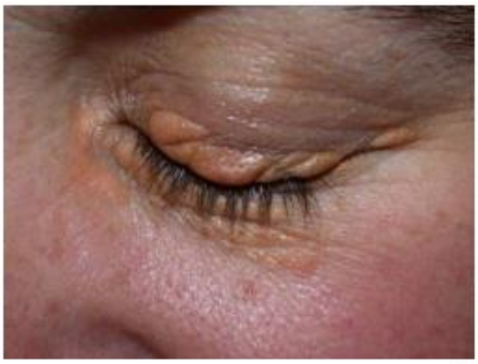
NICE guidelines are useful for everyday practice like managing chronic kidney disease (CKD). Knowing the major points about recent guidelines will also help you in your revision for exams. Guideline 73 is about the diagnosis and management of CKD, the link is below.

It is useful for staging CKD and guiding typical frequency of blood monitoring. In our gentleman's case, his renal function deteriorates due to starting ramipril. NICE guidance says it is acceptable to have a 25% reduction in eGFR OR a 30% rise in creatinine after starting an ACE inhibitor or angiotensin receptor blocker.

Question 139 of 328

A 56-year-old woman presents to her GP with discolouration around her eyes which has been present for some months. She feels very conscious about its appearance but denies any pain, itch or discomfort.

On examination, she appears well. The area in question appears as follows:



Given the likely diagnosis, which of the following would be an appropriate management option?

A. Topical emollient
B. Topical hydrocortisone
C. Topical ketoconazole
D. Topical trichloroacetic acid
E. Urgent referral to secondary care

Not answered

Question 140 of 328

A 38-year-old woman is referred to the cardiology outpatient department with exertional shortness of breath. She has no past medical history.

On examination, the jugular venous pulse is elevated and there is a loud P2 component of the second heart sound.

A transthoracic echocardiogram reveals an elevated mean pulmonary artery pressure (mPAP) of 54 mmHg, which is confirmed with a right heart catheterization (RHC). Acute vasodilator testing at the time of RHC demonstrates a decrease in mPAP to 28 mmHg.

A set of comprehensive investigations does not reveal an identifiable cause of the abnormalities.

Given her diagnosis and subsequent investigations, what class of medications are appropriate to treat her illness?

A. Calcium channel blockers
B. Endothelin receptor antagonists
C. Phosphodiesterase inhibitors
D. Prostacyclin analogues
E. Vitamin K antagonists

A. Calcium channel blockers

Pulmonary arterial hypertension patients with positive response to vasodilator testing should be treated with calcium channel blockers

Calcium channel blockers is the correct answer. The patient has pulmonary hypertension. The gold standard investigation for the investigation of pulmonary hypertension is right heart catheterization. A mean pulmonary artery pressure >= 25 mmHg at rest defines pulmonary hypertension. Patients with pHTN should undergo vasodilator testing. A positive response to vasodilator testing as evidenced by a decline in mPAP suggests the patient may benefit from a calcium channel blocker. An inability to find a secondary cause of her disease suggests she has the idiopathic form of the illness.

Endothelin receptor antagonists is incorrect. An example of this type of medication is bosentan. This class of medication is used in those patients with negative acute vasodilator testing.

Phosphodiesterase inhibitors is not the right answer. An example of this class of medication is sildenafil. It can be used orally. This class of medication is used in those patients with negative acute vasodilator testing. Examples of vasodilators include IV epoprostenol, IV adenosine, or inhaled nitric oxide.

Prostacyclin analogues is incorrect. An example of this class of medication is iloprost. This is given as an infusion. It is used in those patients with negative acute vasodilator testing.

Vitamin K antagonists is not the right answer. An example of this class of medication is warfarin. Chronic thromboembolic disease is a cause of pulmonary hypertension but we are told a comprehensive set of investigations did not reveal a cause of pulmonary hypertension and therefore anticoagulation is not indicated.

Question 141 of 328

A 68-year-old Afro-Caribbean gentleman is short of breath on dressing, washing and climbing the stairs. He has a past medical history of agerelated macular degeneration, systolic heart failure (ejection fraction on echocardiogram = 43%), osteoporosis and myelodysplasia. He is currently taking ramipril, bisoprolol and spironolactone, at the maximum tolerated doses, as well as alendronate once weekly.

Which medical therapy could further improve his prognosis?

A. Erythropoietin
B. Blood transfusion
C. Isosorbide mononitrate and hydralazine
D. Folic acid
E. Furosemide

C. Isosorbide mononitrate and hydralazine

Hydrazine and nitrate should be considered for Afro-Caribbean patients with heart failure who are not responding to ACE-inhibitor, beta-blocker and aldosterone antagonist therapy

This gentleman is symptomatic (New York Heart Association Stage III). He is fully optimised on conventional medical treatment, but NICE recommends that Afro-Caribbean patients are additionally treated with hydralazine and nitrate, to improve prognosis. Furosemide may improve his symptoms, but does not change his prognosis. This gentleman may also be symptomatic from anaemia, due to myelodysplasia, for which folic acid, erythropoietin and blood transfusion may improve his symptoms, but not his prognosis. The management of myelodysplasia in elderly patients with multiple co-morbidities is usually supportive care.

Question 142 of 328

A 56-year-old Caucasian male patient with no history of ischaemic heart disease had a non-ST elevation myocardial infarction 20 days ago and was started on aspirin, atorvastatin, bisoprolol and enalapril as an inpatient. He has been discharged to your care in the cardiology outpatients department. He presents for review 1 month later saying he remains breathless on minimal exertion (walking 50 metres) with no chest pains. There is no evidence of pulmonary oedema on examination. A recent echocardiogram shows a left ventricular ejection fraction of 40%. His beta natriuretic peptide level is 436 pg/mL (normal <100 pg/mL).

What would be most appropriate to add to his oral therapy?

A. Furosemide
B. Spironolactone
C. Hydralazine and isosorbide dinitrate (modified release)
D. Irbesartan
E. Ivabradine

NICE guidelines regarding chronic heart failure with reduced left ventricular ejection fraction:

A. Start an ACE-inhibitor and β blocker in increasing doses to maximum tolerated.

B. Second line treatment most appropriate for this Caucasian patient is spironolactone because of the recent history of myocardial infarction.

C. Furosemide has no prognostic benefit and is not indicated if there are no signs of fluid overload on examination.

D. Eplerenone is a mineralocorticoid antagonist that is specifically marketed for post-myocardial infarction patients. However, it is not available off-patent in the UK and therefore rarely first line on hospital formularies

Question 143 of 328

A 44-year-old man attends with a 2-day history of fevers on rigours. On examination, you note splinter haemorrhages and a pan systolic murmur.

Blood results are as follows:

Hb	130 g/L	Male: (135-180)Female: (115 - 160)
Platelets	380 * 10 /L 9	(150 - 400)
WBC	18.2 * 10 /L 9	(4.0 - 11.0)
Na +	126 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	115 µmol/L	(55 - 120)
CRP	82 mg/L	(< 5)

Three sets of blood cultures are positive for the following organism:

Blood cultures	Gram +ve coagulase positive cocci

What treatment is indicated?

A. Benzylpenicillin and low-dose gentamicin

B. Flucloxacillin

C. Flucloxacillin, rifampicin and low-dose gentamicin

D. Vancomycin and low-dose gentamicin

E. Vancomycin and rifampicin

B. Flucloxacillin

IV flucloxacillin is the treatment of choice for native valve endocarditis caused by staphylococci

Flucloxacillin is correct. The positive cultures are highly suggestive of *S.aureus* infection due to the positive coagulase test result. *Streptococci* are not coagulase producing. Native valve endocarditis caused by *S.aureus* is treated with high-dose intravenous flucloxacillin.

Benzylpenicillin and low-dose gentamicin is incorrect. This combination of drugs is used to treat endocarditis caused by less sensitive *Streptococci*.

Flucloxacillin, rifampicin and low-dose gentamicin is incorrect. This combination of drugs is used to treat prosthetic valve endocarditis caused by *S.aureus*.

Vancomycin and low-dose gentamicin is incorrect. This combination of antibiotics can be used for initial blind therapy in patients with a penicillin allergy, a history of methicillin-resistant *Staphylococcus aureus* (MRSA) or severe sepsis.

Vancomycin and rifampicin is incorrect. This combination of antibiotics can be used for native valve endocarditis caused by *S.aureus* if they have a penicillin allergy or a history of MRSA.

Question 144 of 328

A 27-year-old man presents to the emergency department. He was recently discharged following an internal fixation of his left tibia. The fracture occurred due to a fall whilst intoxicated and he broke his leg as he landed on the pavement.

He has returned because he experienced a sudden onset of shortness of breath and became concerned. He has no cough or chest pain. He has no previous medical problems. His medications include codeine and paracetamol; post-operative analgesia that he was discharged on. He denies any allergies.

Observations demonstrate hypoxia with saturations at 92% on room air and are otherwise unremarkable. Blood tests, including a FBC, U&E and CRP are all within normal ranges. Clinical examination reveals a few leftsided crepitations and there is swelling and tenderness of his left calf. This was the side of his operation. A chest X-ray demonstrates a small left-sided pleural effusion causing blunting of his left costophrenic angle. No CT or US scanning is available as it is 3 AM.

What is the most appropriate next step?

A. Treatment dose apixaban
B. Wait to morning then order CTPA
C. Immediate drainage of effusion
D. Wait to morning and then US guided drainage of effusion
E. Wait to morning then order VQ scan

A. Treatment dose apixaban

Strong suspicion of PE but a delay in the scan: start on treatment dose anticoagulant meanwhile

The correct answer is treatment dose apixaban. This is a young and fit patient who has presented with sudden onset of shortness of breath with a swollen calf following immobilisation and surgery. The most likely diagnosis is a PE from a DVT. The clinical likelihood is very high and therefore immediate treatment is appropriate as the patient is hypoxic. Waiting to confirm the diagnosis should be done but it is more appropriate to start treatment first. The effusion is most likely secondary to an embolus and unlikely to be responsible for the level of hypoxia as it is small on the X-ray.

Question 145 of 328

A 68-year-old male is admitted with crushing chest pain radiating to the left arm and an ECG suggestive of anterior ST-elevation myocardial infarction. He is treated under the local primary percutaneous cardiac intervention protocol and a drug-eluting stent is successfully deployed in his left anterior descending artery. A left ventriculogram is performed during the procedure indicating severely reduced systolic function. An echocardiogram confirms this with an ejection fraction calculated at 32%.

Which rate control medication would be the most appropriate first choice in treating this gentleman?

A. Carvedilol
B. Ivabradine
C. Metoprolol
D. Atenolol
E. Diltiazem

A. Carvedilol

Carvedilol, bisoprolol and nebivolol are the B-blockers that are licensed in the United Kingdom for the treatment of heart failure

This is a patient that has recently suffered a myocardial infarction with residual reduced ejection fraction secondary to that. The beta-blockers currently licensed in the treatment of heart failure and as secondary prevention of ischaemic cardiac disease include bisoprolol, carvedilol and nebivolol.

Ivabradine has a role in the management of angina and rate-control in patients with heart failure however it does not appear to be involved in the first line management and secondary prevention of ischaemic heart disease.

Diltiazem is a rate-limiting calcium channel blocker; all calcium channel blockers (rate limiting) are contraindicated in moderate to severe heart failure.

Metoprolol has previously shown increased rate of adverse events in early use in coronary artery disease (STEMI) while atenolol is not licensed in the UK for heart failure management.

Question 146 of 328

A 62-year-old man sees his GP with complaints of leg pain. Over the last few months, he notices a crampy uncomfortable feeling in the back of both of his calves when he walks to the shops. The discomfort can be so bad that he has to stop and rest for a few minutes after which he notices that his symptoms are improved. On occasions, he also gets the symptoms when he is shopping in the supermarket. He attributes this to overexerting himself and tries to rest on his shopping trolley while walking but does not seem to help. He has a 40-pack year smoking history and takes amlodipine for his blood pressure, and paracetamol and ibuprofen for lower back pain that has troubled him for years.

Physical examination reveals mild atrophy of his thigh and calf muscles bilaterally, in addition to shiny pale skin with significant hair loss throughout his lower limbs. His pedal pulses are bilaterally impalpable, and popliteal pulses are faint. Power in both lower limbs is normal throughout all movements, and he has normal patellar reflexes bilaterally and absent ankle reflexes. His Babinski reflex is downgoing on the left side and equivocal on the right side. A recently obtained ankle brachial pressure index test yielded a result of 0.70 on the right side and 0.95 on the left side. X-rays of his lumbar spine show evidence of joint space narrowing and osteophytes.

Which one of the following is the next best step in the management of this patient?

A. MRI scan of lumbar spine
B. Check his HbA1c to screen for diabetes
C. Refer to vascular surgery for consideration of peripheral arterialstenting or bypass surgery
D. Starting him on duloxetine to manage his pain
E. Screen for coronary artery disease with ECG stress testing

C. Refer to vascular surgery for consideration of peripheral arterialstenting or bypass surgery

In patients with cardiovascular risk factors and symptoms suggestive of claudication with an equivocal/borderline ankle brachial pressure index study result, the next best study is an ankle brachial pressure index after exercise

This gentleman has symptoms of claudication, in particular, vascular claudication. Although he does have a history of chronic back pain for which he takes analgesia, he is less likely to have neurogenic claudication compared to vascular claudication. An important discriminating factor between neurogenic claudication and vascular claudication is that patients with neurogenic claudication have symptoms on exertion that improve with manoeuvers such as leaning forward, and sitting down, whereas vascular claudication does not change with these manoeuvers and only improves with rest. In addition, his physical exam shows evidence of peripheral arterial disease characterised with muscle atrophy, shiny skin with hair loss and impalpable pedal pulses. Absent ankle jerk reflexes and equivocal Babinski reflexes can be normal variants and do not always indicate neurological pathology. This patient has rightly already undergone an ankle brachial pressure index assessment, and the results indicate a diagnosis of peripheral arterial disease. He is functionally impaired by his symptoms and so the next best step in his management would be to refer him to vascular surgery for consideration of treatment strategies which may include percutaneous interventions with stenting and/or surgical bypass.

Although this patient has evidence of degenerative joint disease on his lumbar spine x-ray, his clinical presentation is not consistent with neurogenic claudication and so an MRI scan of his lumbar spine is not indicated.

Although it is important to screen for and aggressively manage cardiovascular risk factors in patients with peripheral arterial disease, this in itself would not address the patient's symptoms or the disease course.

This patient's pain is most consistent with vascular claudication as opposed to neuropathic pain, for which an agent like duloxetine would be appropriate.

Although individuals with peripheral arterial disease have a significant likelihood of having concomitant coronary disease, this patient is not complaining of angina or symptoms suggestive of coronary disease and so screening for this is not indicated. The next best step in managing this patient is to address and treat his symptoms related to his peripheral arterial disease.

Question 147 of 328

A 43-year-old man presents with palpitations to the emergency department. His ECG demonstrates a broad complex tachycardia at 180 beats/min, suggestive of ventricular tachycardia. His blood pressure is 134/80 mmHg, he is uncomfortable but alert. The emergency department doctor has administered a 300mg bolus of amiodarone and the consultant subsequently inserted a central venous line to continue amiodarone treatment with a 900mg infusion over 24 hours. He transiently settles but on the second day of admission, his cardiac monitor demonstrates persistent VT at 180 beats per minute again. His blood pressure is 140/75 mmHg.

What is your treatment?

A. answerNo treatment
B. Repeat bolus of amiodarone 300mg
C. DC cardioversion
D. Intravenous lidocaine infusion
E. Emergency VT ablation

D. Intravenous lidocaine infusion

The patient has entered refractory VT, continuing despite a therapeutic dose of amiodarone and sufficient loading. It is unlikely further boluses of amiodarone will produce additional therapeutic effects. Similarly, no treatment is not an option, his myocardium is unlikely to continue tolerating such a persistent tachycardia without soon reducing left ventricular output and arrest. He is not haemodynamically unstable and hence does not justify DC cardioversion as an emergency procedure. Similarly, emergency VT ablation is not appropriate after only 1st line treatment. Intravenous lidocaine is the second line treatment: first as a bolus, followed by an infusion regime over 6.5 h

Question 148 of 328

A 25-year-old female presents with palpations and dizziness. She states that she has had a few episodes similar to this in the past and each time they have spontaneously resolved. On examination she has a blood pressure of 85/65 mmHg and a heart rate of 180bpm. An ECG shows an irregularly irregular rhythm, no identifiable P waves, and a QRS of 135ms.

Your senior decides to electrically cardiovert her. While the cardioversion is being prepared you instruct the patient to perform a vagal manoeuvre. Shortly after this she loses consciousness and goes into cardiac arrest.

What is the most likely underlying disorder?

A. Torsades de Pointes
B. Atrial fibrillation
C. Atrioventricular nodal re-entry tachycardia (AVNRT)
D. Monomorphic ventricular tachycardia
E. Wolff-Parkinson-White syndrome (WPW)

E. Wolff-Parkinson-White syndrome (WPW)

AV blocking drugs and vagal manoeuvres are absolutely contraindicated in patients with AF and pre-excitation

There are few arrhythmias, which can cause an irregularly irregular broad complex tachycardia. These include irregular atrial arrhythmias with bundle branch block (e.g. atrial fibrillation), and polymorphic ventricular tachycardia (including Torsades de Pointes). Another important group of conditions to be aware of include the pre-excitation syndromes.

Pre-excitation refers to early activation of the ventricles due to impulses bypassing the AV node via an accessory pathway. This results in a broad QRS complex e.g. the slurred upstroke of QRS (delta wave) as is seen in WPW. When present with atrial fibrillation, the accessory pathway allows for rapid conduction directly to the ventricles bypassing the AV node. This results in an irregularly irregular broad complex tachycardia.

The Valsalva manoeuvre increases the vagal tone resulting in AV node block. This promotes conduction of the atrial signals through the accessory pathway with a resultant increase in ventricular rate and possible degeneration into VT or VF, as is seen in this case.

AV blocking drugs and vagal manoeuvres are absolutely contraindicated in patients with AF and pre-excitation. In a haemodynamically unstable patient, urgent synchronised DC cardioversion is required. Medical treatment options in a stable patient include procainamide, although DC cardioversion may be preferred. Procainamide is a class 1 anti-arrhythmic which preferentially blocks the accessory pathway.

Question 149 of 328

A 67-year-old woman is reviewed in cardiology clinic following a GP referral. A recent transthoracic echocardiogram demonstrated severe aortic stenosis with an aortic valve at 0.7cm2 and a mean pressure gradient of 62mmHg and a left ventricular ejection fraction of 43%. Pulmonary arterial pressure is normal. She has a chest X-ray two months ago which was normal. She denies any symptoms of shortness of breath, chest pain or lightheadedness.

She is normally fit and well with a past medical history of hypothyroidism, two caesarian sections, osteoarthritis and migraines. She is a non-smoker.

What is the most appropriate management plan?

A. Review in six months
B. Cardiac MRI
C. Exercise test
D. Aortic valve replacement
E. Transcatheter aortic valve implantation (TAVI)

D. Aortic valve replacement

The correct answer is aortic valve replacement. This is an asymptomatic patient with severe stenosis but she has an ejection fraction of less than 50%. This means that she should be referred for aortic valve replacement or TAVI if unsuitable. Exercise testing would be recommended if her ejection fraction was greater than 50%. Cardiac MRI would not be helpful in this instance. If she had an ejection fraction greater than 50% and passed exercise testing then she could be reviewed in six months

Question 150 of 328

A 62-year-old woman is reviewed prior to discharge by the medical team. She was admitted with a lower respiratory tract infection. She now feels well and is ready for discharge. She has a background of type two diabetes mellitus, hypertension, hypothyroidism, osteoarthritis and dementia. Her medication history includes metformin 500mg BD, ramipril 2.5mg OD, levothyroxine 75 mcg OD and paracetamol 500mg QDS PRN. On the first two days in hospital, her metformin was stopped, but her other medications continued as in the community during her admission.

It is noted that she has persistently high blood pressure despite being confirmed as taking ramipril.

What is the most appropriate plan to control her hypertension?

A. Increase the dose of ramipril and check U&Es within 1-2 weeks
B. Increase the dose of ramipril and check U&Es within 3-4 weeks
C. Add amlodipine, increase the dose of ramipril and check U&Eswithin 3-4 weeks
D. Add on amlodipine at a low dose
E. Stop ramipril and start amlodipine instead

A. Increase the dose of ramipril and check U&Es within 1-2 weeks

The correct answer is to increase the dose of ramipril and to check U&Es within 1-2 weeks. The patient is on a low dose of ramipril and there is room to increase it, and this should be done prior to adding on a second anti-hypertensive. It is important to test renal function within two weeks of either starting or increasing the dose of an ACE inhibitor to exclude deteriorating renal function, which would need to be investigated promptly. Amlodipine would have been a more appropriate antihypertensive choice if she did not have diabetes.

Question 151 of 328

A 56-year-old gentleman is admitted to Emergency Department with back pain. His past medical history included type 2 diabetes and hypertension. Initial observations are as follows: heart rate 112 beats per minute, blood pressure 155/82 mmHg, respiratory rate 26/min, oxygen saturations 95% on 2 litres oxygen via nasal cannula, temperature 37.2ºC.

Examination demonstrates muffled heart sounds I and II. JVP is not elevated and there is no peripheral oedema. Auscultation of the chest is clear with no crackles or wheeze and good air entry bilaterally. An ECG confirms sinus tachycardia with a heart rate of 102 beats per minute and 2mm inferior ST depression. Portable chest x-ray shows poor inspiratory effort with cardiomegaly and clear lung fields.

What single investigation would you arrange next?

A. CT aortogram
B. CT pulmonary angiogram (CTPA)
C. Ventilation/Perfusion scan (V/Q scan)
D. Echocardiogram
E. 12 hour troponin

A. CT aortogram

This patient has clinical features suggestive of type A aortic dissection, and an urgent CT aortogram would be required to exclude this diagnosis. Patients often describe back pain as the aorta is a retroperitoneal structure. A major risk factor is hypertension. The Stanford classification outlines type A dissections which involves the ascending aorta and type B dissections which originate in the descending aorta. Proximal extension of type A dissections can result in rupture of the coronary sinus and secondary ischaemia. They may be associated with pericardial effusions, which often manifests as cardiomegaly on a plain chest x-ray and results in muffled heart sounds. Management of type A dissections involves urgent referral to a cardiothoracic surgical unit

Question 152 of 328

A 65-year-old man is reviewed in the outpatient cardiology clinic and reports palpitations and fatigue when carrying out normal household tasks. He has a history of heart failure (with an ejection fraction of 41%) and chronic obstructive pulmonary disease. He takes bisoprolol 10mg once daily, ramipril 10mg once daily and uses a tiotropium bromide inhaler.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 145/82 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air (95% on exertion)

On examination, the pulse is regular.

What is the most appropriate next step in the patient's management?

A. Add a long-acting beta agonist and inhaled corticosteroid
B. Add digoxin
C. Add ivabradine
D. Add spironolactone
E. Increase the dose of bisoprolol

D. Add spironolactone

Offer a mineralcorticoid receptor antagonist, in addition to an ACE inhibitor (or ARB) and beta-blocker, to people who have heart failure with reduced ejection fraction if they continue to have symptoms of heart failure

Add spironolactone is correct. The patient reports palpitations and fatigue on minimal exertion. These symptoms suggest symptomatic heart failure rather than worsening COPD. This is reaffirmed by the normal SpO2 results following exertion. In a patient that is on maximally tolerated doses of beta-blocker and an ACE inhibitor, the correct next step is to add spironolactone.

Add a long-acting beta-agonist and inhaled corticosteroid is incorrect. Symptoms of palpitations and fatigue are more suggestive of symptomatic heart failure rather than COPD where wheezing and shortness of breath would be more typical. Therefore adjusting his COPD inhaler regimen is incorrect.

Add digoxin is incorrect. Digoxin is indicated in the management of symptomatic heart failure (especially in the context of co-existent atrial fibrillation) but only after other medications such as spironolactone have been initially trialled. This patient is not in AF.

Add ivabradine is incorrect. This is a 3rd line option for those patients with an ejection fraction < 35% and a heart rate > 75.

Increase the dose of bisoprolol is incorrect. 10mg is the maximum dose of bisoprolol that is recommended for heart failure.

Question 153 of 328

A 24-year-old female is brought into the emergency department by ambulance. She has a family history of Wolff-Parkinson-White syndrome and was binge drinking last night. She is complaining of palpitations which she says started suddenly 1 hour ago.

Her observations are as follows

Heart rate 180 bpm

Blood pressure 100/60 mmHg Saturations 98% on air Respiratory rate 26/min Temperature 36.8ºC

An ECG (electrocardiogram) is done which shows pre-excited atrial fibrillation (AF)

Which of the following is an appropriate treatment?

A. Adenosine
B. Atenolol
C. Flecainide
D. Diltiazem
E. Digoxin

C. Flecainide

In pre-excited AF don't give anything that blocks conduction at AV node (including calcium channel blockers, adenosine or digoxin) as this can cause ventricular tachycardia

Flecainide is the only appropriate treatment on this list

All of the other options are drugs which block transmission through the

AV (atrioventricular) node. Giving these drugs in pre-excited AF (atrial fibrillation) can precipitate VT (ventricular tachycardia) or VF (ventricular fibrillation).

Note that flecainide is contraindicated in patients with structural heart abnormalities. In this situation then amiodarone can be given instead.

If any of the following are present: hypotension, signs of shock, altered mental status, chest pain or acute heart failure then synchronised cardioversion should be used rather than medication.

Question 154 of 328

A 48-year-old female presents with chest pain. She describes the pain as central, dull and tight. She has associated nausea. She has no past medical history and takes no regular medicines.

An ECG is performed:

P waves	Normal morphology
PR interval	130ms
QRS	115ms
ST segments	ST elevation in V1-V3

Blood results are as follows:

Troponin (on admission)	< 0.015 µg/l (normal < 0.015)
Troponin (6 hours later)	< 0.015 µg/l (normal < 0.015)

What is the most likely diagnosis?

A. answerAcute STEMI
B. Acute NSTEMI
C. Unstable angina
D. Stable angina
E. Prinzmetal's angina (variant angina)

E. Prinzmetal's angina (variant angina)

In coronary vasospasm (Prinzmetal's angina, or variant angina), the ECG shows ST elevation that is very similar to an acute STEMI. However, unlike acute STEMI the ECG changes are transient, reversible with vasodilators and not associated with myocardial necrosis

The presence of ST elevation and chest pain should alert you to the diagnosis of acute STEMI. However importantly the serial troponins are negative effectively ruling out myocardial infarction. In coronary vasospasm (Prinzmetal's angina, or variant angina), the ECG shows ST elevation that is very similar to an acute STEMI. However, unlike acute STEMI the ECG changes are transient, reversible with vasodilators and not associated with myocardial necrosis. Prinzmetal's angina is therefore the most likely diagnosis.

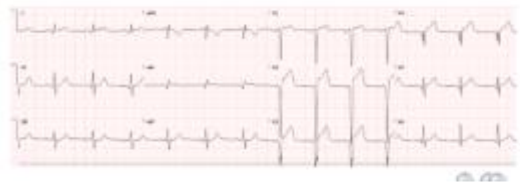
Acute NSTEMI is excluded by the normal serial troponins.

Angina pectoris (stable or unstable) is of course a possibility. However the presence of ST elevation, the relatively young age of the patient, and the absence of cardiovascular risk factors, makes Prinzmetal's angina the more likely diagnosis.

The patient will need coronary angiography. The gold standard test for diagnosing variant angina is to visualise the coronary arteries by angiography before and after injection of a provocative agent such as acetylcholine to precipitate an attack of vasospasm.

Question 155 of 328

A 72-year-old man arrives at the emergency room complaining of chest pain for six hours. It is a crushing pain at the centre of his chest, which radiates to the neck. He was diagnosed with Grave's disease previously, which was treated with radioiodine ablation, following which he developed hypothyroidism. He suffered an ischemic stroke two months ago. His medications include aspirin, atorvastatin and thyroxine. His heart rate is 83 beats/min, BP 130/80 mmHg, respiratory rate 20 breaths/min, and oxygen saturation is 98%. An ECG is taken:



What is the most appropriate next step in managing this patient?

A. Give aspirin and arrange for an emergency CRP, troponin level and ECHO
B. Give aspirin and arrange for an emergency troponin level andECHO
C. Give aspirin and glyceryl trinitrate and arrange for an emergency troponin level
D. Give aspirin and glyceryl trinitrate, and prepare for urgent PCI
E. Give aspirin and glyceryl trinitrate, and prepare for urgentfibrinolysis

D. Give aspirin and glyceryl trinitrate, and prepare for urgent PCI

The most appropriate next step is to **give aspirin and glyceryl trinitrate and plan for PCI**. The ECG in this scenario indicates a STEMI, with ST elevation observable in leads V1 to V5, which typically indicates an occlusion of the LAD. It is important to note that ECG manifestations of STEMI can vary depending on the timing post-ischemia onset. Initially, hyperacute T waves may be observed, followed by ST-segment elevation. As the condition evolves over several hours to days, T wave inversions and Q waves tend to appear within the same leads. Prompt primary PCI is essential for this patient in order to achieve reperfusion as soon as possible. Detailed management guidelines for acute coronary syndromes such as STEMI, NSTEMI, and unstable angina are outlined in the accompanying notes.

Give aspirin and arrange for an emergency CRP, troponin level, and ECHO is incorrect. Acute pericarditis is a close mimic of STEMI. However, it can be differentiated based on clinical features and ECG findings. Clinically, patients with pericarditis present with a sudden onset of a sharp pain over the anterior chest wall, similar to pleuritic pain, which increases on inspiration and decreases on leaning forwards. ECG findings include global ST elevations and PR-segment depressions in most limb leads (I, II, III, aVL, aVF) and precordial leads (V2 - V6). Initial investigations for pericarditis include CRP to check for infection, an ECHO scan to look for associated pericardial effusion and a troponin level. However, the history and ECG in this case do not suggest pericarditis.

Give aspirin and arrange for an emergency troponin level and ECHO

is not appropriate in this scenario. This patient has typical features of STEMI in the ECG and should be taken up for PCI immediately. Troponin level and ECHO will be requested in all cases of myocardial infarction, but they will take time. Given that the patient has a STEMI, preparing for PCI is the most appropriate strategy here.

Giving aspirin and glyceryl trinitrate and arranging for an emergency troponin level would be misguided. In instances where STEMI has been identified by ECG findings'as it has been in this case'immediate reperfusion strategies such as PCI or fibrinolysis are warranted without delay. Troponin levels might still fall within normal ranges early after an acute coronary syndrome has occurred; therefore, they should not be solely relied upon for diagnosing STEMI.

Giving aspirin and glyceryl trinitrate and preparing for urgent fibrinolysis would be contraindicated due to the patient's recent history of ischemic stroke within the past three months. Fibrinolysis could potentially be considered for patients with no contraindications when they present with STEMI within 12 hours from symptom onset; however, it is only recommended if primary PCI is not accessible at their presenting hospital or if transfer to another facility offering PCI services cannot occur within 120 minutes.

Question 156 of 328

You review a 65 year-old male who was admitted yesterday. He is a diabetic gentleman who was admitted with a non-ST elevation myocardial infarction and subsequent flash pulmonary oedema. He has been treated with aspirin, clopidogrel, fondaparinux and intravenous furosemide. He is achieving a good diuresis - producing 100mls of urine per hour.

You have been asked to see him as he continues to have significant breathlessness but no ongoing chest pain. His blood pressure is 92/87mmHg and oxygen saturations are 83% on 65% humidified oxygen. He has bibasal crepitations and JVP is raised. His ABG results are as follows:

pH	7.32
pCO2	4.6kPa
pO2	7.9kPa

What would be your next clinical intervention?

A. Start non-invasive ventilation
B. Start continuous positive airway pressure ventilation (CPAP)
C. Refer for angiography and primary coronary intervention
D. Start a tirofiban infusion
E. Start a GTN infusion

B. Start continuous positive airway pressure ventilation (CPAP)

Acute heart failure not responding to treatment - consider CPAP

This gentleman has had a non-ST elevation myocardial infarction (NSTEMI) and is now struggling with hypoxia secondary to pulmonary oedema. He has been treated optimally for his NSTEMI and is now pain free. He is diuresing well but continues to be hypoxic with signs of ongoing pulmonary oedema. The next logical intervention would be to try CPAP to improve his oxygenation. GTN, tirofiban and angiography would all look to improve coronary perfusion, however the gentleman is pain free suggesting this is not a priority.

Question 157 of 328

A 72-year-old man attends cardiology clinic for routine follow-up of ischaemic heart disease. The patient had suffered a non-ST elevation myocardial infarction the previous year treated with a drug eluting stent (see below angiogram report). The patient reported being generally well over previous months although did experience retro-sternal chest pain on exertion, typically on walking up hills or climbing stairs. The patient denied any episodes of pain at rest and did not feel his symptoms were worsening. The patients regular medications were aspirin 75 mg daily, clopidogrel 75 mg daily, atorvastatin 80 mg daily and ramipril 5 mg daily. As required medications were sildenafil and a nitrate spray (which he reported as giving effective relief from his chest pain episodes).

Clinical examination did not demonstrate any evidence of cardiac failure. Blood pressure in clinic was 125 / 75 mmHg.

Results of investigations conducted 1 year previously following presentation with NSTEMI are included below.

Angiography: 90 % stenosis to left anterior descending artery treated with drug-eluting stent; 60 % stenosis to mid-right coronary artery; minor disease to other vessels.

Transthoracic echocardiogram: valvular function unremarkable; mild hypokinesis to anterior myocardium; overall ejection fraction approximately 40-45 %.

Electrocardiogram: sinus rhythm at 75 beats per minute; normal axis; normal QRS; no significant ST changes; inverted T waves in V3-V5.

What is most appropriate next line therapy for the patients chest pain?

A. Amlodipine
B. Bisoprolol
C. Percutaneous coronary intervention
D. Long-acting isosorbide mononitrate
E. Nicorandil

B. Bisoprolol

The patients reported symptoms are consistent with a diagnosis of stable angina secondary to known ischaemic heart disease. Medical treatment for symptomatic relief is the appropriate next line therapy. In this patient with a history of NSTEMI and controlled blood pressure a beta-blocker is preferred over a calcium-channel blocker such as amlodipine.

Both ISMN and nicorandil are second-line options for medical therapy after intolerance or failure of beta-blocker and calcium-channel blocker therapy. Such both medications induce systemic vasodilatation they would be contraindicated in this patient while he still was taking sildenafil.

Revascularisation techniques such as PCI have not been show to reduce mortality or rate of MI in stable coronary artery disease. Therefore, medical therapy should be attempted before consideration of invasive treatment.

Question 158 of 328

A 74-year-old man presents to the emergency department with a collapse. He has a past medical history of hypertension and atrial fibrillation. His medications include amlodipine and apixaban. A recent 24-hour tape arranged because of episodes of pre-syncope demonstrates sustained atrial fibrillation with episodes of bradycardia (minimum heart rate 20 beats per minute) associated with symptoms of pre-syncope.

The admission ECG demonstrates slow atrial fibrillation with a heart rate of 24 beats per minute.

The patient has recovered by the time he has been assessed by the medical team and his Glasgow coma scale is 15/15 and his heart rate is 82 beats per minute.

A decision is made to insert a permanent pacemaker.

What is the appropriate mode to programme the pacing system?

A. AAI
B. AOO
C. OOO
D. VAT
E. VVI

E. VVI

VVI or VVR pacemakers are useful for pure sustained AF. Since the atria are not functioning they do not require sensing or pacing

VVI is the correct pacing mode. In this mode, the ventricle is sensed and the ventricle is paced. If a QRS complex is detected, it doesn't fire. If it is not detected i.e. there has been no ventricular electrical activity within the interval specified by its set rate, then it will fire. This is suitable for atrial fibrillation as the atria are not working correctly and there will be no detectable P wave and therefore the atria do not need to be sensed or paced.

AAI is not the correct pacing mode to choose. AAI pacing mode means atrial paced, atrial sensed, and inhibition of pacing output in response to an atrial sensed event (P wave). Since the atria are not functioning in AF, they do not require sensing or pacing. AAI pacing has better hemodynamic features than dual-chamber pacing and is the best mode for patients with sick sinus syndrome without a significant AV conduction disorder. This mode essentially relies on the AV node to fire and guarantees a certain atrial rate.

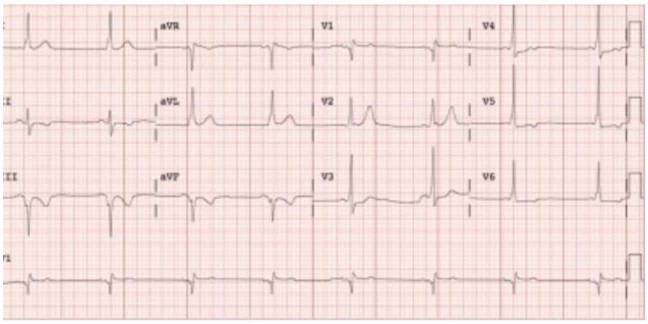
AOO is incorrect. This is asynchronous pacing. This refers to the continuous pacing of the atria irrespective of the presence or absence of an intrinsic rhythm. This pacing mode is limited to rare cases, such as when pacemaker-dependent patients (who do not have a ventricular paced setting) are subject to artefact (e.g., electrocautery during surgery), which could result in asystole due to oversensing and pacing inhibition if the pacemaker has been set to a non-asynchronous mode. It is never a permanent mode.

OOO is incorrect. This essentially means there is no sensing, no pacing and no response to sensing. It means the pacemaker is turned off.

VAT is incorrect. This mode means the atria are sensed and the ventricles are paced. This is suitable for a patient with a dysfunctional AV node but working atria. For example, in someone with a complete heart block and a normal atrial rate, a VAT pacemaker will sense the atrium and pace the ventricle in response.

Question 159 of 328

A 35-year-old man is investigated for recurrent palpitations associated with pre-syncopal symptoms and dyspnoea. Blood tests are unremarkable and a resting 12 lead ECG is shown below:



Given the likely diagnosis it is decided that radiofrequency ablation is the most appropriate treatment. What part of the heart should be ablated?

A. Sinoatrial node
B. Atrioventricular node
C. Junction of right atrium and right ventricle
D. Left atrial appendage
E. Junction of left atrium and left ventricle

C. Junction of right atrium and right ventricle

The ECG shows a short PR interval associated with a slurred upstroke (delta wave). Note the non-specific ST-T changes which are common in WPW and may be mistaken for ischaemia. The left axis deviation means that this is type B WPW, implying a right-sided pathway.

Question 160 of 328

A 34-year-old male presents to the emergency department with chest tightness worse on inspiration. He informs you that over the past 3 days he has had a low-grade temperature and a degree of myalgia. Prior to all this he had no limitations to his activity and never experienced any chest tightness. He was given glyceryl trinitrate spray and aspirin in the ambulance, neither of which have made any difference.

Examination is unremarkable, however you note that his temperature is 37.4ºC. He is a smoker and he informs you that his father, mother and paternal uncle all have had heart attacks around the age of 60. His bloods are the following:

Hb	165 g/L	Male: (135-180)Female: (115 - 160)
Platelets	537 * 10 /L 9	(150 - 400)
WBC	12.3 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Urea	4.6 mmol/L	(2.0 - 7.0)
Creatinine	93 μmol/L	(55 - 120)
CRP	34 mg/L	(< 5)
Troponin T (0hrs)	586 ng/L	(<14)
Troponin T (3hrs)	615 ng/L	(<14)
D-dimer	Negative	

An ECG is performed indicating sinus rhythm, no intraventricular delay and widespread ST elevations; you also notice was subtle PR depression.

What treatment should be initiated in the case of this gentleman?

A. Arrange urgent angioplasty and potential revascularisation
B. Load patient with aspirin and clopidogrel
C. Load patient with aspirin and ticagrelor
D. Prescribe ibuprofen TDS
E. Prescribe ibuprofen TDS and colchicine BD

E. Prescribe ibuprofen TDS and colchicine BD

First line management of acute pericarditis involves combination of NSAID and colchicine

The history, examination and blood investigations are consistent with acute pericarditis/myopericarditis. The high troponin results indicate myocardial injury which in this case can be attributed to myopericarditis. Troponin is a marker of myocardial injury which can result due to primary ischaemia (plaque rupture or intraluminal coronary artery thrombus), ischaemia secondary to misbalance of supply and demand (tachy/bradyarrhythmias, aortic dissection or severe aortic valve disease, sepsis, severe anaemia or respiratory failure etc.) and myocardial injury not necessarily associated to ischaemia or multifactorial (such as myopericarditis, severe pulmonary embolism with right heart strain, cardiac stunning, cardiac surgery or intervention etc.) There is no strong, dynamic rise in the already high troponin level.

The fact that he is a smoker undeniably puts this gentleman at a higher risk of coronary event, however his blood tests, ECG and history point further to the direction of pericarditis. Given this, options 1, 2 and 3 which are associated with the management of acute coronary syndrome (ACS) are wrong.

The current guidelines as per the European Society of cardiology state that the treatment of choice in such patients is a combination of nonsteroidal anti-inflammatory drugs (e.g. ibuprofen) and colchicine (option 5) and do not advocate the use of a single agent, such as ibuprofen (option 4)

Question 161 of 328

A 55-year-old woman presents to the emergency department with chest pain. She is currently pain free, but has had two similar episodes recently lasting approximately 2-3 minutes. She describes the pain as squeezing and central and feels that the pain is brought on by exertion and relieved within a few minutes by resting. Her father died of a heart attack at 72, she has never smoked and has no significant medical history.

On examination, she is slim, her blood pressure is 125/75 mmHg and heart rate is 85 beats per minute, no murmurs are heard and chest sounds are normal. A 12-lead ECG shows normal sinus rhythm.

serum cholesterol	3.2 mmol/L (<5.2)
serum LDL cholesterol	2.0 mmol/L (<3.36)
serum HDL cholesterol	2.65 mmol/L (>1.55)
fasting serum triglycerides	1.0 mmol/L (0.45-1.69)
haemoglobin	125 g/L (115-165)

What is the next most appropriate investigation?

A. Invasive coronary angiography
B. CT coronary angiography
C. Exercise tolerance test
D. Myocardial perfusion scintigraphy with single photon emissioncomputed tomography
E. Stress echocardiogram

B. CT coronary angiography

Question 162 of 328

A 65-year-old man presents to his general practitioner with exertional chest tightness. This occurs stereotypically after walking approximately 100 meters. It stops when he rests. He has a past medical history of hypertension and asthma. His medications include aspirin, atorvastatin, amlodipine, and a regular inhaler.

The examination is unremarkable. His blood pressure is 154/42 mmHg.

What is the most appropriate choice of medication to control his symptoms?

A. Atenolol
B. Bisoprolol
C. Diltiazem
D. Ramipril
E. Ranolazine

E. Ranolazine

For a patient with symptomatic stable angina on a calcium channel blocker but with a contraindication to a beta-blocker, the next line treatment should be long-acting nitrate, ivabradine, nicorandil or ranolazine

Ranolazine is correct. The patient has symptomatic stable angina. A beta blocker would be an obvious choice to add at this point but is contraindicated in this patient due to their history of asthma. It may precipitate bronchospasm due to the effect on beta-adrenoreceptors. The mechanism of action of ranolazine is largely unknown. Ranolazine may have antianginal effects by inhibition of the late sodium current in cardiac myocytes.

Atenolol is incorrect. Beta-blockers are contraindicated in this patient due to the history of asthma.

Bisoprolol is incorrect. This is another beta-blocker. It is more cardioselective than atenolol but still would not be a prudent choice for a patient with asthma when there are alternatives available.

Diltiazem is incorrect. This is another calcium-channel blocker. It should not be used together with amlodipine, which is also a calcium channel blocker. Diltiazem is a non-dihydropyridine calcium channel blocker while amlodipine is a dihydropyridine calcium channel blocker. Dihydropyridine calcium channel antagonists cause predominantly peripheral vasodilatory actions. Nondihydropyridine CCBs have sinoatrial (SA) and AV node depressant effects with lesser amounts of peripheral vasodilation.

Ramipril is incorrect. This has predominantly anti-hypertensive rather than anti-anginal effects. The blood pressure in this patient is elevated but remains at stage 1 grade. Additionally, we were asked to choose a medication to help his *symptoms* rather than control his blood pressure.

Question 163 of 328

A 16-year-old female presents with a swollen knee. She states that she has had several similar episodes previously. She also complains of excessive bleeding after dental work. She states that her father has a bleeding disorder. On examination her right knee is hot and swollen. A knee aspirate reveals a bloody effusion.

Blood results are as follows:

Hb	110 g/l
Platelets	682 * 10 /l9
Prothrombin time (PT)	12 s (normal 10-13)
activated partial thromboplastin time (aPTT)	54 s (normal 25-36)
Factor VIII level	2% of normal (very low)
Factor IX level	Normal
von Willebrand Factor level	Normal

What disorder does she most likely have?

A. Down syndrome
B. Edwards syndrome
C. Marfan syndrome
D. Ehlers-Danlos syndrome
E. Turner's syndrome

E. Turner's syndrome

Females with Turner's syndrome have just one X chromosome. Therefore they have the same probability of being affected by an X linked recessive disease as males

The patient clearly has haemophilia A as indicated by the prolonged aPTT and severely reduced factor VIII levels. Rare cases of females with severe haemophilia can occur due to extreme lyonization, homozygosity, mosaicism, or Turner syndrome.

Females with Turner's syndrome have just one X chromosome. Thus they have the same probability of being affected by an X linked recessive disease as males. For the aforementioned reason, Turner's syndrome is the most likely underlying diagnosis out of the given options.

Question 164 of 328

A 68-year-old man is referred to the cardiology outpatient department with shortness of breath on exertion. He becomes breathless when ascending stairs. There is no chest pain. He has a past medical history of ischaemic heart disease and heart failure with reduced ejection fraction (30%). He is on aspirin, bisoprolol, ramipril, spironolactone, atorvastatin and lansoprazole. He does not smoke or drink alcohol.

His observations are heart rate 83 beats per minute, blood pressure 110/85 mmHg, respiratory rate 18/minute, oxygen saturations 97% on room air and temperature 37.1ºC.

On examination, he is euvolemic. His heart sounds are normal and there is no peripheral oedema. Chest auscultation is normal. The pulse is regular.

From the options listed, what is the best choice of medication to improve his symptoms?

A. Flecainide
B. Ivabradine
C. Nicorandil
D. Ranolazine
E. Verapamil

B. Ivabradine

Ivabradine should be considered in heart failure if the patient has sinus rhythm > 75/min and a LVEF < 35% and have not responded to to ACE-inhibitor, beta-blocker and aldosterone antagonist therapy

Ivabradine is the correct answer. This man has NYHA class II/III heart failure despite treatment with an ace inhibitor, beta-blocker and mineralocorticoid receptor antagonist. Ivabradine is an option in heart failure for those patients who have not responded to the previously described combination of medications and have a heart rate > 75 beats per minute and an LVEF < 35%.

Nicorandil and ranolazine are incorrect. These medications are options for the treatment of angina, not heart failure.

Flecainide is incorrect. This is a medication used to chemically cardiovert atrial fibrillation. This patient is in sinus rhythm.

Verapamil is incorrect. Negatively inotropic calcium channel blockers should be avoided in heart failure, especially in the context of current beta blocker treatment

Question 165 of 328

A 102-year-old man with a previous history of heart failure, amyloid disease and a permanent pacemaker attends the emergency department due to a syncopal episode. He recalls passing out in his chair whilst watching TV and was attended to by nursing home staff who were able to rouse him after 2 minutes of loss of consciousness. This is the third episode in the past week.

On examination, his heart rate is 32 beats per minute and irregular. He has crepitations in his chest and a raised JVP but no leg oedema. He is alert but cool peripherally. He has no pain at present.

Na +	135 mmol/l
K +	4.5 mmol/l
Urea	5.6 mmol/l
Creatinine	76 µmol/l
ECG	p-waves present with no proceeding QRS, widened QRS complexes seen
Chest xray	chronic lower zone changes, pacemaker leads have a necked appearance

What is the likely diagnosis?

A. Lead fracture
B. Lead displacement
C. Twiddlers syndrome
D. Silent myocardial infarction
E. Progression of cardiomyopathy

A. Lead fracture

Early signs of pacemaker lead failure are a 'necked' appeared on imaging

This gentleman has complete heart block despite a permanent pacemaker in situ. Cardiomyopathy progression and silent myocardial infarction would be detected by progression of congestive cardiac failure with worsening pulmonary or peripheral oedema. The presence of complete heart block suggests that the pacemaker may not be functioning correctly. It is noted that the leads have a necked appearance and this occurs after repeat bending of the leads that causes them to weaken and eventually fracture. This is a rare complication.

Despite being intact on chest x-ray. the necking suggests that the wires are starting to fray and function can be lost prior to a complete fracture of the lead is seen. Twiddling of the wires or lead displacement would be seen on chest x-ray.

Question 166 of 328

A 78-year-old gentleman is seen in clinic with long-standing heart failure with reduced ejection fraction (28%). He has had numerous admissions this year with heart failure decompensation and is wondering if there is anything else that you can do for him. You review his ECG, which is in sinus rhythm with a heart rate of 58/min with a QRS of 98 msec and no signs of intraventricular delay. His blood pressure is: 98/55 mmHg. You also review his bloods:

Hb	129 g/L	Male: (135-180)Female: (115 - 160)
Platelets	335 * 10 /L	(150 - 400)
WBC	6.8* 10 /L	(4.0 - 11.0)
Na	137 mmol/L	(135 - 145)
K	4.7 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	125 µmol/L	(55 - 120)

He is currently on carvedilol 25 mg BD, enalapril 10 mg BD, bumetanide 2 mg BD, aspirin 75 mg, ivabradine 2.5 mg BD, spironolactone 25 mg OD.

What alteration to this gentleman's medications could potentially decrease this gentleman's probability of being re-admitted?

A. Increase ivabradine
B. Add sacubitril/valsartan
C. Increase spironolactone
D. Stop enalapril - initiate sacubitril/valsartan
E. Increase bumetanide

B. Add sacubitril/valsartan

Sacubitril-valsartan should be initiated following ACEi or ARB washout period

This gentleman poses the issue of long-standing management of heartfailure. The ESC guidelines advice strictly on the uptitration of medication up to their maximal desired effect taking in consideration the patient's status - the frontline medications include ACE inhibitors, b-blockers and mineralocorticoid receptor antagonists. The patient is on all three. If the patient remains symptomatic then a good choice would be dependable on their QRS morphology with a CRT-P device being appropriate in certain cases (e.g. QRS >130 msec) or ivabradine in someone with a heart rate of more than 70/min. The option of digoxin is also discussed in the ESC guidelines.

However the patient above is already bradycardic and hypotensive with a slightly raised potassium therefore making the possibility of increasing any of his current medications less appealing. In these patients the possibility of introducing sacubitril/valsartan is appropriate, however it is important for the clinician to be aware of the need for a wash-out period between the ACEi and the initiation of sacubitril/valsartan. The wash-out period advised is that of 36 hours.

The increase in diuretic might appear appealing, there is no evidence that diuretics improve mortality rates in such patients. The PARADIGMHF trial that was comparing sacubitril/valsartan and enalapril indicated that sacubitril/valsartan was superior to enalapril in reducing cardiovascular mortality, heart failure hospitalisation and 30-day hospital readmission in heart failure patients with reduced ejection fraction.

Question 167 of 328

An 80-year-old man with a history of atrial fibrillation is admitted following an acute coronary syndrome and is treated with percutaneous coronary intervention. His medication on admission was warfarin, cocodamol and allopurinol.

With regards to antithrombotic therapy, what should he be prescribed in the immediate aftermath of the event?

A. Continue warfarin with the addition of 2 antiplatelets
B. Continue warfarin with the addition of 1 antiplatelet
C. Continue warfarin monotherapy
D. Stop warfarin, start 2 antiplatelets
E. Stop warfarin, start 3 antiplatelets

A. Continue warfarin with the addition of 2 antiplatelets

In the initial phase following an ACS/PCI patients who also have AF are generally given 2 antiplatelets + 1 anticoagulant

Question 168 of 328

You are working in the general medical clinic where a 42 year old woman comes for review following a recent, short admission to hospital where she was treated for a paracetamol overdose. She has a past history of depression but denies any other previous problems.

During the review, she is found to have a manual blood pressure reading of 165/85 mmHg. Clinical examination of cardiovascular and respiratory systems are normal, as is urine dip and fundoscopy.

Given this information what should be your next course of management in relation to her blood pressure.

A. Start ramipril
B. Offer ambulatory blood pressure monitoring
C. Arrange to check blood pressure again following a two week interval
D. Start amlodipine
E. Screen for causes of secondary hypertension

B. Offer ambulatory blood pressure monitoring

In 2011 the National Institute for Clinical Excellence updated its 2006 guideline for the management of hypertension (see the link below for the quick reference guide). Within this guideline, the first line use of ambulatory blood pressure monitoring (ABPM) to confirm hypertension in those found to have an elevated clinic reading (> 140/90 mmHg) is emphasised. When using ABPM to confirm a diagnosis of hypertension, two measurements per hour are taken during the persons waking hours. The average value of at least 14 measurements are then used to confirm a diagnosis of hypertension.

Generally speaking, secondary causes of hypertension should be sought in; patients under 40 who lack traditional risk factors for essential hypertension, patients with other sings and/or symptoms of secondary causes, and patients with resistant hypertension. Although in reality the most common cause of secondary hypertension is hyperaldosteroneism,

and as such a trial of an aldosterone antagonist such as spironolactone is often employed as both a therapeutic and diagnostic measure.

Drug treatment of essential hypertension can be summarised as follows, but for a more detailed explanation see the link below;

- Step 1; Age <55 - ACE inhibitor. Age >55 or of black African or\Caribbean origin - calcium channel blocker
- Step 2; ACE inhibitor + calcium channel blocker
- Step 3; ACE inhibitor + calcium channel blocker + thiazide-like diuretic
- Step 4; consider further diuretic or beta-blockade or alpha blocker and seeking expert advice

Question 169 of 328

A 24-year-old primigravida presents to the emergency department with a 72-hour history of nausea and vomiting with associated right upper quadrant pain. She as no past medical history of note and takes only pregnancy vitamins. During her 32-week midwife appointment 1 week ago, it was noted that she had gained weight and had borderline hypertension. The decision at that appointment was to monitor.

On examination, she is clinically dehydrated and appears unwell. Respiratory and cardiovascular examinations are unremarkable and abdominal examination demonstrates a gravid uterus and right upper quadrant tenderness. There is pitting oedema to the mid-shin. Observations are all within normal limits aside from a blood pressure of 145/90mmHg. She is alert and orientated, reports no headaches and has no rashes.

Blood tests are performed, results are as demonstrated:

Hb	100 g/L	Male: (135-180)Female: (115 - 160)
Platelets	97 * 10 /L	(150 - 400)
WBC	7.3 * 10 /L	(4.0 - 11.0)
PT	13.0 seconds	(9.5-13.5)
APTT	39.0 seconds	(30-40)
Na	132 mmol/L	(135 - 145)
K	3.4 mmol/L	(3.5 - 5.0)
Bicarbonate	22 mmol/L	(22 - 29)
Urea	7.5 mmol/L	(2.0 - 7.0)
Creatinine	100 µmol/L	(55 - 120)
Bilirubin	45 µmol/L	(3 - 17)
ALP	150 u/L	(30 - 100)
ALT	350 u/L	(3 - 40)
Albumin	34 g/L	(35 - 50)

An ultrasound abdomen shows patchy areas of hepatic enhanced echogenicity. Fetal monitoring is satisfactory, but the baby is in the breech position.

Given the likely diagnosis, what is the most appropriate management?

A. Commence IV antibiotics
B. Give steroids and organise an induction of labour
C. Organise a plasma exchange with fresh frozen plasma
D. Rehydrate with IV fluids and monitor
E. Give steroids and organise a caesarean section within 48 hours

A. Give steroids and organise a caesarean section within 48 hours

Delivery of the baby is the treatment of HELLP syndrome

This patient has HELLP syndrome as shown by her anaemia (secondary to haemolysis), thrombocytopenia and deranged LFTs. She is 33 weeks pregnant and thus steroids would be recommended prior to delivery if possible to aid the maturation of her child's lungs. She does not have any evidence of a liver haematoma, disseminated intravascular coagulation or haemodynamic instability and thus she does not need an immediate delivery at this stage. Induction of labour would not be appropriate as her child is breech.

Differentials would include cholecystitis and thrombotic thrombocytopenic purpura (TTP).

IV antibiotics would be appropriate in the treatment of cholecystitis, but this patient has no features of infection, going against a diagnosis of cholecystitis.

Plasma exchange with fresh frozen plasma would be the recommended treatment for TTP, however, TTP would typically present with neurological symptoms such as confusion, headaches, and seizures in severe cases, which our patient does not have.

Question 170 of 328

A 24-year-old female presents to clinic complaining of several episodes of heart palpitations. She states that during the attacks it feels like her heart skips a bit. She denies pre-syncope or syncope. She states that she has one episode every few days. She drinks approximately 28 units of alcohol per week and several cups of coffee per day.

You arrange a 7 day cardiac holter monitor. The results are as follows:

PR interval	100ms
QRS duration	110ms
Events	24 single ectopics with normal P wave morphology and a QRS of110ms

What is the most appropriate initial management plan?

A. Bisoprolol
B. Ablation
C. Reassurance and lifestyle modifications
D. Implantable Cardioverter Defibrillator (ICD)
E. Verapamil

C. Reassurance and lifestyle modifications

Patients with ventricular ectopics can usually be managed by reassurance and lifestyle modifications. If pharmacological management is required, then beta blockers are first line

The ectopics captured have normal P wave and QRS duration suggestive of supraventricular ectopics of sinus or atrial origin. The first line management of supraventricular ectopics is generally reassurance and lifestyle modifications. The patient should be advised to reduce alcohol and caffeine intake. If symptoms persisted then a beta blocker would be first line.

Question 171 of 328

A 74-year-old man attends the emergency department with epistaxis. He denies any other bleeding. He has a past medical history of atrial fibrillation and severe mitral stenosis for which he takes warfarin. Observations are as follows: heart rate 85 beats per minute, blood pressure 135/75 mmHg, respiratory rate 16 breaths per minute, SpO2 95% (on air), and temperature 37.5ºC.

Blood results are as follows:

Hb	140 g/L	Male: (135-180)Female: (115 - 160)
Platelets	88 * 10 /L 9	(150 - 400)
WBC	6.2 * 10 /L 9	(4.0 - 11.0)
Prothrombin time (PT)	96 secs	(10-14 secs)
INR	6.8	(<1.1)
Activated partial thromboplastin time (APTT)	44 secs	(25-35 secs)
Fibrinogen	3.2 g/L	(2 - 4)

You withhold the patient's warfarin. What further measures are required?

A. Fresh frozen plasma
B. Intravenous 10mg vitamin K
C. Intravenous 3mg vitamin K
D. Platelet transfusion
E. Prothrombin complex concentrate

C. Intravenous 3mg vitamin K

NR 5.0-8.0 (minor bleeding) - stop warfarin, give intravenous vitamin K 1-3mg, restart when INR < 5.0

The results of the coagulation screen suggest warfarin toxicity. The INR (derived from the PT) is used to monitor warfarin since it is the most representative, however, it is important to remember that warfarin can also prolong the APTT.

Intravenous 3mg vitamin K is correct. The patient has a minor bleed with an INR between 5.0 - 8.0. Thus the warfarin should be withheld and the patient should receive intravenous vitamin K 1-3mg. The warfarin should be restarted when the INR < 5.0

Fresh frozen plasma is incorrect. Fresh frozen plasma (FFP) is not recommended for use as a warfarin reversal agent as it can take hours to work due to the volume required. In major haemorrhages, FFP should only be given if prothrombin complex concentrate is not available.

Intravenous 10mg vitamin K is incorrect. For minor haemorrhage, the dose of intravenous vitamin K recommended is 1-3mg.

Platelet transfusion is incorrect. In the context of haemorrhage, a platelet level of <50 is the standard trigger, with the exclusion of CNS or posterior eye bleeds in which the transfusion trigger is <100.

Prothrombin complex concentrate is incorrect. Prothrombin complex concentrate (PCC) is recommended only for major bleeding. PCC will reverse anticoagulation within minutes of administration however administration of vitamin K is also required to counteract the long halflife of warfarin.

Question 172 of 328

You are asked to chase up the INR result for a patient. The patient is currently admitted and being treated for a lower respiratory tract infection with clarithromycin. They take warfarin due to atrial fibrillation. The INR result is returned as below:

INR	6.8	(<1.5)

You review the patient who looks well, though they report persistent oozing of blood from where their cannula had been removed earlier that day. The gauze dressing has required changing 4 times.

What is the most appropriate course of action?

A. Hold warfarin and administer IV vitamin K

B. Hold warfarin and administer IV vitamin K and humanprothrombin complex
C. Hold warfarin and administer oral vitamin K
D. Hold warfarin and repeat INR the next day
E. Re-prescribe warfarin at a lower dose

A. Hold warfarin and administer IV vitamin K

INR 5.0-8.0 (minor bleeding) - stop warfarin, give intravenous vitamin K 1-3mg, restart when INR < 5.0

In this case, we have a patient with a raised INR which is likely secondary to clarithromycin use. The patient also has some minor bleeding as indicated by persistent ooze from a wound site.

Hold warfarin and administer IV vitamin K is correct. 1-3mg of IV vitamin K should be administered to this patient with minor bleeding and an INR of 5.0-8.0 as per NICE guidelines.

Hold warfarin and administer IV vitamin K and human prothrombin complex is incorrect. Human prothrombin complex should be administered in the case of major bleeding, fresh frozen plasma can be used as an alternative if human prothrombin complex is not available. As this patient is only having minimal bleeding, the use of human prothrombin complex is not recommended.

Hold warfarin and administer oral vitamin K is incorrect. This would be appropriate if the patient had no evidence of bleeding at all with an INR of >8.0. In this case, the INR is between 5.0 and 8.0 and associated with minor bleeding, intravenous vitamin K would therefore be more appropriate.

Hold warfarin and repeat INR the next day is incorrect. This would be appropriate if the INR was between 5.0 and 8.0 without any bleeding, you would then also want to reduce the maintenance dose. In this case, because there is evidence of bleeding, a dose of IV vitamin K is recommended.

Re-prescribe warfarin at a lower dose is not correct. This patient has a raised INR in the context of minor bleeding, the warfarin needs to be held and reversed in view of this.

Question 173 of 328

A 26-year-old patient comes into the Emergency Department in cardiac arrest. The paramedics tell you that she was pulled out of a lake by friends after she had suddenly become unresponsive while swimming. Her friends started cardiopulmonary resuscitation (CPR) at the scene. On arrival, the paramedics noted that the patient was in Ventricular Fibrillation (VF). The patient was defibrillated, given IV amiodarone and adrenaline. Her friends tell you she has no significant past medical history and was always fit and well until this point.

Despite continued attempts to resuscitate the patient, she dies in the Emergency Department. A post-mortem is carried out which is normal.

What is the most likely diagnosis?

A. Hypertrophic Obstructive Cardiomyopathy (HOCM)
B. Long QT1 Syndrome
C. Long QT3 Syndrome
D. Right Arrhythmogenic Ventricular Dysplasia (RAVD)
E. Wolf-Parkinson White Syndrome

B. Long QT1 Syndrome

All of these differentials can result in sudden cardiac death in a young patient. However, you have been told here that the patient's postmortem was normal which makes HOCM and RAVD unlikely.

This leaves Long QT1 Syndrome, Long QT3 Syndrome and WolfParkinson-White as possible differentials. The big clue here is that the patient became unresponsive when swimming which is typical of Long QT1 Syndrome.

Long QT syndromes can result in sudden cardiac death when patients are exposed to an adrenergic surge which can put the patient into VF or VT.

Long QT1: adrenergic surge due to intense physical activity such as swimming

Long QT2: adrenergic surge due to intense emotion such as excitement or fear

Long QT3: death during sleep

Question 174 of 328

You are asked to review a 22-year-old female with a heart murmur. Her height is 4ft 7 inches and she reports having always been short for her year. She has been diagnosed with autoimmune hypothyroidism, for which she is taking levothyroxine replacement and is also taking 'hormone replacement to protect her bones' after her GP noted she had not started her periods by 19 years old.

On examination, you note short 4th metacarpals on both hands and lymphoedematous in her hands and feet. Auscultation of her precordium reveals an ejection systolic murmur at the left infraclavicular region. Her body mass index is 22.4 kg/m². The patient's blood tests are as follows:

Hb	123 g/l
Platelets	380 * 10 /l9
WBC	6.5 * 10 /l9
Na +	144 mmol/l
K +	4.8 mmol/l
Urea	7.2 mmol/l
Creatinine	110 µmol/l
Adjusted calcium	2.40 mmol/l
Phosphate	1.1 mmol/l
PTH	9 mg/dl (8.5-10.2mg/dl)

What is the underlying unifying diagnosis?

A. Turner's syndrome
B. Pseudohypoparathyroidism
C. Pseudopseudohypoparathyroidism
D. Noonan syndrome
E. Down's syndrome

A. Turner's syndrome

A syndromic presentation appears most likely in this patient. An acute infective endocarditis is unlikely for someone who is systemically well, a regurgitant murmur would also be more likely. The symptoms cannot be attributed to delayed puberty, defined as onset of puberty outside 95% of the normal population and typically before 18 years old. The combination of primary amenorrhoea, short stature, lymphoedema, shortened 4th metacarpal, autoimmune predisposition and an ejection systolic murmur suggestive of aortic coarctation should infer a diagnosis of Turner's syndrome, a disorder caused by loss of an X chromosome.

Noonan syndrome, an autosomal dominant disorder, is a reasonable differential in a patient with short stature, lymphoedema and cardiac problems. However, patients with Noonan syndrome typically presents with learning difficulties, facial dysmorphisms and webbed neck. While valvular abnormalities are less common, hypertrophic cardiomyopathy is more commonly present.

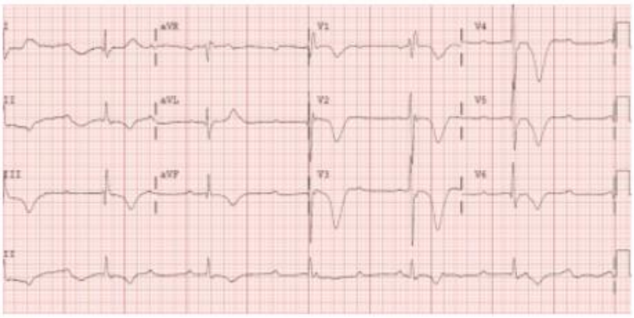
Similar to Noonan syndrome, Down's syndrome, caused by trisomy 21, also classically presents with facial dysmorphisms such as upslanting palpebral fissures, low-set ears and epicanthic folds. Cognitive impairment and learning difficulties are also common. However, similar to our patient, short stature, thyroid dysfunction and cardiac problems, predominantly ASD, VSD and PDA are frequently associated.

Pseudohypoparathyroidism is caused by normal parathyroid hormone release but end organ resistance to hormonal effects, resulting classically in round facies and shortened fourth and fifth metacarpals. The patient is commonly obese with possible learning difficulties.

Pseudopseudohypoparathyroidism presents with the phenotype of pseudohypoparathyroidism but with normal calcium chemistry.

Question 175 of 328

A 56-year-old man is brought to the Emergency Department. He works as a window cleaner. His colleague describes him suddenly falling from the ladder without warning. On admission he is conscious with a bradycardia of around 36/min. His blood pressure is 110/62 mmHg and he is well perfused with no signs of heart failure. An ECG is taken on account of his bradycardia:



A previous ECG taken four months ago was completely normal.

What is the most likely diagnosis?

A. Sick sinus syndrome
B. Stokes-Adams attack with associated complete heart block
C. Myocardial infarction with new left bundle branch block
D. Second-degree atrioventricular block (Mobitz II)
E. Second-degree atrioventricular block (Mobitz I / Wenckebach)

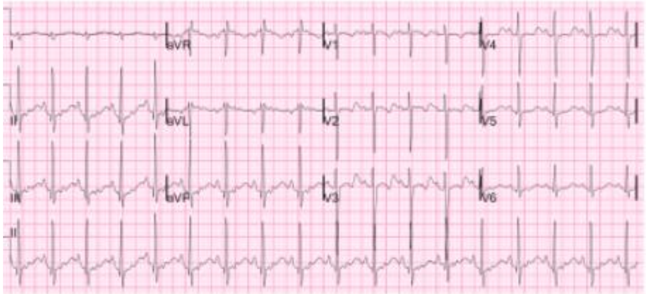
B. Stokes-Adams attack with associated complete heart block

There are regular p waves at a rate of around 90 / min but they do not conduct. The ventricular escape rhythm has a rate of about 36 / min and has a right bundle branch block (RBBB) like morphology. The bizarre, wide, inverted T-waves can be seen in Stokes-Adams attacks and do not necessarily imply new ischaemia.

Question 176 of 328

A 22-year-old woman presents to the emergency department with syncope. She also states that he has had profuse vomiting and diarrhoea for the last 3 days. Observations are as follows: heart rate 100 bpm, blood pressure 100/60 mmHg, respiratory rate 18 breaths per minute, SpO2 98% on air, temperature 37.2 ºC.

An ECG is performed in the department:



What is the likely cause of this ECG abnormality?

A. Arrhythmogenic right ventricular dysplasia (ARVD)
B. Hyperkalaemia
C. Hypokalaemia
D. Hypothermia
E. Wolff-Parkinson-White syndrome

C. Hypokalaemia

The ECG demonstrates sinus rhythm with a rate of approximately 100 beats per minute. There are prominent U waves following the T wave.

Hypokalaemia is correct. The electrocardiographic features are most in keeping with hypokalaemia. U waves are present and classic of hypokalemia, however, it is important to remember that they can be present in other conditions (e.g. bradycardia, hypocalcaemia, hypomagnesaemia, hypothermia and raised intracranial pressure). Other ECG features of hypokalaemia include small or absent T waves (occasionally inversion), prolonged PR interval, ST depression, and long QTc.

Arrhythmogenic right ventricular dysplasia (ARVD) is incorrect. ARVD is characterised by an epsilon wave which is a small deflection buried at the end of the QRS complex usually best seen in the ST segment of V1 and V2.

Hyperkalaemia is incorrect. ECG features of hyperkalaemia include peaked T waves, P wave widening/flattening, PR prolongation, bradyarrhythmias, and QRS widening with bizarre QRS morphology.

Hypothermia is incorrect. Hypothermia classically presents with sinus bradycardia and Osborn waves (J wave) defined as positive deflection seen at the J point in precordial and true limb leads. Osborn waves are characteristically seen in hypothermia, however, they are not pathognomonic and can be seen in other conditions such as hypercalcaemia and myocarditis.

Wolff-Parkinson-White syndrome is incorrect. This condition is associated with a short PR interval (< 120ms), broad QRS (> 100ms), and a slurred upstroke to the QRS complex (the delta wave).

Question 177 of 328

A 19-year-old woman presents to the acute medical take with three days of acute shortness of breath. She initially had a dry cough and sore throat but became increasingly lethargic. She is usually fit and well and is fully vaccinated. She is taking the combined oral contraceptive pill. On examination, she had bibasal crepitations with dullness to percussion at the bases. Her observations show a respiratory rate of 25 breaths per minute, heart rate 105 beats per minute and saturations of 96% maintained on 60% venturi mask. Her JVP is seen at 5 cm above her sternal angle and there are no murmurs.

Na +	130 mmol/l
K +	4.9 mmol/l
Urea	5.6 mmol/l
Creatinine	90 µmol/l
Troponin	20,000 ng/ml (normal range <20)
ECG	ST elevation seen in V1-V4

What is the most likely diagnosis?

A. Myocarditis
B. Myxoedema coma
C. Nephrotic syndrome
D. Myocardial infarction
E. Takotsubo cardiomyopathy

A. Myocarditis

Myocarditis presents with ST elevation and acute pulmonary oedema in a young patient with a recent flu-like illness

Bibasal crepitations and a raised JVP show acute heart failure. She has no chest pain making an acute myocardial infarction unlikely and there is no recent emotional distress as would be in Takotsubo cardiomyopathy. Given her recent viral illness, this is the most likely cause of her sudden deterioration in someone who was formerly well. Nephrotic syndrome and myxoedema coma would not have ST elevation.

Question 178 of 328

A 58-year-old woman was admitted with a stroke following a month's history of recurrent fevers, anorexia and weight loss. On examination, she had a left-sided hemiparesis and facial droop. Cardiovascular examination revealed splinter haemorrhages in 5 of her fingers across both hands, and a soft diastolic murmur heard loudest in expiration over the aortic area.

A trans-thoracic echocardiogram showed an oscillating vegetation on an aortic leaflet, in the path of regurgitant jets. Two blood cultures were positive for Streptococci spp. She was diagnosed with infective endocarditis and started on intravenous benzylpenicillin 1.2g every 4 hours and gentamicin 1mg/kg twice daily therapy.

She was reviewed after 5 days on antibiotic therapy with the following results.

Na+	139 mmol/l
K+	4.7 mmol/l
Urea	14.2 mmol/l
Creatinine	178 µmol/l
Serum bilirubin	16 µmol/l
Serum alkaline phosphatase	115 IU/l
Serum aspartate aminotransferase	18 IU/l
C Reactive protein	89 mg/l
Haemoglobin	138 g/l
White cell count	13.6 x 10^9/L
INR	1.1
Blood cultures	Streptococcus Bovis
Penicillin Minimum Inhibitory Concentration (MIC)	0.6 mg/L (high)
ECG	Prolonged PR interval (not present on admission ECG)

What is the next most important management?

A. Increase antibiotics to intravenous benzylpenicillin 2.4g every 4 hours and gentamicin 1mg/kg twice daily
B. Organise an urgent colonoscopy
C. Switch antibiotics to ceftriaxone 2g once daily
D. Refer to cardiothoracic surgeons
E. Organise urgent trans-oesophageal echocardiogram

E. Refer to cardiothoracic surgeons

This patient has infective endocarditis, as diagnosed by two positive major criteria from the Duke's criteria for infective endocarditis. In addition, she has a number of minor criteria, including fever, vascular events (stroke), immunological events (splinter haemorrhages, renal impairment secondary to glomerulonephritis). Despite starting on appropriate empirical treatment she appears to have an ongoing infection from her blood tests, and her ECG demonstrates a prolonged PR interval which may be reflective of an enlarging aortic abscess disrupting the atrioventricular node, which is an indication for referral for cardiothoracic surgery in infective endocarditis.

Other surgical indications include

- Heart failure: valve obstruction resulting in pulmonary oedema or shock, severe acute regurgitation
- Uncontrolled infection: abscess, false aneurysm, persisting fever and positive blood cultures for greater than 10 days despite appropriate antibiotics, multiresistant microorganisms
- Prevention of embolism: large vegetations resulting in one or more embolic episodes despite appropriate antibiotic therapy, or other predictors of complications eg. heart failure.

She has a penicillin-resistant streptococci, according to the British Society of Antimicrobial Chemotherapy guidelines, should be treated with vancomycin and gentamicin, so options (a) and (c) are incorrect. *Streptococcus Bovis* bacteraemia is associated with bowel malignancy, and a colonoscopy should be arranged to rule out malignancy, however, the worsening PR prolongation takes priority and should be managed first.

An urgent trans-oesophageal echocardiogram may be useful to evaluate the size of the aortic abscess, however, it would not change management as this patient needs to be referred to the cardiothoracic surgeons as there is already evidence of enlarging vegetation.

Question 179 of 328

A 75-year-old man is an inpatient on the orthopaedic ward recovering from an elective knee replacement performed three days previously. The patient's immediate post-operative recovery had been unremarkable and he had begun to mobilise with the ward physiotherapist. Routine observations recorded on the ward had been unremarkable during the previous 24 hours.

During her drug round, the patient's nurse saw the patient suddenly become unable to breathe and clutch at his chest. After calling for help the nurse went to her patient and found him to be in cardiac arrest. Resuscitations attempts were initiated following advanced life-support protocol. Please see the below table for a summary of the patient's electrical rhythm and treatments administered during the initial phases of the resuscitation attempt.

The patient was noted to be in good physical health with his only comorbidity being hypertension, well controlled with medication. The patient's admission clerking recorded that he was a retired schoolteacher who lived independently at home with his wife. A review of the patient's drug chart indicated that he had been receiving subcutaneous enoxaparin as prophylaxis against venous thromboembolism, but that the patient had refused to wear compression stockings during his admission as he found them uncomfortable.

Number of rhythm check	Result of rhythm check	Treatment administered
1	Pulseless electrical activity	IV adrenaline 1 mg
2	Ventricular fibrillation (coarse)	DC shock 150 J
3	Ventricular fibrillation	???

In addition to a further DC shock, what is the appropriate choice of IV drug treatment following the third rhythm check?

F. IV adrenaline 1 mg
G. IV atropine 400 micrograms & IV amiodarone 300 mg
H. No IV drug treatment indicated
I. IV adrenaline 1 mg & IV amiodarone 300 mg
J. IV atropine 400 micrograms

A. IV adrenaline 1 mg

The advanced life support algorithm for pulseless electrical activity (PEA) and asystole requires adrenaline to be given immediately and then continued every 3 to 5 minutes (in practice, after every second rhythm check). By contrast, the algorithm for ventricular fibrillation and ventricular tachycardia (VF / VT) requires IV adrenaline to not be given until after the third shock and then continued every 3 to 5 minutes.

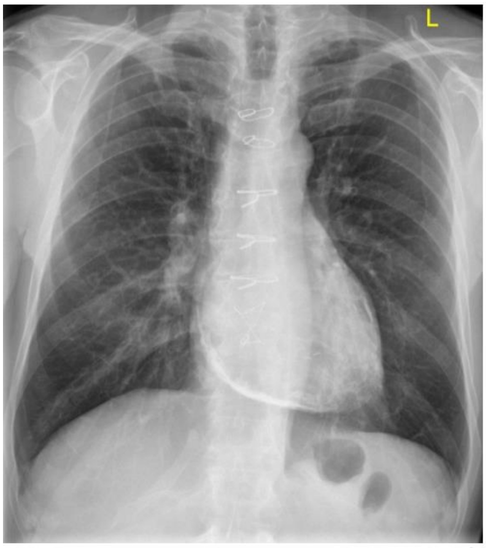
However, once adrenaline has been given during a resuscitation attempt it should be given every 3-5 minutes even if the type of rhythm changes from PEA/asystole to VF / VT, even if this is only the second cycle of the rhythm being VF / VT (as in the example in the question).

As part of the VF / VT algorithm, IV amiodarone 300 mg should be given after three defibrillation attempts. A further dose of IV amiodarone 150 mg should be considered after a total of five defibrillation attempts. Atropine is not used as part of the advanced life-support algorithm.

Question 180 of 328

A 60-year-old man is admitted to the Emergency Department with acute dyspnoea. He is unable to give a full history and his notes are not yet available.

His chest x-ray is shown below:



What is the most likely explanation for these changes seen over the heart?

A. Left ventricular aneurysm
B. Sarcoidosis
C. Atrial myxoma
D. Primary hyperparathyroidism
E. Previous episodes of uraemia

E. Previous episodes of uraemia

Pericardial calcification most commonly develops following repeated episodes of acute pericarditis. Calcification of the pericardium often results in constrictive pericarditis.

Question 181 of 328

A 19-year-old female presents to the medical outpatient with a history of palpitations. She suffers from bouts of anxiety and dizziness associated with these palpitations and has had one episode of syncope. She has had bouts of atrial fibrillation in the past, although documentary evidence is not available.

On examination, her blood pressure is 125/85 mmHg and her pulse is 140 bpm.

Her ECG reveals a broad complex regular tachycardia with a short PR interval and a slurred upstroke of the QRS complex. There is additionally a tall R wave in V1.

Which of the following would be the most appropriate initial step in medical management?

A. IV adenosine
B. IV verapamil
C. IV digoxin
D. IV propranolol
E. IV procainamide

E. IV procainamide

The description of the ECG given is that of WPW syndrome, a form of Atrio-Ventricular Reciprocating Tachycardia that results from conduction over an accessory pathway.

There are two types of WPW syndrome, Type A and Type B.

In case of type A (left atrioventricular connections), a positive R wave will be seen in V1 ('positive delta') on the precordial leads of the electrocardiogram,

In type B (right atrioventricular connections), a predominantly negative

delta wave will be seen in lead V1 ('negative delta').

The treatment of choice in the long term management is radiofrequency catheter ablation of the accessory pathway.

Care must be taken in the use of AV nodal blocking agents, especially when the tachycardia is broad complex, since these may paradoxically increase the conduction over the accessory pathway and lead to a 1:1 atrioventricular conduction which may result in ventricular fibrillation.

A simple mnemonic to remember for drugs to avoid in WPW syndrome is ABCD (Adenosine, -Blockers, Calcium Channel Blockers, Digoxin).

Question 182 of 328

A 58-year-old man is admitted with chest pain and shortness of breath. His breathlessness is worsening and he has a new oxygen requirement. His past medical history includes metastatic melanoma, hypertension and diabetes mellitus. He had surgical removal of the original melanoma lesion but now has extensive metastases. He has been seen regularly by the palliative care team as his pain has been very difficult to manage.

His pulse is regular on examination and chest sounds clear on auscultation. His ECG shows sinus rhythm with a rate of 61bpm and QTC is 455ms. His chest x-ray demonstrates clear lung fields. The results of his blood tests are shown below:

Hb	115 g/L	(135-180)
Platelets	451 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Na +	142 mmol/L	(135 - 145)
K +	3.7 mmol/L	(3.5 - 5.0)
Urea	9.6 mmol/L	(2.0 - 7.0)
Creatinine	133 µmol/L	(55 - 120)
CRP	9 mg/L	(< 5)

Which of the following may account for his ECG findings?

A. Digoxin
B. Cyclizine
C. Bisoprolol
D. Amlodipine
E. Methadone

E. Methadone

Methadone is a common cause of QT prolongation

This man's ECG shows a prolonged QT interval at 455ms (normal for a male is <430ms).

Methadone is not a drug commonly used but can be used by the palliative care team for patients who are intolerant of opioids and their pain is unmanageable. One of the side effects of methadone is that it prolongs the QT interval and so is the correct answer.

Digoxin is used in the management of atrial fibrillation. Digoxin toxicity is associated with the 'reverse tick' ST morphology change.

Anti-emetics such as ondansetron, not cyclizine are associated with a prolonged QT interval.

Bisoprolol can be associated with bradycardia and atrioventricular block.

Amlodipine may cause palpitations and tachycardia but has no effect on the QT interval.

Question 183 of 328

A 67-year-old male presents with increasing chest pain on exertion over the past 3 weeks, stopping him from going to work. His past medical history includes hypertension, type 2 diabetes mellitus, sick sinus syndrome, recent abstinence from alcohol after a history of excess (with an episode of acute liver decompensation 9 months ago) and stable angina. He previously tried isosorbide mononitrate but reported significant headaches and facial flushing. He has not previously suffered myocardial infarctions, with a recent echo demonstrating 70% ejection fraction. An ECG demonstrates first-degree heart block with normal QRS complexes at 50 beats/ minute, blood pressure is 140/76 mmHg. He currently takes bisoprolol 5mg OD alone and has been using his GTN spray with increasing frequency without effect.

What is the most appropriate next step in management?

A. Reperfusion therapy with coronary artery bypass graft or percutaneous coronary intervention
B. Ranolazine
C. Ivabradine
D. Diltiazem
E. Nicorandil

Not answered

Question 184 of 328

A 73-year-old man presents to the medical take with a 3-month history of thoracic back pain. Over the last week, he had been having episodes of sweats and shivers, particularly at night.

He was admitted and blood tests were taken.

Haemoglobin	87 g/L
White cells	11.6x10^9/L
Platelets	214 x10^9/L
MCV	70 fl
MCH	20 pg
Blood cultures	Streptococcus gallolyticus

MRI showed a discitis at thoracic disks 8/9. ECHO: No vegetation seen

What is the next investigation for this patient?

A. Colonoscopy
B. CT chest/abdomen/pelvis
C. Ultrasound abdomen/pelvis
D. Repeat blood cultures

E. PET scan

A. Colonoscopy

Streptococcus bovis endocarditis is associated with colorectal cancer

Streptococcus gallolyticus is a subtype of *Streptococcus bovis*. *Streptococcus bovis* bacteraemia is associated with underlying colonic malignancies in approximately 10 to 25 percent of patients, therefore, all patients presenting with this should be investigated for rectal cancer. The gold standard investigation is a colonoscopy.

If a malignancy was found on colonoscopy then a CT chest/abdomen/pelvis would be warranted to look for metastases, but it would not be as sensitive as a colonoscopy to look for colonic malignancies. An ultrasound of the abdomen would also be less sensitive to diagnose colonic malignancies than a colonoscopy.

A CT-PET scan may well show a malignancy in the colon, but the patient must be exposed to radioactive dye and radiation, therefore is not the first line investigation.

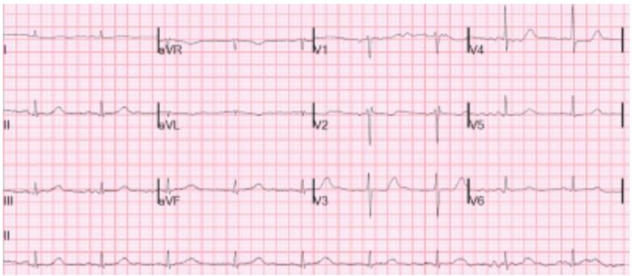
Repeat blood cultures would be useful when determining the length of treatment needed for this patient, however, they would not aid in the discovery of the underlying diagnosis.

Question 185 of 328

A 26-year-old woman presents to the emergency department with generalised weakness. She has a past medical history of type 1 diabetes mellitus and reports having been vomiting repeatedly over the past 4 days and cannot keep any food or liquids down. There is no history of fever or diarrhoea.

On examination, she appears lethargic with dry mucous membranes. Chest sounds are clear and heart sounds are normal. Her abdomen is soft with generalised tenderness mostly within the epigastric region.

Her blood glucose is recorded as 7.4 mmol/L. An ECG is taken on arrival at the emergency department, as shown below:



What is the recommended initial management for this patient?

A. Intravenous 0.9% sodium chloride with 40 mmol potassium
B. Intravenous 1.26% sodium bicarbonate
C. Intravenous calcium gluconate
D. Intravenous magnesium sulphate
E. Warmed intravenous 0.9% sodium chloride

A. Intravenous 0.9% sodium chloride with 40 mmol potassium

This patient's ECG shows U waves that are most noticeable in leads V2 and V3. U waves are small positive deflections that appear shortly after a T wave and frequently represent hypokalaemia. There is also a prolonged QTc interval (> 440ms). Other features of severe hypokalaemia include increased P wave amplitude, PR interval prolongation and T wave flattening.

Intravenous 0.9% sodium chloride with 40 mmol potassium is correct. There are several causes of U waves including hypothermia, bradycardia, hypocalcaemia, hypomagnesaemia and severe hypokalaemia. There are also multiple causes of a prolonged QTc interval including hypokalaemia, hypomagnesaemia, hypocalcaemia and hypothermia. Given the presentation of prolonged vomiting in a patient with type 1 diabetes (likely representing gastroparesis), this patient is at high risk for having hypokalaemia. The clinical history and ECG are suggestive of hypokalaemia and therefore intravenous potassium replacement is necessary.

Intravenous 1.26% sodium bicarbonate is incorrect. Sodium bicarbonate 1.26% can be administered in instances of metabolic acidosis and certain arrhythmias (eg broad complex tachycardia associated with salicylate overdose). It is not indicated for this patient.

Intravenous calcium gluconate is indicated for severe hypocalcaemia and hyperkalaemia with ECG changes such as tall tented T waves, QRS widening and flattened P waves. Although hypocalcaemia can cause a prolonged QTc interval which is seen here, it is a less common cause of U waves making calcium gluconate a less appropriate drug to administer.

Intravenous magnesium sulphate is given in the management of acute arrhythmias including atrial fibrillation and Torsades de Pointes (a monomorphic ventricular tachycardia associated with QTc prolongation). Although hypomagnesaemia can cause QTc prolongation, it is a less common cause of U waves in comparison to hypokalaemia, making potassium replacement the most appropriate initial management. However, it is important to remember that a normal magnesium level is required for the maintenance of a potassium level within the normal range and, therefore, replacement may also be necessary.

Warmed intravenous 0.9% sodium chloride is incorrect. Hypothermia is a less common cause of U waves and QTc prolongation and more commonly produces J waves which are not seen here. Secondly, there is no indication from the clinical presentation that this patient is hypothermic.

Question 186 of 328

A 67-year-old gentleman is brought to the resuscitation area of the Emergency Department after an out of hospital cardiac arrest. The paramedics are performing CPR and a laryngeal mask airway in place for ventilation. They inform you that the patient is in asystole and they have already administered IV adrenaline. On the next rhythm check you notice some P-waves on the monitor.

Which of the following is the best management option?

A. answer300mg IV amiodarone
B. IV fluid bolus
C. External pacing
D. Defibrillation
E. 3mg IV atropine

C. External pacing

This patient is in P-wave systole, a special case which does not follow the main cardiac arrest algorithm. In this scenario, external pacing can result in a return of spontaneous circulation.

Atropine is no longer used in any rhythm associated with cardiac arrest, while amiodarone and defibrillation are part of the shockable rhythm protocol. IV fluid bolus is recommended in cardiac arrest where hypovolaemia is suspected as an underlying cause, however, in this scenario, external pacing is more likely to result in the return of spontaneous circulation.

Question 187 of 328

A 80-year-old man with a past medical history of gout, reflux and ischaemic heart disease is admitted to the emergency department with a atrial fibrillation with fast ventricular response. He is managed according to ALS protocol and is stabilised.

A full set of bloods are sent and are displayed below:

Hb	135 g/l
Platelets	260 * 10 /l9
WBC	6 * 10 /l9
Mg	0.34 µmol/l
Ca (adj)	2.1 u/l
PO4	0.8 u/l

This is discussed with the cardiology registrar, who advises correction of the magnesium.

What medication is the most likely cause of hypomagnesaemia in this case?

A. Aspirin
B. Omeprazole
C. Ranitidine
D. Colchicine
E. Ramipril

B. Omeprazole

Careful electrolyte balance is important in the management of arrhythmias. During the generation of the action potential in cardiac pacemaker cells, phase 4 (inflow of potassium) is dependant on magnesium channels, and, although the exact effect in vivo of magnesium administration is unclear, restoring normomagnesaemia is important in patient presenting with dysrhythmias.

PPI use is associated with hypomagnesaemia - the exact mechanism of this is not known, but may be related to poorer intestinal absorption from dietary sources in patients on PPIs.

Question 188 of 328

A 66-year-old man was admitted from the community with an anterior STEMI to the local district general hospital. He complained of severe chest pain before his wife rang for help. She noted he was clammy and sweaty. About five minutes after being transferred into the emergency department a nurse observed that the patient looked unwell, appeared grey and poorly responsive, . The nurse put out a peri-arrest call.The cardiac monitor showed a broad complex tachycardia. His femoral pulse was faintly palpable and his blood pressure was 76/36 mmHg.

What should be the carried out immediately ?

A. Start CPR
B. IV fluids
C. DC cardioversion
D. IV amiodarone
E. Transfer to tertiary center for immediate PCI

C. DC cardioversion

DC cardioversion should be given to a patient presenting with ventricular tachycardia with haemodynamic compromise

The answer is immediate DC cardioversion for a patient with ventricular tachycardia presenting with haemodynamic compromise. If the patient was stable, amiodarone and magnesium could be considered. It is important to check the electrolytes. Ideally, the patient needs PCI but must be stable before transfer can take place. There is no role for CPR as this is not a cardiac arrest situation.

Question 189 of 328

A 51-year-old man is referred to the cardiology clinic by his GP.

He complains of a 1-year history of exertional breathlessness. He also feels breathless when lying flat.

He has a past medical history of hypertension, chronic kidney disease, and atrial fibrillation and is prescribed ramipril, bisoprolol, and apixaban.

On examination, his pulse is 70bpm and his blood pressure is 134/92mmHg. He has coarse crackles at both lung bases.

His blood tests are shown below:

Hb	141 g/L	Male: (135-180)Female: (115 - 160)
Platelets	177* 10 /L 9	(150 - 400)
WBC	6.7 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	5.5 mmol/L	(3.5 - 5.0)
Urea	12.9 mmol/L	(2.0 - 7.0)
Creatinine	188 µmol/L	(55 - 120)

The echocardiogram shows:

Summary: Left ventricular systolic function is moderately impaired. The ejection fraction is visually estimated at ~40%.

Regular furosemide is started.

What additional medication should be prescribed?

A. Amlodipine
B. Dapagliflozin
C. Ivabradine
D. Sacubitril and valsartan
E. Spironolactone

B. Dapagliflozin

SGLT-2 inhibitors should be considered as second-line therapy in patients with HFrEF in addition to optimised standard care

Dapagliflozin is correct. This patient has evidence of heart failure with reduced ejection fraction on his echocardiogram. The first-line treatment would be an ACE inhibitor and a beta blocker, but this patient already takes both of these agents. The second-line treatment is usually an aldosterone antagonist such as spironolactone, which can then be complemented with an SGLT2 inhibitor such as dapagliflozin to reduce mortality further. Given that this patient is already hyperkalaemic, spironolactone would be an inappropriate choice, and an SGLT2 inhibitor would be preferable.

Amlodipine is incorrect. Amlodipine would be indicated if the patient required an additional antihypertensive agent, but in this case, the blood pressure is within acceptable parameters, and amlodipine is not otherwise indicated in the management of heart failure. It may even worsen symptoms due to its vasodilatory effect, leading to fluid retention

Ivabradine is incorrect. Ivabradine is an inhibitor of the funny current in cardiac pacemaker cells. It is used in the management of angina and heart failure. In heart failure, however, it is only recommended as thirdline therapy and only in those in sinus rhythm with a ventricular rate over 75 bpm AND an ejection fraction of less than 35%. If ivabradine is used in patients with a resting heart rate below 75 bpm, the risk of bradycardia increases significantly. This patient is not yet on second-line therapy and meets neither of the above criteria, so this answer is incorrect.

Sacubitril and valsartan is incorrect. The combination of sacubitril and valsartan is recommended as a third-line therapy in the management of chronic heart failure, but only in those with a left ventricular fraction of less than 35%. This combination requires initiation by a specialist after an ACE inhibitor or ARB wash-out period. This patient has not yet been tried on second-line therapy; however, aldosterone antagonists +/—SGLT2 inhibitors would be considered first.

Spironolactone is incorrect. Second-line therapy in the management of stable heart failure is an aldosterone antagonist such as spironolactone. SGLT2 inhibitors may also be added at this stage. Given that this patient is already hyperkalaemic, an aldosterone antagonist would be contraindicated, making an SGLT2 inhibitor the correct answer in this case.

Question 190 of 328

A 52-year-old gentleman works as a lorry driver. His past medical history includes hypertension and raised BMI. He is admitted to the Emergency Department with chest pain. An ECG confirms ST depression in V1 to V4, with no pathological Q waves. Subsequent blood tests reveal a troponin of 10,000 consistent with a non-ST-elevation myocardial infarction (NSTEMI). He is commenced on appropriate secondary prevention, including aspirin 75mg OD, clopidogrel 75mg OD and fondaparinux 2.5mg SC. The patient is transferred to the cardiology unit and awaits inpatient angiography.

You are asked to review him urgently as he describes acute breathlessness. He denies chest pain. Observations are as follows: heart rate 130 beats per minute, blood pressure 95/62 mmHg, temperature 36.1ºC, respiratory rate 28/min, saturations 94% on 10 litres oxygen. On examination, heart sounds are normal with no added sounds. JVP is mildly elevated. There is no evidence of ascites or peripheral oedema. A repeat ECG confirms sinus tachycardia (heart rate 130bpm) but no dynamic changes. A portable chest x-ray reveals cardiomegaly with upper lobe diversion and peri-hilar shadowing. An urgent bedside echocardiogram demonstrates significant LV systolic dysfunction with a 2cm of pericardial effusion but no features of tamponade.

What is the single next best management step?

A. Continuous positive airway pressure (CPAP)
B. Ultrasound-guided pericardiocentesis
C. Urgent angiography
D. IV fluids
E. Inotrope and IV diuretics

E. Inotrope and IV diuretics

This patient is demonstrating features of cardiogenic shock, secondary to anterior wall myocardial infarction. With anterior infarcts, the mainstay of treatment includes diuretics to reduce pulmonary congestion and inotropic support to enhance cardiac output and perfusion.

Echocardiography demonstrates a reasonable-sized pericardial effusion but there is no indication for pericardiocentesis in the absence of features consistent with cardiac tamponade. Intravenous fluids would exacerbate pulmonary oedema in the context of anterior infarcts and are relatively contraindicated for this reason. They are of relevance, however, in inferior infarcts where preload needs to be maintained. This patient is preserving oxygen saturations via Venturi mask and therefore, CPAP is not currently indicated. Angiography is required to clarify the extent of coronary disease in due course, but the patient requires stabilisation before this can occur.

Question 191 of 328

A 35-year-old man presents to the emergency department with palpitations that came on suddenly earlier that afternoon. He has had symptoms like this on 3 previous occasions which resolved by themselves after a few minutes. He smokes a pack of cigarettes a day and drinks 5-6 pints of beer during the weekends.

He works as a builder on a construction site. He has no significant medical conditions and does not take any regular medication. In the emergency department, his heart rate is 180 beats per minute and his blood pressure 134/62 mmHg. He has no shortness of breath or chest pain but continues to have significant palpitations. His ECG shows a rapid regular rhythm with a QRS interval of 89 ms. On physical examination, he is comfortable at rest, and peripherally warm and well perfused. His JVP is not visible, and heart sounds are normal without any added sounds or murmurs, his chest is clear to auscultation, his abdomen is soft and nontender, and he has no swelling of his lower limbs. He is attached to a cardiac monitor and is asked to blow forcefully into a syringe on 2 separate occasions which does not improve his symptoms.

What is the next step in management?

A. Perform carotid sinus massage at the bedside
B. Administer 5 mg of IV verapamil
C. Administer 6 mg of IV adenosine
D. Administer 12 mg of IV adenosine
E. Administer sedation and prepare for direct current cardioversion

C. Administer 6 mg of IV adenosine

Patients with SVT who are haemodynamically stable and who do not respond to vagal manoeuvres, the next step is treating with adenosine

This young man presents with a likely supraventricular tachycardia. He has symptoms with palpitations, but does not have hemodynamic compromise, nor does he have signs or symptoms of cardiac ischemia or acute heart failure. He, therefore, does not need to be managed with direct current cardioversion. He has already tried vagal manoeuvres, by blowing forcefully into a syringe. The next step in his management is administrating a bolus of IV adenosine at a dose of 6 mg initially, in an attempt to slow down his heart rate and reveal the underlying rhythm.

He has already tried vagal manoeuvres on 2 occasions unsuccessfully and it would be inappropriate to try vagal manoeuvres again while forgoing giving adenosine which would be the next step in his management.

If the initial dose of 6 mg of IV adenosine is unsuccessful then he can be trialled with further adenosine at a higher dose of 12 mg. If these higher doses of adenosine are unsuccessful and he remains hemodynamically stable he could be treated with IV verapamil.

This patient is hemodynamically stable and does not have clinical features to suggest cardiac ischemia or acute heart failure and so does not require direct current cardioversion at present.

Question 192 of 328

A 13 year-old girl presents with chest pain and fever.

On examination the temperature is 38.1ºC, heart rate is 90 beats/minute and respiratory rate is 18 breaths/minute. The chest is clear to auscultation. There is an early diastolic murmur at the left sternal edge.

ECG reveals sinus rhythm, PR interval 210ms. Blood tests reveal:

Hb	121 g/l
Platelets	420 * 10 /l
WBC	9.3 * 10 /l
Na	136 mmol/l
K	3.7 mmol/l
Urea	3.8 mmol/l
Creatinine	72 µmol/l
Bilirubin	22 µmol/l
ALP	110 u/l
ALT	53 u/l
Albumin	36 g/l
C-reactive protein	36
Antistreptolysin O antibody titre	320 units/ml

Which other sign may also be present in this patient?

A. Dermatitis herpetiformis
B. Erythema marginatum
C. Pyoderma gangrenosum
D. Vitiligo
E. Livedo reticularis

B. Erythema marginatum

Acute rheumatic fever (ARF) is caused by a reaction to a bacterial infection with particular strains of group A streptococcus.

Symptoms of ARF generally develop several weeks after an episode of streptococcal pharyngitis

ARF causes a variety of characteristic clinical features:

- Polyarthritis
- Carditis
- Sydenham's chorea
- Erythema marginatum (A characteristic skin rash that occurs in about 10% of first attacks of ARF in children. it is rare in adults). The rash appears as pink or red macules (flat spots) or papules (small lumps), which spread outwards in a circular shape. As the lesions advance, the edges become raised and red, and the centre clears.

Question 193 of 328

A 55-year-old managing director presents with sudden onset retrosternal chest pain associated with light-headedness. She is a nonsmoker and has no other past medical history, except undergoing the menopause 6 years ago and taking a short course of hormone replacement therapy. On examination, she has cool peripheries and normal heart sounds. Her chest is clear with no peripheral oedema. Her calves are soft and non-tender. Her ECG demonstrates ST elevation in V2-V4, troponin 0.8 (normal range <0.03). Percutaneous coronary intervention was performed overnight, demonstrating no occlusions in her coronary arteries. However, ballooning of her left ventricular midcavity and apex was noted, in addition to left ventricular hypokinesia.

What is the most likely diagnosis?

A. Inferior non-ST elevation myocardial infarction (NSTEMI)
B. Hypertrophic obstructive cardiomyopathy
C. Prinzmetal angina
D. Pulmonary embolus
E. Takotsubo cardiomyopathy

E. Takotsubo cardiomyopathy

This is a patient with cardiac sounding chest pain with a troponin positive event, in the absence of vascular risk factors, and in the context of normal coronary vessels. The diagnosis is made on the LV description: apical ballooning is pathognomonic of Takotsubo cardiomyopathy, with the shape of the heart named after the Japanese octopus trap. It classically presents in post-menopausal women and is particularly triggered by anxiety and emotional stress. Treatment is supportive as per heart failure, possibly requiring inotropes if there is no LV outflow tract obstruction and with beta blockade, if there is LV outflow tract obstruction. Patients generally recover their LV ejection fraction within 4 weeks.

Question 194 of 328

A 69-year-old gentleman presents to the emergency department with shortness of breath. He has been experiencing worsening palpitations since he was diagnosed with a chest infection two days ago by his GP and started on oral antibiotics. He is now feeling very unwell and severely short of breath. He has a past medical history of myocardial infarction, AF and type 2 diabetes mellitus. On examination he has a heart rate of 167bpm, blood pressure of

87/50mmHg, oxygen saturations of 93% on 5 litres of oxygen and a temperature of 36.5ºC. He appears very unwell and distressed with bilateral crepitations to his midzones and peripheral oedema to his thighs. His ECG shows atrial fibrillations.

What is the most appropriate immediate management?

- A. IV fluids
- B. Synchronised DC cardioversion
- C. Unsynchronised DC cardioversion
- D. IV amiodarone
- E. IV adenosine

B. Synchronised DC cardioversion

In AF with decompensation the correct management is synchronised DC cardioversion

The patient should have a synchronised DC cardioversion attempted immediately. This patient has a tachyarrhythmia which has clearly decompensated him with evidence of acute heart failure and shock. This may have occurred due to underlying infection. The shock must be synchronised to deliver it during an R wave. This means that the defibrillator will detect R waves and when the shock is administered the machine will pause until it identifies an R wave and then deliver the shock. The purpose of this is primarily to avoid shocking during a T wave which could cause asystole. A shock without synchronisation is used in the resuscitation algorithm during VF and pulseless VT. Amiodarone should be used if three shocks fail to restore rhythm and adenosine is used in haemodynamically stable narrow complex tachycardia. Fluids may worsen pulmonary oedema in this setting

Question 195 of 328

A 53-year-old woman is found to have a systolic murmur on a routine check-up. A transthoracic echocardiogram reveals severe primary mitral regurgitation and a left ventricular ejection fraction of 55%, with other valves showing no significant pathology. A routine ECG demonstrates sinus rhythm. On questioning, she has no attributable symptoms such as shortness of breath, reduced exercise tolerance or chest pain. She is normally very active and works in an insurance firm. She has a past medical history of well-controlled asthma, post-partum depression and a tibial fracture one year ago. She has a salbutamol inhaler but no other regular medications.

What is the most appropriate management plan?

- A. Follow-up in six months
- B. Start nitrites
- C. Stop salbutamol
- D. Exercise testing
- E. Referral for mitral valve surgery

E. Referral for mitral valve surgery

The correct answer is a referral for mitral valve surgery. This asymptomatic patient with mitral regurgitation who has an ejection fraction of 55%. As this is below 60% the patient should be referred for surgery. Other surgical indications include new onset of AF or high likelihood of durable repair with low surgical risk and absence of risk factors. Follow-up in six months would be appropriate if there were no indications for surgery and medical management, such as nitrites, would be indicated if the patient was symptomatic and at too high risk for surgery. Stopping the salbutamol is unlikely to make any significant difference.

Question 196 of 328

A 55-year-old man with type 2 diabetes comes to the Emergency department with symptoms of worsening cardiac failure. Current medication includes metformin and empagliflozin for blood glucose control, ramipril, doxazosin, furosemide, aspirin and atorvastatin. His blood pressure is 112/70 mmHg, his pulse is 80 beats per minute and regular. There are bilateral crackles to the mid zones on auscultation of the chest, and he has pitting oedema to the mid-shins bilaterally.

Investigations

Na +	138 mmol/l
K +	4.5 mmol/l
Urea	6.2 mmol/l
Creatinine	112 µmol/l

Which of the following medications would you discontinue?

- A. Atorvastatin
- B. Doxazosin
- C. Empagliflozin
- D. Metformin
- E. Ramipril

B. Doxazosin

In this situation of worsening heart failure, discontinuation of the alphablocker doxazosin may well improve symptoms. The ALLHAT trial suggested that alpha blockade versus other antihypertensive options was associated with a 25% greater risk of congestive cardiac failure. Guidelines recommend that heart failure is best managed with ACE inhibition, a cardioselective beta blocker rather than an alpha blocker, and loop diuresis if required for fluid overload.

Although atorvastatin may be associated with myositis, it isn't thought to exacerbate heart failure. Evidence for empagliflozin, as one of the SGLT2 inhibitor class, is that it promotes sodium excretion and has a thiazide diuretic like effect with some benefit in patients with incipient cardiac failure. Metformin has no negative impact on heart failure. Metformin is only really contraindicated in a period of acute hypotension, not the chronic heart failure setting seen here.

Question 197 of 328

An 89-year-old woman presents to the emergency room with increased shortness of breath and decreased mobility of 1-week duration. Her shortness of breath is worse at night and she sometimes wakes up gasping for breath. She has fallen over twice in the last week which isn't normal for her. She has a past medical history of diabetes mellitus type 2 and hypertension. She has had no previous surgeries. She lives independently with her husband and her daughter lives close by and helps with the shopping.

On examination, she is found to have coarse crackles bi-basally on auscultation of her chest. She has a regular heart rate with a pan-systolic murmur loudest over the apex.

Investigations show:

Haemoglobin	11g/dl
WCC	6 x 10^9/l
Platelets	178 x 10^9/l
Sodium	139 mmol/l
Potassium	4.2 mmol/l
Urea	8 mmol/l
Creatinine	92 µmol/l
Blood cultures	Methicillin-sensitive Staphylococcus aureus

Echocardiogram severe mitral regurgitation with large mobile structure on valve leaflet

Chest X-ray: bilateral blunting of the costophrenic angles and upper lobe diversion

What is the best treatment for this lady?

A. Flucloxacillin orally
B. Flucloxacillin intravenously
C. Amoxicillin orally and vancomycin intravenously
D. Ceftriaxone intravenously
E. Amoxicillin intravenously and vancomycin intravenously

B. Flucloxacillin intravenously

This lady has a native mitral valve endocarditis with a bacteraemia caused by a methicillin-sensitive *Staphylococcus aureus*. Once cultures have grown the causative bacteria and it is found to be sensitive to methicillin guidelines suggest flucloxacillin intravenously to be the treatment of choice. Flucloxacillin orally would not provide sufficient antimicrobial cover nor will ceftriaxone, amoxicillin and vancomycin.

There is some debate about the optimal length of treatment, but 6 weeks of intravenous therapy is generally accepted as the length of treatment needed. Shorter therapeutic regimens may be effective in selected patients with right-sided endocarditis and with endocarditis due to highly susceptible *Streptococcus viridans* treated with synergistic antimicrobials.

Question 198 of 328

An 82-year-old presents with suprapubic discomfort. He reports urgency but has been unable to pass any urine for over 24 hours. Three months ago, he underwent a third failed transurethral resection of the prostate for benign prostatic hypertrophy (PSA was normal). His past medical history includes hypertension, type 2 diabetes mellitus, chronic kidney disease (baseline creatinine 150 µmol/l) previous MI in 2007 and 2010. He remains relatively active, with an exercise tolerance of 500 yards. On examination, his mucous membranes are moist, his peripheries are warm and his JVP at 3 cm above the angle of Louis. His heart sounds and chest are unremarkable. His abdomen is tender and distended in the suprapubic region. On insertion of a urethral catheter, 900mls of residual urine is noted. His blood tests are as follows:

Hb	115 g/l
Platelets	282 * 10 /l9
WBC	6.8 * 10 /l9
Na +	144 mmol/l
K +	5.8 mmol/l
Urea	12.1 mmol/l
Creatinine	201 µmol/l
Troponin T	0.08 (normal <0.03)

His ECG demonstrates left bundle branch block (old) and first-degree heart block at a rate of 49 beats/ minute and regular.

What is the appropriate management?

A. Treat as acute coronary syndrome only
B. Intravenous fluids only
C. Monitor renal function and consider long term catheter only
D. Treat as acute coronary syndrome, monitor renal function and consider long term catheter
E. Treat as acute coronary syndrome, intravenous fluids, monitorrenal function and consider long term catheter

C. Monitor renal function and consider long term catheter only

This patient is a typical elderly admission with multiple co-morbidities involving multiple organ systems. The key to this question is recognising which aspects are important and which are not. The patient is clearly euvolaemic and intravenous fluids at this stage are not required. However, it would be prudent to monitor urine output and if significant amounts are produced, to replace output with oral intake or intravenous input. Troponin is raised but this is in the context of an acute on chronic kidney injury. In the context of no reported chest pain and no new dynamic ECG changes, treatment as an acute coronary syndrome is unnecessary. The patient is at greater risk of post-renal injury and his renal function tests should instead be monitored. A long-term catheter is a reasonable suggestion considering the number of failed TURPs.

Question 199 of 328

A 59 year-old man with history of ischaemic heart disease and type 2 diabetes mellitus is eight hours post right curative hemicolectomy for bowel malignancy. In the surgical high-dependency unit he is noted to be tachycardic on the monitor

On examination the patient appears comfortable. The pulse rate is 200bpm and the blood pressure is 148/79mmHg. Oxygen saturations are

98% on 2L/min nasal oxygen. Capillary refill is 2 seconds. The chest is clear to auscultation.

A 12-lead ECG reveals a regular broad complex tachycardia with a monomorphic waveform at a rate of 200bpm.

Post-operative blood tests reveal:

Hb	131 g/l
Platelets	563 * 10 /l9
WBC	13.4 * 10 /l9
Na +	141 mmol/l
K +	4.1 mmol/l
Mg ++	0.87 mmol/l
Urea	4.2 mmol/l
Creatinine	121 µmol/l
Bilirubin	23 µmol/l
ALP	109 u/l
ALT	34 u/l
Albumin	33 g/l

What is the most appropriate initial management?

A. Magnesium sulphate 2g IV
B. Amiodarone 300mg IV
C. Synchronised DC shock

D. Metoprolol 5mg IV
E. Adenosine 6mg IV

B. Amiodarone 300mg IV

This case outlines a description of ventricular tachycardia.

Following the resuscitation council guidelines, in the absence of shock, syncope, myocardial ischaemia or heart failure (which would necessitate DC cardioversion), the most appropriate initial management is 300mg amiodarone intravenously.

Question 200 of 328

A 65-year-old obese female with known type 2 diabetes mellitus presents with one-week history of unstable angina. Her troponin was negative and she presented with no dynamic ECG changes. She undergoes an angiogram and a drug-eluting stent was inserted into a 90% stenosis of his LAD.

On discharge, what should her antithrombotic regime be?

A. Aspirin and prasugrel for 1 month, followed by lifelong aspirin
B. Aspirin and prasugrel for 1 month, followed by lifelong prasugrel
C. Aspirin and prasugrel for 1 year, followed by lifelong aspirin
D. Aspirin only, lifelong
E. Prasugrel only, lifelong

C. Aspirin and prasugrel for 1 year, followed by lifelong aspirin

The correct answer for this question is **aspirin and prasugrel for 1 year, followed by lifelong aspirin**. This is because the patient has undergone percutaneous coronary intervention (PCI) with a drug-eluting stent (DES) insertion, which requires dual antiplatelet therapy (DAPT) for at least one year according to UK guidelines. Aspirin is given as a lifelong therapy, while prasugrel, a P2Y12 inhibitor, is given in combination with aspirin for the first year. This regimen helps to prevent stent thrombosis and reduce the risk of recurrent ischemic events.

The option **aspirin and prasugrel for 1 month, followed by lifelong aspirin** is incorrect because DAPT duration of only 1 month is too short after DES placement. The minimum recommended duration of DAPT following DES implantation in patients with stable coronary artery disease or acute coronary syndrome (ACS) without high bleeding risk is 6 months and 12 months respectively.

The option **aspirin and prasugrel for 1 month, followed by lifelong prasugrel** is also incorrect because it does not provide adequate duration of DAPT after DES placement. Moreover, switching from DAPT to monotherapy with only prasugrel would not be appropriate as aspirin remains the cornerstone of long-term antithrombotic therapy in these patients.

Aspirin only, lifelong is not an appropriate option either since it does not include a P2Y12 inhibitor like prasugrel or clopidogrel that should be added to aspirin during the first year following PCI with DES insertion to minimize the risk of stent thrombosis.

Lastly, **prasugrel only, lifelong** would not be suitable as it does not include aspirin, which is a crucial component of long-term antithrombotic therapy in patients with coronary artery disease. Furthermore, prasugrel monotherapy has not been shown to be superior to DAPT with aspirin and a P2Y12 inhibitor in preventing recurrent ischemic events.

In summary, the best antithrombotic regimen for this patient would be **aspirin and prasugrel for 1 year, followed by lifelong aspirin**, as it provides optimal protection against stent thrombosis and recurrent ischemic events following PCI with DES insertion.

Question 1 of 129

A 45-year-old man is being worked up for chest pain.

He has a background of bipolar disorder for which he takes olanzapine but is otherwise fit and well.

He has had a cardiac MIBI scan that is reported as follows:

Images display a moderate perfusion abnormality in the right ventricle on the stress images with associated dyskinesis. This defect is also present at rest.

Given the above information, what is the most likely cause of these imaging findings?

A. Atherosclerosis
B. Hypertrophic cardiomyopathy
C. Kawasaki disease
D. Soft tissue attenuation defect
E. Transmural scarring

E. Transmural scarring

If a cardiac MIBI scan shows that the defect is present on both stress and rest, this is suggestive of a fixed defect such as myocardial necrosis and fibrosis secondary to infarction

Here we have a patient with a perfusion defect in the right ventricle at rest and during stress. This indicated that the lesion was not reversible.

Transmural scarring is correct. When scar tissue is formed within the myocardium, there will be a fixed perfusion defect as blood supply to this area never normalises.

Atherosclerosis is incorrect. Atherosclerosis commonly causes reversible defects that normalise at rest.

Soft tissue attenuation defect is incorrect. Although soft tissue attenuation defects can cause the appearance of fixed defects, there would not be associated wall motion abnormalities.

Kawasaki disease is incorrect. Although this vasculitis can be a cause of myocardial infarction it is very rare. It usually affects children under the age of five and is associated with fever, strawberry tongue, rash, and lymphadenopathy, none of which are seen in this case.

Hypertrophic cardiomyopathy is incorrect. This would be visible on MIBI scan as ventricular hypertrophy, if a defect is present, it is likely to be present only during stress.

Question 2 of 129

A 69-year-old man presents with central crushing chest pain. He also feels nauseous. He states that the pain came on at rest. He has a past medical history of hypertension and poorly controlled type 2 diabetes mellitus.

An ECG is performed:

P waves	Normal morphology
PR interval	120ms
QRS	115ms
T waves	Deeply inverted T waves in V2-V3
ST segments	No elevation or depression

What is the most likely diagnosis?

A. Critical stenosis of the right coronary artery
B. Critical stenosis of the left main stem coronary artery
C. Critical stenosis of the left anterior descending artery (LAD)
D. 75% stenosis of the left anterior descending artery (LAD)
E. 75% stenosis of the right coronary artery

C. Critical stenosis of the left anterior descending artery (LAD)

Wellens' syndrome is a pattern of deeply inverted or biphasic T waves in V2-3. It is highly specific for critical stenosis of the left anterior descending artery (LAD). It should be treated as a STEMI with urgent angiography and revascularisation

The patient has multiple major risk factors for cardiovascular disease making an acute coronary syndrome high up the differential list. The deeply inverted T waves in V2-V3 are very suggestive of Wellens' syndrome which is highly specific for critical stenosis of the left anterior descending artery (LAD). It should be treated as a STEMI with urgent angiography and revascularisation.

Right coronary artery pathology tends to present with ECG changes in the inferior leads (II, III and AVF).

Left main stem coronary artery occlusion tends to present with widespread ECG changes with horizontal ST depression (most prominent in leads I, II and V4-6), and ST elevation in aVR.

Question 3 of 129

A 28-year-old man is admitted with 4 episodes of shocks from his ICD in the past 24 hours. He states that the chest pain is like an electric shock, which is brief and lasts for only a second or two. He also complains of palpitations. He has a past medical history of hypertrophic obstructive cardiomyopathy (HOCM) and has an ICD due to previous episodes of ventricular tachycardia.

Whilst in the emergency department he suffers from 8 consecutive shocks from the ICD. A 12 lead ECG shows an irregularly irregular rhythm with a QRS of 0.10s, and absence of P waves. His heart rate is 140bpm and blood pressure = 130/75 mmHg. There is no signs of heart failure on examination.

What is the most appropriate initial management?

A. Apply a ring magnet over the ICD to temporarily deactivate it pending device interrogation
B. Rate control with calcium channel blocker
C. Chemical cardioversion with amiodarone
D. Synchronised electrical cardioversion
E. Rate control with beta blocker

A. Apply a ring magnet over the ICD to temporarily deactivate it pending device interrogation

Multiple episodes of inappropriate shocks from an ICD can be both unpleasant and dangerous. Ultimately the device will need interrogated from a pacemaker technician, however the most immediate management should be to place a ring magnet over the ICD to prevent further inappropriate shocks.

The patient has presented with multiple episodes of shocks from his ICD. The ICD was inserted to cardiovert life threatening arrhythmias such as ventricular tachycardia and fibrillation. However in this case, he has developed new onset AF, and has received multiple inappropriate shocks from his ICD.

Ultimately he will need the device interrogated from a pacemaker technician, however the most immediate management should be to place a ring magnet over the ICD to prevent further inappropriate shock, which can both be painful, and cause harm. This must only be done while the patient is on a cardiac monitor or telemetry so that one can monitor for any life threatening arrhythmias. If, at any time, you identify ventricular tachycardia or ventricular fibrillation on the cardiac monitor, the ring magnet must be removed immediately allowing normal firing of the ICD to resume after approximately 15 seconds.

One could argue that pharmacological cardioversion or rate control would resolve the problem. However the most immediate management would involve preventing further shocks with a ring magnet while the device is interrogated.

Question 4 of 129

A 48-year-old hypertensive, male who smokes presents with central crushing chest pain and nausea. His ECG shows new deeply inverted T waves in V2 and V3.

These ECG findings are consistent with critical stenosis to which coronary artery?

A. Left anterior descending artery
B. Left circumflex artery
C. Left main artery
D. Posterior descending artery
E. Right coronary artery

A. Left anterior descending artery

Wellens' syndrome is a pattern of deeply inverted or biphasic T waves in V2-3. It is highly specific for critical stenosis of the left anterior descending artery (LAD). It should be treated as a STEMI with urgent angiography and revascularisation

This patient presents with typical symptoms of acute coronary syndrome. Deeply inverted or biphasic T waves in V2 and V3 are consistent with a diagnosis of Wellens' syndrome. Wellens' syndrome is caused by critical stenosis of the left anterior descending (LAD) artery and is associated with a high risk of extensive anterior wall myocardial infarction. Patients may be pain-free at presentation or have minimally elevated cardiac enzymes. Patients with Wellens' syndrome typically require intervention with urgent angiogram and revascularisation, as in an acute ST-elevation myocardial infarction. The other listed coronary arteries are not associated with Wellens' syndrome.

The left circumflex artery supplies the left ventricle. The left main artery supplies the left ventricle and atrium.

The posterior descending artery supplies the inferior aspect of the myocardium.

The right coronary artery supplies the right ventricle, right atrium and the sino-atrial and atrioventricular nodes of the heart.

Question 5 of 129

An 8-year-old boy presents to the emergency department with seven days of fever. He originally attended six days previously and was discharged home with advice to return if the fever persisted. There has been no response to paracetamol treatment. He has not past medical history.

Observations:

- Heart rate 84 beats per minute
- Blood pressure 100/70 mmHg
- Temperature 39.4C

On examination, his conjunctivae are erythematous. He has red, cracked lips and a 'strawberry tongue'. There is unilateral cervical lymphadenopathy. The palms of his hands and soles of his feet are red. The examination is otherwise normal.

Urinalysis and a chest x-ray are unremarkable. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L	(150 - 400)
WBC	8.9 * 10 /L	(4.0 - 11.0)
Na	140 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	77 µmol/L	(55 - 120)
CRP	35 mg/L	(< 5)
Bilirubin	14 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	64 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

In addition to aspirin, what other treatment has the most evidence for benefit in treating this condition?

A. Antibiotic treatment
B. Cyclophosphamide
C. Intravenous immunoglobulin
D. Prednisolone
E. Rituximab

C. Intravenous immunoglobulin

Intravenous immunoglobulin , uses include: Kawasaki disease

Intravenous immunoglobulin is correct. The child has Kawasaki disease as evidenced by a fever lasting > 5 days, bilateral conjunctival congestion, cervical lymphadenopathy and changes of the lips and extremities. This is a medium-vessel vasculitis that occurs in children. In addition to aspirin, intravenous immunoglobulin should be administered to prevent the formation of coronary artery aneurysms, which is a feared complication of this condition.

Antibiotic treatment is incorrect. The clinical syndrome, in this case, suggests Kawasaki disease as the cause of fever, rather than infection. This is an inflammatory rather than infective condition and does not require antibiotic treatment.

Cyclophosphamide is incorrect. This has been used occasionally in refractory Kawasaki disease but it has less evidence than IVIG. Additionally, there is a risk of infertility associated with this treatment and therefore it should be avoided in people of child-bearing age unless absolutely necessary.

Prednisolone is incorrect. There is more limited evidence for the benefit of corticosteroids in this condition compared with IVIG. Adjunctive treatment with corticosteroids could be considered in particular high risk groups (Age < 12 months, Asian ethnicity) and in the setting if particular blood test abnormalities (ALT >100 IU/L, albumin ≤30 g/L, sodium ≤133 mmol/L, platelets ≤30 x 109/L, CRP >100 mg/L, anemia) or cardiac or coronary artery involvement on echo at presentation.

Rituximab is incorrect. This is an anti-CD20 monoclonal antibody that is used in the treatment of some vasculitis. There is limited evidence for its use in Kawasaki disease but it has been used occasionally in IVIG refractory disease.

Question 6 of 129

A 67-year-old woman attends Cardiology clinic. She has recently had a permanent pacemaker (PPM) inserted due to pre-syncopal episodes associated with bradycardia. She reports an improvement in these symptoms since insertion, but notes exertional chest pain since the procedure. She has a past medical history of type 2 diabetes mellitus and hypercholesterolaemia, for which she takes metformin and atorvastatin.

What is the most cause of her symptoms?

A. Pacemaker lead malposition
B. Costochondritis
C. Bornholm disease
D. Pacemaker syndrome
E. Coronary ischaemia

E. Coronary ischaemia

Pacemaker lead malposition, costochondritis and Bornholm disease (a viral infection causing pain in the lower chest) would not typically be associated with specifically exertional chest pain.

Pacemaker syndrome is typically associated with a VVI pacemaker that results in simultaneous atria and ventricle conduction. This can cause fatigue, dizziness and hypotension.

This patient is a good candidate for coronary artery disease with type 2 diabetes mellitus and hypercholesterolaemia. Pre-pacemaker insertion her heart had lower energy requirements due to conduction system disease. Pacing has improved her potential heart rate and therefore increased energy demands. This has unmasked her underlying coronary ischaemia. She now needs an angiogram!

Question 7 of 129

A 28 year old woman is admitted to the medical assessment unit complaining of pleuritic chest pain. She is 32 weeks pregnant into her first pregnancy. An ECG reveals a sinus tachycardia. Her blood tests are unremarkable, although the referring accident and emergency doctor added on a D-dimer test for completion and this has come back positive.

According to the Royal College of Obstetricians and Gynaecologists guidelines, what is the next suitable investigation for this patient?

A. Chest x-ray
B. Ventilation/perfusion scan
C. Compression duplex doppler of the legs
D. CT pulmonary angiogram (CTPA)
E. Cardiac catheterisation to assess right sided pressure

A. Chest x-ray

In suspected pulmonary embolism in pregnant patients the Royal College of Obstetricians and Gynaecologists recommend the following:

1. Chest xray to look for an alternative diagnosis.

2. If the chest xray is normal consider a compression duplex Doppler of both legs to exclude a DVT. If this is positive, the patient is treated with full dose low molecular weight heparin (LMWH) (warfarin is of course teratogenic).

3. If both the above investigations are normal, and there remains a strong suspicion of a pulmonary embolism, then clinicians should consider. a CTPA or ventilation perfusion/scan weighing up the risks vs benefits of each and also the local hospital protocol. Current guidance however favours a perfusion scan as it has lower lung radiation doses than a CTPA.

Question 8 of 129

A 54-year-old male previously treated for lymphoma is seen in clinic with a 6-month history of exertional dyspnoea which is progressive. He was treated four years ago and was told that there was no evidence of disease on the final CT scan. His GP treated him for a presumed lower respiratory tract infection two weeks ago. He returned from a business trip to Thailand six months ago, during which he consumed more alcohol than he usually does. He takes no medications and is otherwise fit and well, and is a non-smoker. On examination there is mild pedal oedema, his chest is clear and jugular venous pressure(JVP) is raised on inspiration. Auscultation of his heart reveals an extra heart sound very soon after S2.

What is the likely cause of his symptoms?

A. Superior vena cava obstruction
B. Cardiac tamponade
C. Left ventricular failure
D. Chronic obstructive pulmonary disease
E. Constrictive pericarditis

E. Constrictive pericarditis

Examination of this patient demonstrates Kussmaul's sign - paradoxical elevation of the JVP on inspiration. This sign is seen in constrictive pericarditis, cardiac tamponade and restrictive cardiomyopathy. This presentation gives no other features to suggest tamponade. His constrictive pericarditis here is likely cause by the previous radiotherapy for lymphoma. Other causes of constrictive pericarditis include TB and chronic pericarditis. Definitive management involves surgical pericardial stripping.

Question 9 of 129

A 38-year-old female presenting with 3 months of increasing abdominal and lower limb swelling. She has a past medical history of myasthenia gravis, associated with a thymic mass. Five years ago, she underwent a thymectomy and after positive margins were noted, she was commenced on a course of radiotherapy. She has no other past medical history. On examination, her heart sounds are quiet with no added sounds. Her chest is clear on auscultation. Her JVP is located at 6 cm above the angle of Louis. Abdominal examination reveals a pulsatile liver and smooth hepatomegaly. A chest x-ray demonstrates only minimal pleural and pericardial calcification.

What is the definitive treatment?

A. Intravenous furosemide
B. Intravenous methylprednisolone
C. Intravenous immunoglobulin
D. Pericardial drain insertion
E. Pericardiectomy

E. Pericardiectomy

The patient presents with clinical features of constrictive pericarditis. Her previous radiotherapy increases the aetiology of radiation-induced pericarditis. The patient has prominent and persistent symptoms for which pericardiectomy is the only definitive treatment available. While diuretics may hold the symptoms prior to surgery or be used in patients not suitable for surgery, pericardiectomy should be the definitive treatment despite the high operative risks. However, radiation induced constrictive pericarditis is known to demonstrate a worse long-term prognosis than other causes.

Question 10 of 129

A 76-year-old man with diabetes, hypertension, rheumatoid arthritis and gout presents with a 3 month history of deterioration. He is generally lethargic with reduced energy and has changed from someone who was walking with sticks to now using a frame. He occasionally vomits and has sweating at night time. His wife is concerned that he has lost weight.

On examination, he has clubbing present and a red macular rash across his hands. He complains of his fingers itching and in the abdomen, the spleen is palpable three centimeters below the costal margin. He has a pan systolic murmur and there are crepitations in both lungs. He starts to shake vigorously but remains awake and feels clammy. He is tender across his gluteal muscles.

Hb	109 g/l	Na +	130 mmol/l
Platelets	276 * 10 /l 9	K +	3.7 mmol/l
WBC	10.4 * 10 /l 9	Urea	4.5 mmol/l
Neuts	9.8 * 10 /l 9	Creatinine	89 µmol/l
Lymphs	0.4 * 10 /l 9	CRP	42 mg/l
Eosin	0.1 * 10 /l 9	ESR	32 mm/hr

Blood film	some microcytosis, schistocytes and cell fragments seen
ECG	sinus tachycardia rate 102/min
Chest x-ray	globular heart, bilateral interstitial shadowing

What is the likely diagnosis?

A. Lymphoma
B. Infective endocarditis
C. Congestive cardiac failure
D. Mycoplasma pneumonia
E. Polymyalgia rheumatica

B. Infective endocarditis

Strep endocarditis presents insidiously with new murmur

Important for me Less imp

This is a chronic inflammatory condition and it can be hard to tell apart the options. Congestive cardiac failure usually has a history of myocardial infarctions and an elevated JVP or ankle oedema which is not seen here. Lymphoma has palpable (cervical, axillary, inguinal) or radiological (mediastinal) evidence of lymphadenopathy although there is splenomegaly here. Polymyalgia rheumatica can present in unusual forms like this but we should look at the other options. *Mycoplasma* can give erythema multiforme which is a macular rash and there is hyponatraemia too. However, the history is too chronic for *mycoplasma* and the unexplained murmur, fevers and raised inflammatory markers should prompt thoughts of a *streptococcus* endocarditis.

Question 11 of 129

A 23-year-old woman is referred by the emergency department with sudden onset shortness of breath and pleuritic chest pain. She describes no cough or sputum. The pain is constant and not worse on movement. She is 24 weeks pregnant with her third child. She is normally fit and well and on no regular medication beyond her pregnancy supplements. On examination, she is slightly tachypnoeic at 21/min but her sats are 98% on room air. Her blood pressure is 110/78 mmHg and her heart rate is 86/min. Her chest is clear and the JVP is not elevated and her heart sounds are normal. Examination of her right leg reveals a swelling from above the right knee down to the ankle. There is pitting oedema on the right side as well as collateral superficial veins.

The emergency department registrar has sent several blood tests. The results are:

Hb	118 g/l
Platelets	443 * 10 /l
WBC	9.8 * 10 /l
Trop T	6ng/L (<14ng/L excludes cardiac damage)
D-dimer	1.3 mg/L (<0.5)
CRP 16	mg/L (<10)

Her chest x-ray is unremarkable. Her ABG shows:

pH	7.39
pO2	8.6kPa
pCO2	2.9kPa
HCO3-	21mmol/L (22-29)
Sats	97%
BE	1.1

She is seen on the post take ward round and the Consultant would like to exclude a pulmonary embolism.

What is the most appropriate first investigation for this lady?

A. Half dose CTPA
B. V/Q scan
C. USS Doppler of legs
D. Full dose CTPA
E. No need for investigation treat with LMWH

C. USS Doppler of legs

This lady could well have a PE. However, she also has signs of a deep vein thrombosis in the right leg.

The current guidelines in these situations recommend a CXR followed by USS Doppler of the legs. If a DVT is found they are anticoagulated without any radiation exposure to the baby. If the USS is negative and CXR normal they should then be offered the informed choice of V/Q scan or CTPA. V/Q carries a slightly higher risk to the baby of childhood cancers whilst a CTPA carries a slightly increased lifetime risk of breast cancer to the mother.

Question 12 of 129

A 22-year-old male presents to clinic complaining of several episodes of heart palpitations. He states that during the attacks his heart beats extremely fast and he feels dizzy.

You arrange a 7 day cardiac holter monitor. The results are as follows:

PR interval	95ms
QRS duration	105ms
Events	One episode of tachycardia of 145 bpm with normal QRS morphology and QRS 110ms

What is the most likely diagnosis?

A. Lown-Ganong-Levine syndrome
B. Wolff-Parkinson-White syndrome type A
C. Wolff-Parkinson-White syndrome type B
D. Monomorphic ventricular tachycardia
E. Polymorphic ventricular tachycardia

A. Lown-Ganong-Levine syndrome

Lown-Ganong-Levine syndrome (LGL) is a pre-excitation syndrome of the heart characterised by a short PR interval and normal QRS width

The key thing to note is the short PR interval. The normal PR interval is 120-200ms. A short PR interval is suggestive of a pre-excitation syndrome. Pre-excitation syndromes occur due to an accessory pathway between the atria with the ventricles, resulting in early depolarisation of the ventricles and a tendency for tachyarrhythmias. Pre-excitation through the accessory pathway results in a short PR interval.

The normal QRS width (normal width <120ms) precludes the diagnosis of Wolff-Parkinson-White syndrome which is characterised by a wide QRS with a slurred upstroke (delta wave). The normal QRS also rules out ventricular tachycardia.

The diagnosis is therefore Lown-Ganong-Levine syndrome (LGL) which is a pre-excitation syndrome of the heart characterised by a short PR interval and normal QRS width.

Question 13 of 129

A 60 year old man with a known history of congestive cardiac failure and asthma is reviewed in a cardiology clinic. He is noted to have a blood pressure of 95/63mmHg and a heart rate of 98bpm. An ECG confirms sinus rhythm. He has previously developed symptoms of wheeze with beta blockade. He is commenced on ivabradine 5mg twice daily by his cardiologist.

Which of the following should the patient be warned of as a recognised side effect of ivabradine?

A. Neutrophilia
B. Hypotension
C. Phosphenes
D. Diaphoresis
E. Renal failure

C. Phosphenes

Ivabradine use may be associated with visual disturbances including phosphenes and green luminescence

Ivabradine is a second line agent for rate control in the treatment of chronic heart failure in those in whom beta-blockade is contraindicated, not tolerated or therapy fails. Other rate limiting drugs such as the calcium channel blockers diltiazem or verapamil may sometimes be used but hypotension often limits their use. Digoxin too can sometimes be used, even in sinus rhythm although the rate limiting effect it has is relatively modest; often digoxin and ivabradine are ultimately used in conjunction.

NICE guidelines on the use of ivabradine give clear criteria on its use; the patient must have at least a moderate degree of heart failure with a left ventricular ejection fracture of <35%, they must be stable on optimal doses of other heart failure medications including angiotensin system modulators, an aldosterone receptor antagonist and a beta blocker if not contraindicated. It is important the patient is regularly monitored by a community heart failure team to titrate the dose. Ivabradine can also only be used in patients in sinus rhythm. It works by selectively inhibiting the If [ionic funny] channel which is a sodium/potassium symporter channel largely expressed within the sinoatrial node. Inhibition of this channel slows the intrinsic rhythmicity of the hearts pacemaker function. Pharmaceutical bradycardia aids in the management of cardiac failure as it allows improved diastolic filling and reduced myocardial oxygen usage.

Side effects of ivabradine include bradycardia, ventricular escape rhythms, dizziness, headache, muscle cramps and eosinophilia. Neutrophilia is rarely seen with ivabradine. Hypotension is also not seen with ivabradine use which makes it an important drug in the arsenal when treating patients with cardiac failure in whom other rate limiting drugs may be relatively contraindicated.

An important side effect with ivabradine however is that of visual disturbance including the phenomenon of phosphenes, or 'flashing lights'. Other visual symptoms described include green discolouration of visual field, blurring of vision and scintillating scotomata. These visual symptoms are usually transient and mild. They arise due to inhibition of similar ionic channels in the retina to the sinoatrial If channels. Approximately 20% of patients taking the drug develop some form of visual disturbance but only 1% need to discontinue therapy because of it.

The use of ivabradine in renal dysfunction is not well established however manufacturers recommend it may be used with estimated glomerular filtration rates above 15ml/min. There is no evidence its use causes renal dysfunction although mild rises in plasma creatinine levels may be seen

Question 14 of 129

A 44-year-old gentleman is admitted to hospital with a 2 week history of flu-like symptoms, wheeze, shortness of breath on lying flat and palpitations. There is no background history of note. His observations include a heart rate of 98/min, blood pressure of 96/50 mmHg and saturations of 96% while on 2L of oxygen. He is apyrexial.

On examination you note a low volume pulse with a raised JVP and a raised Y decent. A third heart sound is audible. There are no murmurs. There are bilateral crepitations and pitting oedema of the legs.

Blood investigations indicate:

Hb	158 g/L	Male: (135-180)Female: (115 - 160)
Platelets	335 * 10 /L	(150 - 400)
WBC	11.7 * 10 /L	(4.0 - 11.0)
Neuts	8.0 * 10 /L	(2.0 - 7.0)
Lymphs	2.3 * 10 /L	(1.0 - 3.5)
Mono	0.7 * 10 /L	(0.2 - 0.8)
Eosin	0.69 * 10 /L	(0.0 - 0.4)

Na	138 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	5.3 mmol/L	(2.0 - 7.0)
Creatinine	78 µmol/L	(55 - 120)
CRP	12 mg/L	(< 5)

Three blood cultures have been sent and the preliminary report is negative.

The ECG on admission shows sinus rhythm with left ventricular hypertrophy pattern but no features of ischaemia; the PR interval is normal.

An echocardiogram is performed and notes shows preserved systolic function with moderate concentric left ventricular hypertrophy. Both atria are dilated and there is evidence of diastolic dysfunction. There is no valvular pathology and no suspicious lesions surrounding the valves.

Given this scenario, which imaging modality would be most appropriate in identifying the diagnosis of this patient?

A. Transoesophageal echocardiography
B. Right and left cardiac catheterisation
C. Myocardial perfusion scan
D. Cardiac MRI
E. High resolution CT thorax

D. Cardiac MRI

Cardiac MRI is the investigation of choice alongside echocardiography in order to identify the potential cause of cardiomyopathy

The echocardiography and examination findings suggest the potential of restrictive cardiomyopathy. In addition this gentleman has significant eosinophilia which could alert us to the possibility of Loffler's endocarditis.

The options provided cover a wide spectrum of cardiac imaging modalities, however cardiac MRI yields the greatest detail with regards to function and structure of the heart in such scenarios.

The possibility of infective endocarditis remains low and a transoesophageal echocardiogram would not necessarily add anything further with regards to the diagnosis.

A catheterisation or myocardial perfusion scan will provide excellent information regarding ischaemia however the information regarding the cause of this restrictive cardiomyopathy will not be revealed.

There is no indication for a high resolution CT thorax given the high grade of suspicion regarding a cardiac primary problem.

Question 15 of 129

A 53-year-old man with a history of diabetes presents to the Emergency Department with crushing central chest pain, vomiting, and diaphoresis.

Observations :

- Pulse: 32 beats per minute.
- Blood pressure: 70/40 mmHg.
- Oxygen saturation: 88%

Examination reveals pale and cool skin. An ECG shows ST-elevation in leads II, III, and aVF, along with complete heart block, and his troponin test is positive. Following initial management, including percutaneous coronary intervention (PCI) with stenting, he is admitted to the intensive care unit.

Three days post admission, he develops severe dyspnoea, cold extremities, and diaphoresis. Auscultation reveals a holosystolic murmur on the left sternal edge. His observations:

Pulse: 123 per minute Blood pressure: 65/45 mmHg. Oxygen saturation: 80%

What is the most appropriate next step in management?

A. CT coronary angiography
B. Cardiac MRI
C. Immediate surgical consultation
D. Re-transfer to the catheter lab
E. Transthoracic echocardiography

E. Transthoracic echocardiography

Acute heart failure: echocardiography is indicated in new-onset heart failure, cardiogenic shock, suspected valvular or post-MI problems

Transthoracic echocardiography is the correct answer. In this scenario, the patient developed cardiogenic shock (hypotension, tachycardia and cool skin) with a holosystolic murmur following a complicated inferior wall STEMI (as denoted by complete heart block on ECG). The differential diagnoses include acute mitral regurgitation (MR) and acute ventricular septal rupture (VSR). A holosystolic murmur heard over the left sternal edge suggests an acute VSR. An urgent transthoracic echocardiogram is warranted to delineate the site and extent of the defect. This diagnostic step should be performed concurrently with medical therapy, preceding an immediate surgical consultation.

CT coronary angiography is not appropriate in this context. Although CT coronary angiography can be useful for patients with suspected stable angina, in this case, where acute VSR is likely following a wellestablished inferior wall STEMI, echocardiography will provide rapid and precise information about the lesion that will inform surgical management decisions.

Cardiac MRI would not be suitable in this setting. Although it can sometimes provide superior detail compared to echocardiography, its longer scan times, limited availability, and inadequacy for haemodynamically unstable patients render it a less favourable choice for imaging in this emergency.

Immediate surgical consultation plays a pivotal role in managing both acute MR and VSR; however, it should be preceded by a detailed lesion assessment using echocardiography to inform subsequent surgical intervention.

Re-transfer to the catheter lab would not benefit this patient. Such a step may be considered if re-infarction is suspected. Given that the clinical picture points towards an acute VSR post-myocardial infarction, echocardiographic evaluation remains crucial for diagnosis, and coronary angiography will not diagnose such a complication

Question 16 of 129

A 54-year-old female presents with heart palpitations. She has no past medical history and takes no regular medicines. Her cardiorespiratory exam is normal.

An ECG is performed:

Rate and rhythm	145 beats per minute. Regular rhythm
P waves	Not visible
QRS	145ms. RBBB pattern
QTc	420ms
Axis	Right axis deviation

What is the most likely explanation of these ECG results?

A. Ventricular tachycardia
B. Supraventricular tachycardia with bundle branch block
C. Torsades de pointes (TdP)
D. Atrial fibrillation with bundle branch block
E. Supraventricular tachycardi

B. Supraventricular tachycardia with bundle branch block

Distinguishing between VT and SVT with BBB can be challenging. The presence of RBBB and RAD favours a diagnosis of SVT with BBB

The ECG results confirm a broad complex tachycardia with a regular rhythm. The differential is therefore between supraventricular tachycardia (SVT) with bundle branch block (BBB) and ventricular tachycardia (VT). Distinguishing between VT and SVT with BBB can be challenging. The presence of RBBB and RAD favours a diagnosis of SVT with BBB. If you are unsure of the diagnosis, it is always safer to assume the the patient has VT and treat accordingly.

The absence of P waves should make you consider a diagnosis of atrial fibrillation (AF) with BBB, however the regular rhythm precludes this diagnosis. In SVT, the P waves are often buried within the QRS complex.

The normal QTc and regular rhythm precludes the diagnosis of Torsades de pointes (TdP).

Question 17 of 129

A 39-year-old male is admitted with sharp central chest pain which is worse on inspiration. He states that the pain is partially relieved by leaning forward. He has no past medical history and takes no regular medicines.

ECG results are as follows:

PR segment	Depression
ST segment	Global concave ST elevation

Blood results are as follows:

Troponin	9.82 ug/l (normal range 0.015 - 0.045)

What investigation is most useful diagnostically?

A. Cardiac magnetic resonance imaging
B. Serial troponins
C. Transesophageal echo
D. Myocardial Perfusion Imaging (MPI)
E. Serial ECGs

A. Cardiac magnetic resonance imaging

Cardiac magnetic resonance imaging has been shown to be very useful in diagnosing myocarditis by visualising markers for inflammation of the myocardium

The patient has clinical and electrocardiographic features of pericarditis. Although a small rise in troponin can be expected in pericarditis, a significant rise should alert you to the possibility of myopericarditis.

Cardiac magnetic resonance imaging has been shown to be very useful in diagnosing myocarditis by visualising markers for inflammation of the myocardium e.g. regional myocardial oedema, hyperaemia and inflammatory necrosis.

All the other options may be useful, however the most sensitive investigation for diagnosing myopericarditis is cardiac MRI.

Question 18 of 129

A 64-year-old man presents to cardiology outpatients with intermittent exertional chest pain. He has suffered from angina for several years and finds his glyceryl trinitrate spray effective, but he is keen on further treatment to help his symptoms. His past medical history includes angina, asthma, and type 2 diabetes. His current medication includes salbutamol, montelukast, Fostair, metformin, amlodipine, glyceryl trinitrate, aspirin and simvastatin.

Observations are temperature 37ºC, heart rate 52 beats/min, blood pressure 98/59 mmHg, respiratory rate 14 breaths/min, and oxygen saturation 96%.

What is the most appropriate additional therapy?

A. Bisoprolol
B. Isosorbide mononitrate
C. Ivabradine
D. Ranolazine
E. Verapamil

D. Ranolazine

For a patient with symptomatic stable angina on a calcium channel blocker but with a contraindication to a beta-blocker, the next line treatment should be long-acting nitrate, ivabradine, nicorandil or ranolazine

The correct answer is **ranolazine**. This patient has stable angina despite the use of first-line anti-anginal therapy with amlodipine. NICE recommends using either a beta-blocker or a dihydropyridine calcium channel blocker as first-line anti-anginal.

There are a number of options for next-line treatment for patients on a calcium channel blocker, including the addition of a beta-blocker, longacting nitrate, ivabradine, nicorandil or ranolazine. In this case, **ranolazine** would be the most appropriate, as the other options have either cautions or contra-indications.

Given that this patient has asthma, it would be best practice to avoid a beta-blocker such as **bisoprolol**, especially if other equally appropriate therapy options are available.

Given that this patient already has a slightly low blood pressure on the candesartan alone, it would be best to avoid adding in **isosorbide mononitrate** as this risks dropping the blood pressure further.

Ivabradine is contra-indicated in bradycardia. The BNF states 'do not initiate for angina if heart rate below 70 beats per minute'.

The patient is already on a dihydropyridine calcium channel blocker, therefore adding a non-dihydropyridine calcium channel blocker such as **verapamil** should be avoided.

Question 19 of 129

A 35-year-old woman presented to the emergency department with intermittent palpitations, breathlessness, and non-specific chest discomfort. The previous day she had found out that she was 14-weeks pregnant which had caused significant stress and anxiety. She has a long history of anxiety and depression, managed by cognitive behavioural therapy. She reported that she had intermittently had episodes of palpitations and shortness of breath for the past 10 years and had attributed this to her anxiety. These symptoms had worsened over the past couple of weeks and today her symptoms were intolerable. Her medications consisted of over-the-counter vitamin supplements.

She looked anxious, but otherwise, the examination was unremarkable. An ECG was performed:

ECG #1: Normal sinus rhythm. T wave inversion in V1 - V3.

Whilst in the emergency department, she complained of severe palpitations and dizziness.

Her ECG was repeated:

ECG #2: Wide complex regular tachycardia with left bundle branch block (LBBB) pattern. Heart rate 150bpm. Fusion beats and capture beats present.

As she was being transferred into resus, she spontaneously cardioverted back to sinus rhythm.

An echocardiogram was performed:

The right ventricle is dilated with depressed right ventricular systolic function and localised apical aneurysm. Left ventricular size and function are normal.

What is the most likely cause of her presentation?

A. Aortic dissection
B. Takutsubo cardiomyopathy
C. Peripartum cardiomyopathy
D. Arrhythmogenic right ventricular cardiomyopathy
E. Brugada syndrome

D. Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy - T wave inversion in V1-3

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterised by the replacement of the myocardium of the right ventricle with fibrofatty tissue. The abnormal fibrofatty tissue predisposes to ventricular tachycardia (VT), right ventricular systolic dysfunction, and can cause sudden death. It is often inherited but can be sporadic. Presentation is often with nonspecific palpitations, chest discomfort, and syncope. This patient has a typical presentation: the pregnancy-associated increase in stroke volume is likely the trigger for her symptoms recently worsening. Her two ECGs are characteristic: typical changes include inverted T waves in the precordial leads V1-V3 (looking at the right ventricle) with episodes of ventricular tachycardia originating in the right ventricle (giving the ECG a LBBB morphology as the arrhythmia takes an abnormal route of conduction from right to left through slowly-conducting myocardium rather than conducting tissue). Epsilon waves may also be seen in ARVC. Her echocardiogram is also characteristic - infiltration and thinning of the right ventricular wall can occur to the point that systolic function is impaired and an aneurysm forms.

Note that the differential for a wide-complex regular tachycardia on an ECG includes SVT with aberrant conduction (as well as VT). However, the fusion beats and capture beats are more in keeping with VT in this case.

This patient's presentation is not typical for aortic dissection. An echo might see cardiac tamponade or new aortic regurgitation if this was the diagnosis but this is not the case here.

Takutsubo cardiomyopathy is caused by transient systolic dysfunction of the left ventricle (LV), presenting similarly to an acute coronary syndrome. Patients typically have chest pain, a raised troponin, and ECG findings consistent with ischaemia such as ST elevation/T wave inversion. This is typically triggered by recent physical or emotional stress. Patients are initially managed as an ACS but cardiac angiography shows no significant coronary artery disease. Instead, the LV wall shows hypokinesis or akinesis which creates the shape of an 'octopus pot' during systole. It may be argued that this patient has experienced a recent stressor (the news of pregnancy) however her presentation, long history of symptoms, and echo findings are more in keeping with AVRC.

Peripartum cardiomyopathy (PPCM) is a rare type of cardiomyopathy that is often dilated and occurs in late pregnancy or early postpartum (typically one month before or after birth). The aetiology is unclear but is thought to be multifactorial. Criteria for diagnosis of PPCM include impairment of LV systolic function (LVEF <45%) which was not the case in this patient. Furthermore, this patient presented in the early second trimester - too early for PPCM but late enough for pregnancy-related haemodynamic changes to trigger her underlying ARVC.

Lastly, Brugada syndrome is another important differential to consider in young patients with palpitations, ECG changes in V1-V3, and episodes of VT. Brugada is caused by an inherited mutation in the cardiac sodium channel. However, echocardiography is typically normal and an ECG may show unusual ST elevation in V1-V3 with T wave inversion in these leads.

Question 20 of 129

A 67-year-old woman with recurrent pulmonary emboli secondary to antiphospholipid syndrome presents with worsening dyspnoea on exertion. The dyspnoea is accompanied by chest pain when she climbs the stairs.

On examination, she is on 2L oxygen and saturating at 94%, there is cyanosis seen under the tongue, a raised jugular venous pressure is seen and a right ventricular heave is felt.

Troponin	3 ng/L	(<14)
Pro-Brain Natriuretic Peptide	2300 pg/ml	(<100)

The CT pulmonary angiogram does not demonstrate any large pulmonary emboli. An echocardiogram shows right ventricle hypertrophy and moderate tricuspid regurgitation. Upon right heart catheterisation, the pressures in the pulmonary artery are 30mmHg and after inhaled nitric oxide drops to 20mmHg.

What is the next best management option?

A. Bosentan
B. Iloprost
C. Increase apixaban dose
D. Nifedipine
E. Sildenafil

D. Nifedipine

Pulmonary arterial hypertension patients with positive response to vasodilator testing should be treated with calcium channel blockers

Nifedipine is the correct option as an oral calcium channel blocker to treat this vasodilator (nitric oxide) responsive form of pulmonary arterial hypertension. The calcium channel blocker has proven efficacious in dilating the pulmonary vasculature to a sufficient degree to improve her symptoms.

Bosentan is an incorrect option as it is an endothelin receptor antagonist, which is used in patients who do not respond to vasodilator testing.

Iloprost is an incorrect option as it is a prostacyclin analogue, best utilised when the patient has not responded to vasodilator testing.

Sildenafil is an incorrect option as this would be a viable treatment option for the majority of patients because the majority do not respond to vasodilator testing. Sildenafil is a phosphodiesterase type 5 inhibitor.

Increase apixaban dose when the patient is on the recommended dose is an incorrect option because this will be an unlicensed use of the apixaban and would not reverse pulmonary hypertension which has likely been established from previous, recurrent pulmonary emboli.

Question 21 of 129

A 55-year-old man presents to the emergency department with sudden cardiac arrest. The patient has no known history of heart disease. The initial pulse and rhythm analysis confirms pulseless ventricular tachycardia.

What medications are indicated as part of the advanced life support algorithm?

A. Adrenaline after third shock
B. Adrenaline and amiodarone after third shock
C. Adrenaline and amiodarone immediately
D. Adrenaline immediately
E. None

B. Adrenaline and amiodarone after third shock

In ALS, amiodarone 300 mg should be given to patients who are in VF/pulseless VT after 3 shocks have been administered.

This patient has a shockable rhythm (pulseless ventricular tachycardia (VT)) and therefore requires adrenaline and amiodarone to be administered after the third cycle.

Adrenaline after the third cycle is incorrect; this should be given with amiodarone for shockable rhythms.

As per the resuscitation guidelines, giving **adrenaline + amiodarone immediately** is incorrect as these should only be given after three cycles.

Adrenaline immediately is incorrect as this is the treatment for nonshockable rhythms, however pulseless VT is considered a shockable rhythm.

To give **none** is incorrect as the resuscitation guidelines state that both adrenaline and amiodarone have a role in shockable cardiac arrests.

Question 22 of 129

A 64-year-old man is reviewed on the coronary care unit and is making a good recovery 2 days post-myocardial infarction. On examination, he appears well and is haemodynamically stable. His heart rate is 72 beats/min and his blood pressure is 132/84 mmHg.

A 12-lead ECG is performed and shows isorhythmic dissociation between P waves and QRS complexes. The QRS complexes are wide and fusion beats are visible on the ECG.

Given the likely diagnosis, which of the following is the most appropriate management?

A. Amiodarone
B. Atropine
C. Discharge with standard follow up
D. Magnesium
E. Pacemaker insertion

C. Discharge with standard follow up

Accelerated idioventricular rhythm is common and unconcerning following recent MI

The diagnosis here is accelerated idioventricular rhythm (AIVR). This is a benign ectopic rhythm of ventricular origin. It usually occurs with reperfusion following a myocardial infarction. It is differentiated from ventricular bradycardias and tachycardia by its normal rate - in this case, 72 beats/min. Reperfusion of ischaemic tissue leads to increased depolarisation rate of ventricular myocytes, which then override the sinoatrial node, leading to dissociation between the atrial and ventricular rhythms as seen here (P waves and QRS are isorhythmically dissociated). As the patient is hemodynamically stable, treatment is not necessary;

AIVR is generally self-limiting.

Amiodarone would be used in the cases of ventricular tachycardia. Although there are some overlapping features on the ECG, the patient's heart rate is normal and AIVR is strongly suggested here. Antiarrhythmics are therefore unnecessary.

Atropine is occasionally used to increase the sinus rate and overcome AIVR, however, this is mainly in symptomatic patients. Generally, the condition is self-limiting and in hemodynamically stable patients no treatment is required.

Magnesium is used to treatment torsades de pointes, a polymorphic form of ventricular tachycardia which is recognisable on ECG. It plays no role in the management of AIVR.

Pacemaker insertion is unwarranted. As described above, this condition is self-limiting.

Question 23 of 129

You receive a phone call requesting advice from a GP. A patient who is on long term warfarin for atrial fibrillation has been found to have an INR of 10.0 following a recent course of antibiotics. She is not bleeding and only has long standing senile purpura on her arms with no new bruising.

What is the most appropriate advice to give?

A. Admit for intravenous vitamin K and monitoring
B. Give oral vitamin K and continue warfarin at usual dose
C. Give oral vitamin K and stop warfarin until INR < 5
D. Give oral vitamin K and stop warfarin until INR < 3
E. Stop warfarin and restart when INR < 3

C. Give oral vitamin K and stop warfarin until INR < 5

INR > 8.0 (no bleeding) - stop warfarin, give oral vitamin K 1-5mg, repeat dose of vitamin K if INR high after 24 hours, restart when INR < 5.0

The correct answer is to **give oral vitamin K and stop warfarin until INR < 5**. This is because the patient has a significantly elevated INR of 10.0 but no active bleeding or high risk of bleeding. According to the UK guidelines, in this situation, it is appropriate to give oral vitamin K (usually 1-5 mg) and withhold warfarin until the INR is below 5. This will allow for a rapid reduction in INR and reduce the risk of bleeding complications.

The option **admit for intravenous vitamin K and monitoring** is not the most appropriate choice in this case, as the patient does not have any active bleeding or high risk of bleeding. Intravenous vitamin K and hospital admission are generally reserved for patients with lifethreatening bleeding or an extremely high risk of bleeding.

The option **give oral vitamin K and continue warfarin at usual dose** would not be suitable, as continuing warfarin without interruption would maintain an elevated INR level, increasing the risk of bleeding complications. It is important to withhold warfarin temporarily to allow the INR to decrease.

The option **give oral vitamin K and stop warfarin until INR < 3** might seem reasonable; however, stopping warfarin until an INR of less than 3 could lead to subtherapeutic anticoagulation levels for this patient with atrial fibrillation. The goal therapeutic range for most patients on warfarin with atrial fibrillation is an INR between 2 and 3. Stopping warfarin until the INR falls below this range may increase their thromboembolic risk.

Finally, choosing to simply **stop warfarin and restart when INR < 3**, without administering oral vitamin K, would result in a slower reduction of INR. This could leave the patient at an increased risk of bleeding complications for a longer period. Oral vitamin K helps to lower the INR more rapidly and safely.

Question 24 of 129

A 65-year-old man is reviewed in the Emergency Department. Twelve months ago he had a prosthetic aortic valve replacement for progressive aortic stenosis. Since the operation he has been well but over the past two weeks he has been complaining of lethargy, fever and anorexia. Blood tests show a CRP of 215 mg/l. The chest x-ray and urine dip are unremarkable.

Given the suspicion of infective endocarditis an transoesophageal echocardiogram is performed which demonstrates a large vegetative lesion around the prosthetic aortic valve.

What is the most appropriate antibiotic treatment whilst awaiting blood cultures?

A. IV amoxicillin
B. IV teicoplanin + vancomycin
C. IV flucloxacillin + low-dose gentamicin
D. IV vancomycin + rifampicin + low-dose gentamicin
E. IV teicoplanin + rifampicin

D. IV vancomycin + rifampicin + low-dose gentamicin

IV vancomycin + rifampicin + low-dose gentamicin is the empirical treatment of choice in prosthetic valve endocarditis

The correct answer is **IV vancomycin + rifampicin + low-dose gentamicin**. In a patient with a prosthetic valve and suspected infective endocarditis, the most likely causative organisms are staphylococci (including methicillin-resistant Staphylococcus aureus [MRSA]), streptococci, and enterococci. The combination of IV vancomycin, rifampicin, and low-dose gentamicin provides coverage against these organisms while awaiting blood culture results. Vancomycin is effective against MRSA and other gram-positive bacteria, rifampicin has good penetration into biofilms on prosthetic material and enhances the activity of vancomycin, and gentamicin provides additional synergistic bactericidal activity.

IV amoxicillin is not the most appropriate choice in this case because it does not provide adequate coverage for MRSA or resistant enterococci. Amoxicillin is typically used as part of empirical treatment for native valve endocarditis caused by streptococci but would not be sufficient for a prosthetic valve infection where staphylococcal involvement is more common.

IV teicoplanin + vancomycin would not be an appropriate choice because combining two glycopeptides offers no additional benefit over using just one of them. Both teicoplanin and vancomycin have similar spectra of activity against gram-positive bacteria; however, they do not cover gram-negative organisms or provide synergy with other antibiotics.

IV flucloxacillin + low-dose gentamicin would be inadequate in this situation as flucloxacillin does not cover MRSA or resistant enterococci. Flucloxacillin is effective against methicillin-sensitive staphylococci but would not provide broad enough coverage for a prosthetic valve infection where resistant organisms are more likely to be involved.

IV teicoplanin + rifampicin is not the best choice because it lacks the synergistic bactericidal activity provided by the addition of low-dose gentamicin. Although teicoplanin and rifampicin would cover most gram-positive organisms, including MRSA, the absence of gentamicin could result in suboptimal treatment for enterococci and other resistant bacteria.

In conclusion, **IV vancomycin + rifampicin + low-dose gentamicin** is the most appropriate empirical antibiotic treatment for a patient with suspected infective endocarditis involving a prosthetic valve. This regimen provides broad coverage against common causative organisms while awaiting blood culture results and can be adjusted based on culture sensitivities once available.

Question 25 of 129

A 71-year-old patient presents to the Emergency Department with a 30 minute history of crushing central chest pain. ECG shows tall R waves in V1-2.

Which coronary territory is likely to be affected?

A. Lateral
B. Posterior
C. Anteroseptal
D. Anterolateral
E. Inferior

B. Posterior

Posterior MI typically present on ECG with tall R waves V1-2

Question 26 of 129

A 64-year-old man with mitral regurgitation attends the cardiology clinic for review. An ECG reveals new atrial fibrillation.

He is well and denies any shortness of breath or chest pain. His blood pressure is 115/98 mmHg and his heart rate is 64 beats per minute. On examination, he has an audible S3 and a 3/5 pansystolic murmur heard loudest in the mitral area, his apex beat is displaced.

A recent echo showed a regurgitant mitral valve with evidence of left atrial and ventricular dilatation but a preserved ejection fraction.

His current medications include naproxen for osteoarthritis and overthe-counter vitamin D supplements.

From the following options, what would be the most appropriate next step?

A. S Adopt a 'watch and wait' approach with serial yearly echocardiography
B. Commence bisoprolol
C. Commence sacubitril-valsartan
D. Refer for cardioversion
E. Refer for mitral valve replacementubmit answer

New AF in mitral regurgitation -> refer for mitral valve replacement

Refer for mitral valve replacement is the correct answer. This patient has evidence of asymptomatic severe mitral regurgitation as indicated by narrow pulse pressure, audible S3 and evidence of left ventricular dilatation. Given he has now developed atrial fibrillation on a background of severe mitral regurgitation he should be referred for consideration of a valve repair or replacement.

Commence bisoprolol is incorrect. The patient in this scenario has a preserved ejection fraction as indicated by the echo findings. If there was evidence of reduced ejection fraction current NICE guidelines advises considering starting a beta-blocker and ACE inhibitor.

Commence sacubitril-valsartan is incorrect. This would be considered a second-line treatment for heart failure with reduced ejection fraction. In this case, the patient has a preserved ejection fraction.

Adopt a 'watch and wait' approach with serial yearly echocardiography is incorrect. This could be considered as per patient preference, but in the case of severe mitral regurgitation with the development of new atrial fibrillation patients should be offered a referral for mitral valve replacement.

Refer for cardioversion is incorrect. In this case, the patient has known mitral regurgitation. Mitral disease is associated with the development of atrial fibrillation due to the associated structural changes in the left atrium. There is a much higher chance of maintaining sinus rhythm with mitral valve replacement compared to cardioversion. Mitral valve replacement is therefore the preferred option.

Question 27 of 129

You are the on-call medical doctor called to review a patient in the Emergency Department. A 54 year old male patient with a past history asthma, ischaemic heart disease and transient ischaemic attack has presented with palpitations. His admission ECG shows a regular, narrow complex tachycardia. Vagal manoeuvres have been tried in the department with no success. You decide to give intravenous adenosine in an attempt to chemically cardiovert. An initial dose of 6mg is given into a proximal vein with a large flush. The patient soon loses consciousness and an 11 second ventricular standstill is noted on the rhythm strip before slow return of sinus rhythm.

Which of the patient's medications is most likely to be responsible for this?

A. Phyllocontin
B. Dipyridamole
C. Bisoprolol
D. Simvastatin
E. Montelukast

B. Dipyridamole

The effects of adenosine are enhanced by dipyridamole

Adenosine is a useful medication in the investigation and treatment of regular narrow complex tachycardias. With reference to the Resuscitation UK guidelines, it has a place as a second line measure to vagal manoeuvres when no 'adverse features' are present. Adenosine works by transiently blocking the AV node by effect on the A1 receptor, causing potassium efflux and hyperpolarisation.

Dont be side-tracked by the fact that this patient is asthmatic, yes this is a relative contraindication to the administration of adenosine, but that is not the question. Theophyllines have been known to antagonise adenosine necessitating higher dosages. Dipyridamole blocks the cellular uptake of adenosine, increasing concentration at receptors and potentiating its effect. Adenosine should therefore be used with caution, if at all, in patients taking dipyridamole, and certainly low starting doses should be considered.

Question 28 of 129

A 65-year-old man is referred to cardiology outpatient clinic with exertional shortness of breath. He becomes breathless after ascending a single flight of stairs. He has a background of ischaemic heart disease and heart failure with reduced ejection fraction (30%). He is on aspirin, bisoprolol, ramipril, spironolactone, atorvastatin and lansoprazole. He does not smoke or drink alcohol.

His observations are heart rate 63 beats per minute, blood pressure 120/77 mmHg, respiratory rate 18/minute, oxygen saturations 96% on room air and temperature 37ºC.

On examination, he is euvolemic. Chest auscultation is normal. There is no peripheral oedema. The pulse is regular.

From the listed options, what is the best medication choice to improve his symptoms?

A. Add ivabradine
B. Add nicorandil
C. Add sacubitril-valsartan
D. Replace ramipril with ivabradine

E. Replace ramipril with sacubitril-valsartan

E. Replace ramipril with sacubitril-valsartan

Sacubitril-valsartan is considered in heart failure patients with a LVEF < 35% who are still symptomatic on ACE-inhibitors & betablockers

Replace ramipril with sacubitril-valsartan is the correct answer. This man has NYHA class II/III heart failure not controlled with an ace inhibitor, beta blocked and mineralocorticoid receptor antagonist. Given his ejection fraction is < 35%, replacing ramipril with sacubitril-valsartan is a suitable option to improve the clinical situation.

Add ivabradine is incorrect. This would be an option if his heart rate was > 75 beats per minute.

Add sacubitril-valsartan is incorrect. This should replace an ace inhibitor rather than be added to this treatment.

Replace ramipril with ivabradine is incorrect. This is not a substitution recommended by guidance and the patient's heart rate is too low for the addition of ivabradine.

Add nicorandil is incorrect. This medication is used in the treatment of stable angina, rather than heart failure.

Question 29 of 129

A 72-year-old man is reviewed in the cardiology outpatient department with worsening shortness of breath, which now occurs at rest. He has a past medical history of heart failure with reduced ejection fraction and ischaemic heart disease. His medications include bisoprolol, ramipril, and spironolactone.

On examination, he is clinically euvolemic.

An ECG demonstrates a QRS of 140ms and a left bundle branch block.

What intervention is most likely to improve the patient's symptoms?

A. Amiodarone
B. Biventricular pacemaker
C. Dual chamber pacemaker
D. Implantable cardiac defibrillator
E. Single chamber atrial pacemaker

B. Biventricular pacemaker

Cardiac resynchronisation therapy can be used in patients with a QRS duration of >130 msec and LBBB morphology to improve symptomatology

Biventricular pacemaker is correct. Cardiac synchronization therapy (CRT) with a biventricular pacemaker has been shown to improve heart failure symptoms in those patients with a QRS duration > 130ms and LBBB morphology, inadequately controlled on optimal medical therapy. He has NYHA class IV heart failure as he has symptoms at rest. Typically, leads of this pacemaker are placed in both ventricles and often one in the right atrium in addition. They are designed to help the heart contract more efficiently

Amiodarone is incorrect. This is typically used to control abnormal tachyarrhythmias. It has not been shown to improve symptoms in patients with chronic heart failure.

Dual chamber pacemaker is incorrect. This type of pacemaker paces both the right atrium and right ventricle. It is indicated in conditions such as high-grade atrioventricular block rather than advanced heart failure as in this patient.

Implantable cardiac defibrillator is incorrect. This is typically indicated in patients with serious ventricular arrhythmias at risk of sudden death. It can be used for some patients with NYHA class I-III heart failure and a prolonged QRS 120-149ms but without LBBB. However, if there is an LBBB morphology as in this case then a CRT is preferred to improve the symptoms of heart failure.

Single chamber atrial pacemaker is incorrect. This is a pacemaker that usually paces just the right atrium. This type of pacemaker has largely fallen out of favour as they require intact atrioventricular conduction and do not safeguard against this failure in the future. Typically, this type of pacing would only be used for severe symptomatic sinus bradycardia or sick sinus syndrome. It would not result in the required synchronization of ventricular contraction which would result in improved symptoms of heart failure

Question 30 of 129

A 56-year-old gentleman has presented with central chest tightness with a strangling feeling in his jaw. This started four hours ago and he has become increasingly breathless. He feels clammy and has vomited twice. He felt well prior to today and only has a history of refractory hypertension.

On examination, he is alert with a Glasgow Coma Scale of 14/15. He is clutching his chest with one hand. Both heart sounds are present with a loud pan systolic murmur and there is air entry heard throughout. His JVP is raised at 4cm and there are cannon V waves present. There is no ankle swelling or oedema. His liver is palpable and pulsatile. His blood pressure is 190/110 mmHg, heart rate 90/min and he is saturating at 92% in

Hb	130 g/l	Na	139 mmol/l
Platelets	356 * 10 /l	K	4.6 mmol/l
WBC	13.4* 10 /l	Urea	5.4mmol/l
Neuts	9.4 * 10 /l	Creatinine	76 µmol/l
Lymphs	2.3 * 10 /l	CRP	14 mg/l
Troponin	1640 ng/ml (normal range <20)		
ECG	ST depression in leads V1-V3, sinus rhythm		
Chest X-ray	enlarged cardiac shadow		

What is the likely diagnosis?

A. Infective endocarditis
B. Right ventricle myocardial infarction
C. Anteroseptal myocardial infarction
D. Dilated cardiomyopathy
E. Aortic dissection

B. Right ventricle myocardial infarction

Right ventricle infarction -> tricuspid regurgitation

This gentleman presents with acute onset chest pain and has been well prior to this. Infective endocarditis would present more insidiously and is typically painless. Cardiomyopathy does not present with chest pain. Aortic dissection usually has a tearing pain that radiates to the back. The ECG changes represent reciprocal changes seen in a posterior myocardial infarction. The cannon V waves are pathognomonic for a right sided heart failure which occurs during infarction of the right ventricle. Furthermore, the pansystolic murmur would reflect tricuspid regurgitation. Both these features occur in right ventricle infarcts.

Question 31 of 129

You review a patient in cardiology outpatient clinic. He has a left ventricular ejection fraction of 15% on maximal medical therapy. On reviewing his ECG you note a QRS duration of 135ms without evidence of left bundle branch block. Upon taking a history you note the patient is breathless at rest and struggles to walk around his bungalow.

Which implantable device would be appropriate to consider?

A. Cardiac resynchronisation therapy without defibrillator
B. Cardiac resynchronisation therapy with defrifibrillator
C. VVI pacemaker
D. No implantable device recommended
E. Implantable cardioverter defibrillator alone

A. Cardiac resynchronisation therapy without defibrillator

The patient has New York Heart Association Class IV symptoms as he is limited by breathlessness at rest and on minimal exertion. The NICE guidance on implantable devices and resynchronisation therapy would suggest cardiac resynchronisation therapy (without defibrillator) in the above case as QRS is between 120 and 149ms without evidence of left bundle branch block.

VVI pacing is useful in atrial fibrillation with slow ventricular response.

NICE TA314: Implantable cardioverter defibrillators and cardiac resynchronisation therapy for arrhythmias and heart failure.

Question 32 of 129

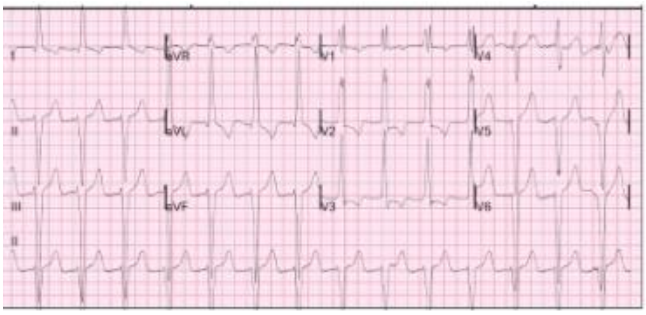
A 70-year-old presents to the outpatients' department having been referred by his GP with on-off palpitations for several months. The patient has a myocardial infarct over 20 years ago which was successfully managed via thrombolysis but otherwise, he has no significant past medical history.

The patient reports he has spontaneous episodes of palpitations approximately once every 2 weeks, and occasional feeling faint. He fainted once when walking quickly for the bus and so now takes it slowly when exerting himself and has no further similar episodes. He is otherwise very well and denies any episodes of chest pain etc.

He is on secondary preventive medication including:

- Aspirin low dose
- Bisoprolol 10mg twice daily
- Atorvastatin 40mgs once daily
- Ramipril 10mg once daily

His examination and observation are normal and an ECG performed is shown below.



What is the most appropriate management plan for the patient?

A. Admit for urgent ablation workup
B. Admit for urgent pacemaker workup
C. No additional management is required
D. Reduce the dose of his beta-blocker
E. Arrange for urgent 24-hour Holter monitor

B. Admit for urgent pacemaker workup

The patient's ECG show trifascicular block with a right bundle branch block (RBBB), left anterior hemiblock and 1st-degree heart block. This with the history of pre-syncope and syncope is concerning and is an indication for admission and pacemaker workup as the patient is at risk of further significant arrhythmias or cardiac blocks.

Trifascicular block is a ventricular escape rhythm that usually arises from the left anterior or posterior fascicle regions following ischaemic heart disease or structural heart disease. As such ablation is not a viable treatment option. Symptomatic trifascicular block is an indication for implantable cardiac pacemaker or permanent pacemaker work up.

The patient has concerning features of symptomatic trifascicular block with pre-syncope and syncope on exertion which warrants urgent assessment for a pacemaker.

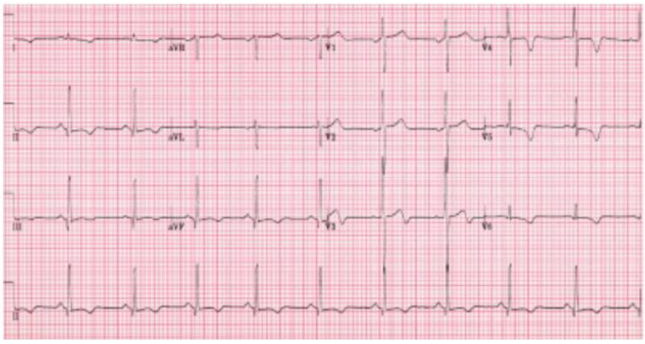
The patient's trifascicular block is very unlikely to be associated with his beta-blocker medication and therefore reducing the dose will not remove the risk of further significant arrhythmias or cardiac blocks.

Arranging for an urgent 24-hour Holter monitor is unnecessary as the patient's ECG is unlikely to change and the current risk of arrhythmias or heart block requires urgent intervention

Question 33 of 129

A 34-year-old is brought into the emergency department following a syncope episode whilst playing tennis. The patient reports he is now feeling well with no symptoms. On further questioning, he only plays tennis occasionally and does not exercise regularly. He reports experienced shortness of breath and chest discomfort when playing and has had a few episodes of feeling light-headed but has never fainted before. He is otherwise well with no recent illness or significant past medical history.

Observations are all within normal range and an ECG performed is shown below



What is the patient's most likely diagnosis?

A. Brugada syndrome
B. Dilated cardiomyopathy
C. Hypertrophic obstructive cardiomyopathy
D. Arrhythmogenic right ventricular dysplasia (ARVD)
E. Wellen's syndrome

C. Hypertrophic obstructive cardiomyopathy

This patient has presented with features in keeping with hypertrophic obstructive cardiomyopathy (HOCM). The condition is due to a genetic defect that causes a disorder of the cardiac muscle and, although patients can be asymptomatic, it is the commonest cause of sudden cardiac death in the young. Patients who do present with symptoms typically experience exertional dyspnoea, angina and syncopal episodes, commonly following or during exertion. ECG findings are of left ventricular hypertrophy, non-specific ST-segment and T-wave abnormalities, progressive T wave inversion and deep Q waves. On this patient's ECG widespread T wave inversion can be seen, especially in lead I & II as well as non-specific ST-segment changes in V2 & 3. The diagnosis can be confirmed via cardiac echo and management is dependant on the extent of obstruction and patient symptoms.

Brugada syndrome is another genetic cardiac disorder however unlike HOCM it results in electrical activity disorders and not structural issues. Features include syncope and sudden cardiac death however it is not always associated with exertion or exercise. There are several types of Brugada syndrome, each with variations seen on ECG. However, the only potentially diagnostic ECG abnormality is of coved ST-segment elevation in 2 or more of V1-3 followed by a negative T wave. This is classical of Brugada type 1 syndrome and is commonly known as the Brugada sign.

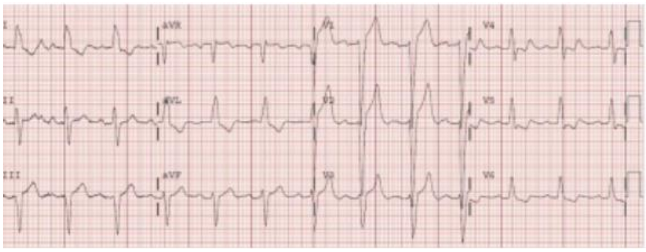
Dilated cardiomyopathy is a disease of the myocardial and characterised by progressive ventricular dilation and dysfunction. Presentation is normal with worsening biventricular failure including peripheral and pulmonary oedema. Syncope episodes are rare and symptoms are not fluctuant, as seen in this patient. ECG abnormalities are those associated with atrial and ventricular hypertrophy with conduction delays (e.g. LBBB), left axis deviation and poor R wave progression.

Arrhythmogenic right ventricular dysplasia (ARVD), also known as arrhythmogenic right ventricular cardiomyopathy (ARVC), is a result of a genetic defect affecting the desmosomes of the myocardium. ARVD results in non-ischemic cardiomyopathy, mainly affecting the right ventricle. The condition leads to hypokinetic areas of the ventricle wall and myocardium fibrofatty replacement with which results in associated arrhythmias. Patients typically present with palpitations, syncope, and potentially sudden cardiac death however ECG findings are of T wave inversion in leads V1 to V3 and of right bundle branch block which are not present in this case.

Wellen's syndrome is the ECG pattern of biphasic or deeply inverted T waves in the chest leads V2-3. It is highly specific for critical stenosis of the left anterior descending artery and therefore is normally seen in patients presenting with ischaemic-like symptoms

Question 34 of 129

A 76-year-old man is brought to the Emergency Department by the paramedics after experiencing an episode of chest pain. This came whilst he was walking his dog and lasted around 20 minutes. He is now pain free. The paramedics report that his blood pressure is 126/88mmHg, pulse 75/min and oxygen saturations 98% on room air. On examination you note a systolic murmur. An ECG is requested:



What does the ECG show?

A. Hypertrophic obstructive cardiomyopathy
B. Anterior myocardial infarction
C. Left bundle branch block
D. Brugada syndrome
E. Arrhythmogenic right ventricular cardiomyopathy

C. Left bundle branch block

The ECG shows typical changes of left bundle branch block (LBBB). The systolic murmur may be explained by aortic stenosis, a known association of LBBB. Cardiac ischaemia should of course be considered in patients with LBBB, particularly if it is new. A troponin level will help clarify matters but patients with ongoing chest pain and LBBB should be transferred to the cath lab.

Question 35 of 129

A 66-year-old gentleman requests to see his general practitioner, concerned regarding one of the medications that he was started on following a myocardial infarction. He tells you that the cardiology team has started him on atorvastatin, which he does not wish to take unless there is no other alternative, as he has had relatives that had bad experience with simvastatin, including muscle pain and disturbed sleep.

He has no family history of hypercholesterolaemia at a young age, but a number of his relatives are on statins following cardiac events.

What options exist with regards to his secondary prevention?

A. Ezetimibe 10 mg OD
B. Continue with atorvastatin at the current dose
C. Fenofibrate 160 mg OD
D. Lomitapide 5 mg OD
E. Niacin (as per product literature)

B. Continue with atorvastatin at the current dose

Statins are the only lipid-regulating drugs that are used in secondary prevention of cardiovascular disease (with the exception of ezetimibe in cases of primary hypercholesterolaemia)

With regards to secondary prevention the only NICE approved medication at the moment is statins. None of the other drugs mentioned above are licensed for secondary prevention with the exception of ezetimibe in primary hypercholesterolaemia. There is no indication, in a 66 year old gentleman that he is suffering from primary hypercholesterolaemia. As no dose is given in the question, one should assume that continuing at the current dose provided that the patient understands that no alternative exists is the right answer. Indeed if a dose was given, reducing the dose or switching to an even more hydrophilic agent (such as pravastatin) would be an appropriate option.

Question 36 of 129

A 50-year-old patient with no prior medical history presents to the Emergency Department with crushing central chest pain. On examination you find:

- Respiratory rate - 22/min
- Oxygen saturations 95% on room air Chest clear
- Pulse 118bpm
- Blood pressure 92/61mmHg
- JVP elevated 4cm above sternal angle

An ECG done in the department shows 3mm ST segment elevation in leads II, III and aVF. The patient undergoes a primary PCI to his right coronary artery with a good angiographic result. An echocardiogram is performed the following day.

What would you expect to see?

A. Regional wall motion abnormality in the inferior wall of the LV
B. Regional wall motion abnormality in the inferior wall of the LVwith a dilated and impaired RV
C. Normal biventricular function
D. Constrictive pericarditis
E. Regional wall motion abnormality in the inferior wall of the LVwith mitral regurgitation

B. Regional wall motion abnormality in the inferior wall of the LVwith a dilated and impaired RV

This patient has had an inferior STEMI, as evidenced by the fact that he has ST elevation is leads II, III, aVf. Given this presentation, you would expect an echocardiogram to show a regional wall motion abnormality (RWMA) in the inferior wall of the LV. However, there are some additional key points in his examination findings that are necessary to appreciate in order to correctly answer this question. Firstly, he has significant hypotension which is not usual in the setting of an uncomplicated inferior STEMI. In addition, the patient has an elevated JVP which is indicative of elevated RV filling pressures and therefore RV failure. The fact that he has a clear chest indicates that he has relatively normal LV filling pressures, thus ruling out RV failure secondary to LV failure. Putting these findings together, the diagnosis is an inferior STEMI with right ventricular infarction. Therefore you would expect an echo to demonstrate an inferior LV wall RWMA with a dilated and impaired RV.

Question 37 of 129

A 74-year-old man was admitted with chest pain. He had a past history of type 2 diabetes mellitus and hypertension. He underwent coronary angiography and a stent was inserted into his right coronary artery. Following the procedure he was noted to be oliguric.

On examination his blood pressure was 148/80 mmHg and he was euvolaemic. Mottled skin changes were noted over his legs.

Na +	138 mmol/L	(135 - 145)
K +	5.6 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	17.6 mmol/L	(2.0 - 7.0)
Creatinine	228 µmol/L	(55 - 120)
Creatine kinase	560 U/L	(24-170)
Hb	142 g/L	Male: (135-180)Female: (115 - 160)
Platelets	380 * 10 /L 9	(150 - 400)
WBC	13.6 * 10 /L 9	(4.0 - 11.0)
Neuts	9.1 * 10 /L 9	(2.0 - 7.0)
Lymphs	2.5 * 10 /L 9	(1.0 - 3.5)
Eosin	1.2 * 10 /L 9	(0.0 - 0.4)

What is the most likely diagnosis?

A. Contrast-induced nephropathy
B. Acute interstitial nephritis
C. Cholesterol emboli
D. ANCA associated vasculitis
E. Rhabdomyolysis

C. Cholesterol emboli

AKI following angiography can be caused by contrast-induced nephropathy or cholesterol emboli

Although the commonest cause of acute kidney injury following angiography is contrast-induced nephropathy, the raised eosinophil count and skin rash (livedo reticularis) is highly suggestive of cholesterol emboli.

Acute interstitial nephritis can cause eosinophilia but is not associated with contrast.

ANCA associated vasculitis can cause a rash and eosinophilia (e.g. Churg Strauss) but there are no other features such as anaemia or systemic upset to fit with this.

The elevated creatine kinase suggests muscle injury, which would fit with an embolic phenomenon but the CK is not high enough to diagnose rhabdomyolysis (usually >5000).

Question 38 of 129

A 59-year-old man presents with stridor which came on gradually over the course of the day. On examination you note swelling of the tongue and the mucous membranes of the oropharynx. He has a past medical history of rheumatoid arthritis, type 2 diabetes mellitus and heart failure.

He was recently started on a new medication.

What medicine would be the most likely cause of this presentation?

A. Nimodipine

B. Losartan
C. Lisinopril
D. Prednisolone
E. Sitagliptin

C. Lisinopril

Drug-induced angioedema without urticaria is most frequently associated with angiotensin converting enzyme inhibitors or, less frequently, angiotensin II receptor blockers

Angioedema is a well recognised side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. Angioedema can also be seen with angiotensin receptor blocker (ARB) therapy but much less frequently than is the case with ACE inhibitors. Therefore lisinopril is a better answer than losartan.

ACE inhibitors block the enzyme ACE resulting in increased levels of bradykinin. Bradykinin then accumulates potentially resulting in angioedema.

All the other options can cause peripheral oedema, however not specifically angioedema as described

Question 39 of 129

A 22-year-old Afro-Caribbean man presents with chest pain. He states the pain is sharp in nature, worse on inspiration, and localised to the right lateral chest wall. He has no past medical history and takes no regular medicines.

An ECG is performed:

P waves	Normal morphology
PR interval	140ms
QRS	110ms
QTc	420ms
T waves	Inverted in V1-V6
ST segments	No elevation or depression

What is the most likely explanation of these ECG results?

A. NSTEMI
B. STEMI
C. Normal variant
D. Prinzmetal's angina (variant angina)
E. Stable angina pectoris

C. Normal variant

Widespread T wave inversion in the chest leads can be a normal variant in patients with Afro-Caribbean ethnicity

Coronary artery disease would be very unlikely in a man of this age. The absence of ST elevation makes an acute STEMI even more unlikely. Twave inversion can of course be a feature of an NSTEMI or stable angina, however due to the absence of risk factors, and the patients age, it would be a very unlikely diagnosis.

Prinzmetal's angina due to vasospasm would be a possibility. However this usually presents with ST elevation.

Widespread T-wave inversion in the chest leads can be a normal variant in patients with Afro-Caribbean ethnicity and this would be the most likely diagnosis in a young man with no cardiovascular risk factors.

The patients pain is pleuritic in nature and an alternative diagnosis should therefore be considered (e.g. pneumothorax).

Question 40 of 129

A 62-year-old man presents to the medical take with a persistent fever, fatigue, and a new-onset heart murmur. There is no relevant past medical history of note and no allergies.

The patient is clinically septic. He has a respiratory rate of 22/min, pulse of 112/min, blood pressure of 91/47 mmHg, and a temperature of 38.7ºC. Bedside echocardiography reveals vegetation on the mitral valve. Blood cultures are sent and results are awaited.

What is the most appropriate empirical antibiotic regimen in this case?

A. Amoxicillin +/- gentamicin
B. Benzylpenicillin +/- gentamicin
C. Flucloxacillin
D. Flucloxacillin + rifampicin + gentamicin
E. Vancomycin + gentamicin

A. Amoxicillin +/- gentamicin

IV amoxicillin is the empirical treatment of choice in native valve endocarditis

This patient has presented with infective endocarditis. It is important to note that he has native valves and no organism confirmed on blood cultures as of yet. Therefore, empirical treatment with **amoxicillin +/- gentamicin** should be started.

Benzylpenicillin is indicated in endocarditis confirmed to be of streptococcus origin, with gentamicin to be added depending on sensitivities.

Flucloxacillin is indicated when native valve endocarditis secondary to staphylococci has been confirmed on blood cultures.

Flucloxacillin + rifampicin + gentamicin is indicated in prosthetic valve endocarditis caused by staphylococcus.

Vancomycin + gentamicin is an option for empirical treatment in patients who are penicillin-allergic, however, amoxicillin is preferred where this is not the case.

Question 41 of 129

A 65-year-old man presents to his GP for evaluation. He has no acute complaints. He takes amlodipine and chlorothiazide for hypertension and paracetamol as required for back pain. Physical examination reveals a well-appearing man with a heart rate of 78 beats per minute with a regular rhythm and blood pressure of 162/78 mmHg. His JVP is not visible and you note that he has a sustained non-displaced apical impulse. There are no thrills or audible murmurs and his heart sounds are normal. His chest is clear to auscultation, his abdomen is soft, nontender, and there are no palpable masses or organomegaly, and he has trace pedal oedema. His GP reviews his ECG which was performed earlier that morning.

Which of the following is most likely to be identified on this gentleman's ECG?

A. Third degree heart block with a ventricular escape rhythm
B. Absent P-waves
C. Deep S waves in V1 and V2 and tall R-waves in V5 and V6
D. PR-segment depression and global ST-segment elevation
E. A tall S wave in lead I and Q wave with T wave inversion in lead III

C. Deep S waves in V1 and V2 and tall R-waves in V5 and V6

During a cardiology clinical examination, a sustained apical impulse is consistent with left ventricular hypertrophy, which can be verified on an ECG by identifying deep S waves in V1 and V2 and tall Rwaves in V5 and V6

This gentleman presents to his GP for a routine checkup. He has a medical history of hypertension and is on medication for this, but has evidence of elevated blood pressure in clinic today. Furthermore, on physical examination, he has a sustained non-displaced apical impulse, a finding that typically represents left ventricular hypertrophy, which can arise as a consequence of longstanding hypertension especially when it is not well controlled. Features of left ventricular hypertrophy can be identified on an ECG, and most typically include deep S waves in V1 and V2 and tall R-waves in V5 and V6.

Third-degree heart block with a ventricular escape rhythm typically results in significant bradycardia. This patient has a normal heart rate and so is unlikely to have a complete heart block.

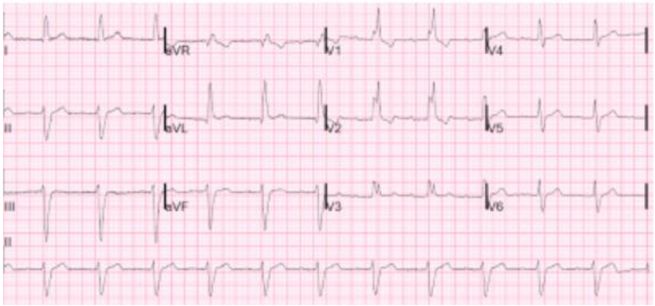
Absent P-waves is a feature of atrial fibrillation which can be detected on a clinical exam as an irregularly irregular pulse. This gentleman has a regular rhythm and is therefore unlikely to have atrial fibrillation.

PR-segment depression and global 'saddle-shaped' ST-segment elevation are findings consistent with acute pericarditis, which typically presents with pleuritic chest pain worse when lying flat, and relieved when sitting forward. This patient has no symptoms at present and so is unlikely to have acute pericarditis.

A tall S wave in lead I and Q wave with T wave inversion in lead III, socalled 'S1 Q3 T3' is a finding associated with an acute pulmonary embolus. This patient is asymptomatic and is unlikely to have a pulmonary embolus.

Question 42 of 129

A 77-year-old man is reviewed in the cardiology. He presented to his GP with intermittent dizziness and reduced exercise tolerance. An ECG accompanies the referral letter:



What does the ECG show?

A. Left bundle branch block
B. Long QT syndrome
C. ECG changes consistent with hypokalaemia
D. Bifascicular block
E. Trifascicular block

E. Trifascicular block

RBBB +left anterior or posterior hemiblock + 1st-degree heart block = trifascicular block

The ECG demonstrates RBBB + left anterior hemiblock + 1st-degree heart i.e. trifascicular block.

Question 43 of 129

A 56-year-old lady with previously diagnosed rheumatic heart disease with mitral stenosis attends for her annual review. She remains fit and well and can walk 100 metres before she develops breathlessness. She gets occasional burning pains in her chest that come on after rich meals and last 20-30 minutes.

She currently takes aspirin, ramipril and a statin. She does not smoke and is taking regular walks each day. On examination, she has a loud S1 heart sound with a mid-diastolic murmur heard in full expiration when in the left lateral position. Her face has a red flush in the cheeks and there is no JVP visible. Her chest is clear and there is no oedema.

Hb	104 g/l	Na +	139 mmol/l
Platelets	450 * 10 /l 9	K +	5.2 mmol/l
WBC	5.6 * 10 /l 9	Urea	4.5 mmol/l
Neuts	4.5 * 10 /l 9	Creatinine	78 µmol/l
Lymphs	0.3 * 10 /l 9	CRP	14 mg/l
Troponin	negative		
ECG	sinus rhythm, left ventricular hypertrophyChest X-ray enlarged cardiac shadow with loss of the aorto-pulmonary window		
ECHO (today)	mitral valve cross sectional area 0.8cm , LV ejection fraction 60%2		
ECHO (1yr ago)	mitral valve cross sectional area 1.1cm , LV ejection fraction 62%2		

What is the most appropriate intervention?

A. Refer to cardiothoracic surgery
B. Furosemide
C. Routine follow up with ECHO in 1 year
D. Repeat ECHO in 6 months
E. Coronary angiogram

A. Refer to cardiothoracic surgery

Mitral stenosis with cross sectional area of <1cm2 warrants surgical intervention

This lady has known mitral stenosis. She has a valve cross sectional area of less than 1cm which is an indication for mitral valve surgery and should be referred immediately. Furosemide would not benefit her as there is no sign of overload. She could continue ECHO surveillance but this will not change her situation. The burning chest pains do not sound cardiac in nature and it would probably be worth trialling omeprazole.

Question 44 of 129

A 64-year-old gentleman is admitted to the hospital's coronary care unit following an anterior ST-elevation myocardial infarction requiring revascularisation. This was successfully done using two drug eluding stents in his left anterior descending artery. Angiography during the procedure did not indicate any further lesions.

He has been pain free since his percutaneous intervention and his current examination is unremarkable. His observations include a blood pressure of 124/88 mmHg, a heart rate of 62/min, a respiratory rate of 18/min and he is apyrexial.

He has now had an echocardiogram which indicated moderate ventricular dysfunction (ejection fraction 40-42%), with no residual valvular disease.

His ECG currently is in sinus rhythm, with normal PR interval, a QRS complex of 100 ms, and normal QTc.

His bloods are as follows:

Hb	142 g/L	Male: (135-180)Female: (115 - 160)
Platelets	325 * 10 /L	(150 - 400)
WBC	8.6 * 10 /L	(4.0 - 11.0)
Na	139 mmol/L	(135 - 145)
K	3.9 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)

He is currently on bisoprolol 5 mg OD, enalapril 2.5 mg BD, aspirin 75 mg OD, ticagrelor 90 mg BD, atorvastatin 80 mg OD and GTN spray PRN.

You are asked by your consultant to optimise his medications/management.

What would be your next step?

A. Add ivabradine
B. Increase the bisoprolol
C. Add isosorbide mononitrate modified release
D. Add eplerenone
E. Change ticagrelor to clopidogrel

D. Add eplerenone

Following myocardial infarction, patients with objective heart failure (moderate to severe left ventricular dysfunction) should be initiated on an ACE inhibitor, a beta-blocker, a statin and a mineralocorticoid receptor antagonist provided no contra-indications exist

Given the findings of his echocardiography, one should consider the possibility of addition of a mineralocorticoid receptor antagonist such as eplerenone.

He is currently not symptomatic at all, therefore there is no place in adding isosorbide mononitrate in this patient.

Additionally, given his heart rate one could wonder whether any increase in bisoprolol would render this patient bradycardic.

There is no indication to change his current dual antiplatelet therapy regime.

Ivabradine is a specific inhibition of the pacemaker current, which is used in the management of symptomatic heart failure and ischaemic heart disease that is not managed via the use of typical agents

Question 45 of 129

A 75-year-old gentleman has recently been diagnosed with heart failure following a myocardial infarction. You review him in clinic. He is currently not complaining of any dyspnoea, orthopnoea or paroxysmal nocturnal dyspnoea and he has no persistent leg oedema. There is no other relevant background medical history.

Examination indicates that he is euvolaemic.

His ECG shows sinus rhythm, Q waves in the inferior leads, a PR interval of 208/msec, normal QRS and no signs of intraventricular conduction delay.

He appears rather anxious and is wondering whether there is anything else that he can do in order to reduce his rate of hospitalisation other than maintaining a healthy lifestyle and taking his medications. He is aware that his brother, who suffers with chronic obstructive pulmonary disease, has a just-in-case box at home and is entitled to vaccinations. He is wondering whether there is any vaccinations or additional antibiotics/medications that could be useful to him.

What would you offer this gentleman?

A. Annual pneumococcus vaccination should be offered
B. Phenoxymethylpenicillin prescription (prophylactic)
C. Annual influenza vaccination
D. Haemophilus influenzae B vaccination
E. Pill-in-the-pocket bumetanide

C. Annual influenza vaccination

As part of the broad lifestyle approach to heart failure, annual influenza vaccine should be offered

Patients with heart failure are encouraged to have the influenza and pneumococcus vaccine, as common respiratory infections are more prevalent in that population and have also the propensity of worsening heart failure and causing decompensation.

The correct answer in this case is annual influenza vaccine; pneumococcus vaccination is usually an once-off regime, provided that the patient is not asplenic or suffering from other chronic diseases.

Haemophilus influenzae B vaccination is advocated in patients with asplenia as they are particularly vulnerable to encapsulated organisms but it has no position in the long-term management of heart failure patients.

Phenoxymethylpenicillin and other antibiotics as prophylaxis are not advocated in heart failure management with regards to reducing infection rates.

There is no strong evidence in supporting a 'pill-in-the-pocket' strategy in patients with heart failure, however patients are encouraged to be aware of the potential manipulation needed when it comes to diuretic therapy and when to seek urgent medical care.

Question 46 of 129

A 31-year-old woman is brought into the Emergency Department by her husband. He tells you that she is abnormally drowsy and he has difficulty rousing her. She has a background of depression which is medicated by her General Practitioner, but is otherwise well.

On examination she is afebrile but has dry, warm skin. Her heart rate is 140bpm with a blood pressure of 105/90mmHg. She has a respiratory rate of 8 breaths per minute and saturating at 92% on air. Her Glasgow coma scale (GCS) is 12 (E3V4M5) and she appears agitated. Her pupils are dilated and she has hyperreflexia. Whilst examining her abdomen it is noted that she has a palpable bladder and bowel sounds are absent.

Investigations: Arterial blood gas (ABG):

pH	7.29	(7.35-7.45)
PCO2	7.2 kPa	(4.9-6.1 kPa)
PO2	10.1 kPa	(10-13.1 kPa)
Bicarbonate (HCO3-)	28 mmol/L	(22-28 mmol/L)
Base Excess (BE)	3.1 mmol/L	(-2 to 2 mmol/L)
Sodium	134 mmol/L	(135-145 mmol/L)
Potassium	4.4 mmol/L	(3.5-5.5 mmol/L)
Chloride	105 mmol/L	(95-110 mmol/L)
Lactate	2.1 mmol/L	(0.2-1.6 mmol/L)
Glucose	5.3 mmol/L	(4-7 mmol/L)

ECG - Polymorphic ventricular tachycardia, QTc 500ms.

What is the most important next step in the management of this patient?

A. Synchronised DC cardioversion
B. Intravenous amiodarone
C. Intravenous magnesium sulphate
D. Intravenous lidocaine
E. Intravenous sodium bicarbonate

C. Intravenous magnesium sulphate

IV magnesium sulfate is used to treat torsades de pointes

This woman has had a tricyclic antidepressant (TCA) overdose. In excess, TCAs can cause QT interval prolongation which can predispose to ventricular arrhythmias. A polymorphic ventricular arrhythmia with a prolonged QT interval is characteristic of torsades de pointes. The treatment for this is intravenous magnesium sulphate.

As she currently has a stable blood pressure (systolic > 90mmHg), DC cardioversion would not be appropriate at this stage. Intravenous amiodarone and lidocaine can be used to medically cardiovert a monomorphic ventricular tachycardia, but are not the treatment of choice in torsades de pointes.

Sodium bicarbonate is the first-line treatment of TCA overdose. However, in the presence of torsades de pointes, intravenous magnesium sulphate is the more appropriate choice to give initially.

Question 47 of 129

A 72-year-old man attends the emergency department with mild epistaxis. He denies any other bleeding. He has a past medical history of atrial fibrillation and severe mitral stenosis for which he takes warfarin. Observations are as follows: heart rate 80 beats per minute, blood pressure 145/85 mmHg, respiratory rate 14 breaths per minute, SpO2 96% (on air), and temperature 37.5ºC.

Blood results are as follows:

Hb	144 g/L	Male: (135-180)Female: (115 - 160)
Platelets	72 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
(PT)	114 secs	(10-14 secs)
INR	10.2	(<1.1)
(APTT)	54 secs	(25-35 secs)
Fibrinogen	3.4 g/L	(2 - 4)

You withhold the patient's warfarin.

What further measures are required?

A. Fresh frozen plasma
B. Intravenous 10mg vitamin K
C. Intravenous 3mg vitamin K
D. Platelet transfusion
E. Prothrombin complex concentrate

C. Intravenous 3mg vitamin K

INR > 8.0 (minor bleeding) - stop warfarin, give intravenous vitamin K 1-3mg, repeat dose of vitamin K if INR high after 24 hours, restart when INR < 5.0

The results of the coagulation screen suggest warfarin toxicity. The INR (derived from the PT) is used to monitor warfarin since it is the most representative, however, it is important to remember that warfarin can also prolong the APTT.

Intravenous 3mg vitamin K is correct. The patient has a minor bleed with an INR >8.0. Thus the warfarin should be withheld and the patient should receive intravenous vitamin K 1-3mg. The warfarin should be restarted when the INR < 5.0.

Fresh frozen plasma is incorrect. Fresh frozen plasma (FFP) is not recommended for use as a warfarin reversal agent as it can take hours to work due to the volume required. In warfarin-associated major haemorrhages, FFP should only be given if prothrombin complex concentrate is unavailable.

Intravenous 10mg vitamin K is incorrect. For minor haemorrhage, the dose of intravenous vitamin K recommended is 1-3mg.

Platelet transfusion is incorrect. In the context of haemorrhage, a platelet level of <50 is the standard transfusion trigger, with the exclusion of CNS or posterior eye bleeds in which the transfusion trigger is <100. The patient in this clinical case has a platelet count of 72 and thus does not require a platelet transfusion.

Prothrombin complex concentrate is incorrect. Prothrombin complex concentrate (PCC) is recommended only for major bleeding. PCC will reverse anticoagulation within minutes of administration however administration of vitamin K is also required to counteract the long halflife of warfarin.

Question 48 of 129

A 50-year-old female is admitted on the acute medical take with palpitations. She recalls on-and-off palpitations for over one year, however today they have been ongoing. On examination, she is haemodynamically stable with an irregularly irregular pulse of 140 b.p.m. There is no clinical evidence of heart failure. Her ECG shows atrial fibrillation.

Which of the following medical conditions is a contraindication to initiating beta-blocker therapy in this patient?

A. Intercurrent treatment with dihydropyridine calcium-channel
B. blockers
C. Phaeochromocytoma on phenoxybenzamine
D. Sick sinus syndrome with a permanent pacemaker
E. Second-degree heart block
F. Mild peripheral vascular disease

E. Second-degree heart block

Given the ubiquity of beta-blockers in medical practice it is important to know contra-indications for their use.

Although the most commonly cited contraindication to beta-blocker therapy is asthma / COPD, there is increasing evidence that in the latter cohort, cardioselective beta-blockers (atenolol, bisoprolol, metoprolol) are well-tolerated with a favourable safety profile.

Beta-blockers slow conduction at the AV node and therefore should be avoided in AV nodal disease as they can lead to complete heart block. Thus they should be avoided in second-degree heart block.

Beta-blockers also inhibit beta1-adrenoceptor activity at the sinoatrial node (i.e. are negative chronotropes) so are contraindicated in sick sinus syndrome. However, in the presence of a permanent pacemaker (PPM), beta-blocker use is safe.

Due to the synergistic effect of beta- and calcium-channel blockade on myocardial excitability, non-dihydropyridine calcium channel blockers (diltiazem and verapamil) should not be co-administered with beta blockers.

An untreated phaeochromocytoma causes increased alpha- and betaadrenergic activity. Thus the administration of a beta-blocker alone will lead to unopposed alpha-agonism which can lead to vasoconstriction and refractory hypertension. However, if a patient is taking an alphablocking agent (e.g. phenoxybenzamine), then beta-blockers may also be initiated.

Question 49 of 129

A 57-year-old man with a 2 year history of hypertension is referred for further evaluation due to his blood pressure being difficult to control. The following results were obtained prior to commencing medications:

Na +	148 mmol/l
K +	3.2 mmol/l
Creatinine	130 µmol/l
Renin	102 (7-50 IU/mL ambulatory)
Aldosterone	1105 (N: 80-800 ng/dL ambulatory)
Renin:Aldosterone Ratio	10.8 (< 500)
Plasma Metanephrines	0.35 (<0.50 nmol/L)

These results are most consistent with which of the following:

A. Congenital Adrenal Hyperplasia
B. Phaeochromocytoma
C. Cushing's disease
D. Renovascular disease
E. Primary hyperaldosteronism

D. Renovascular disease

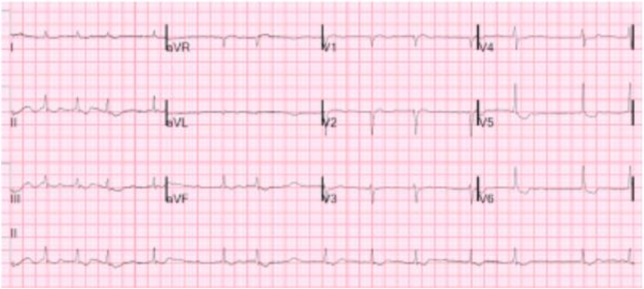
The key underlying diagnosis is renal artery stenosis. The key is that the renin-aldosterone ratio is normal. If it was Conn's disease, or primary hyperaldosteronism the renin would be suppressed. The plasma metanephrines indicate that no pheochromocytoma is present as the sensitivity of plasma metanephrines for a pheochromocytoma approaches 100%.

Question 50 of 129

A 77-year-old woman is seen in a heart failure clinic. Her past medical history includes congestive cardiac failure, atrial fibrillation, hypertension, and depression. Her regular medications include bisoprolol, digoxin, amlodipine, furosemide, and citalopram.

Repeat digoxin levels are displayed below:

Digoxin level	1.1 ng/mL	(0.7-2.0)



Which agent is responsible for the abnormalities displayed in her ECG?

A. Amlodipine
B. Bisoprolol
C. Citalopram
D. Digoxin
E. Furosemide

D. Digoxin

This woman's ECG displays 'scooped' ST depression in leads II, III, aVF, V5, and V6 in the context of atrial fibrillation. This is a classical sign seen in the digoxin effect, the ECG changes that arise with digoxin within normal therapeutic levels. It is important to note that in digoxin toxicity, the most common dysrhythmias are supraventricular tachycardia with a slow ventricular response due to blocking of the AV node.

Whilst calcium channel blockers can significantly disrupt the ECG, this is associated primarily with non-dihydropyridines such as verapamil or diltiazem, rather than dihydropyridines such as amlodipine which are less cardioselective.

Bisoprolol can give rise to bradycardia and PR prolongation on ECG but the ST changes observed here are consistent with the digoxin effect. Therefore, bisoprolol is incorrect.

Citalopram is a selective serotonin reuptake inhibitor and therefore can result in QT prolongation. The ST changes as described here are not consistent with this syndrome and therefore this is an incorrect answer.

Furosemide is a loop diuretic that can result in hypokalemia and therefore flattened and inverted T waves. The ST segment in this ECG shows the classical 'scooped' appearance and therefore is more consistent with the digoxin effect rather than hypokalemia. Furosemide is therefore incorrect

Question 51 of 129

An 82-year-old man sees his GP to discuss his medication. He complains of shortness of breath on minimal exertion and says that he now has to sleep upright in his armchair. His medication includes lisinopril, metoprolol, spironolactone, furosemide, aspirin, simvastatin, nifedipine and metformin.

Physical examination shows a heart rate of 69 beats per minute with a regular rhythm and blood pressure of 118/100 mmHg. His peripheries are cool, and his carotid pulse is difficult to palpate. He has a sustained apical impulse palpable in the 5th intercostal space in the mid-clavicular line. He has a palpable thrill in the second intercostal space at the right sternal border where his GP hears a loud crescendo-decrescendo murmur which radiates into his neck. He has a quiet S1, an inaudible S2, and a loud S4. His chest is clear to auscultation and he is noted to have 1+ peripheral oedema.

Which of the following physical examination findings are most suggestive of severe aortic stenosis?

A. Loud crescendo-decrescendo murmur
B. Quiet S1
C. Inaudible S2
D. Palpable thrill
E. Narrow pulse pressure

C. Inaudible S2

Aortic stenosis - a soft S2 is a feature of severe disease

The feature identified on physical examination that is most suggestive of severe aortic stenosis is an inaudible second heart sound.

The loudness of a murmur does not correlate with its severity. In the case of regurgitant murmurs, for example, quiet murmurs can represent severe regurgitation as there is early equalisation between the two cardiac chambers involved.

A quiet S1 may reflect significant aortic valve calcification but does not necessarily reflect the severity of the stenosis

A palpable thrill and narrow pulse pressure can occur in severe aortic stenosis but are not as indicative of severe aortic stenosis as an absent second heart sound

Question 52 of 129

A 71-year-old patient presents to the Emergency Department with a two hour history of crushing central chest pain. He is known to have a history of ischaemic heart disease. The ECG shows the following:

ST elevation greater in lead II than in lead III with abnormal Q waves in II, III, and aVF

ST depression, tall, broad R waves and upright T waves in V1-3. Dominant R wave in V2

ST elevation in V5-V6

Where is the lesion most likely to be?

A. Left anterior descending
B. Left circumflex
C. Right coronary artery
D. Left main stem
E. Posterior interventricular

B. Left circumflex

Ischaemic changes in leads I, aVL +/- V5-6 - left circumflex

These are classical findings of a circumflex occlusion. The table below shows how the changes correspond to the cardiac anatomy:

ECG changes	Component of infarction
ST elevation greater in lead II than in lead III with abnormal Q waves in II, III, and aVF	Inferior component of infarction
ST depression, tall, broad R waves and upright T waves in V1-3. Dominant R wave in V2	Posterior component of infarction
ST elevation in V5-V6	Lateral component of infarction

Question 53 of 129

A 24-year-old male presents to the emergency department with a collapse. The previous night he had been out drinking heavily with his friends in a nightclub. A friend attends with him and states that some of the lads had taken MCAT (Mephedrone) but he is unsure whether Michael also took MCAT. Michael felt well when he woke up but realised that he was late for his football match so rushed out of the house without any breakfast. He had just scored the first goal of the match when he collapsed. When he came around he complained of palpitations.

His past medical history includes asthma and hay fever for which he takes regular antihistamines. During the ambulance ride to hospital the paramedic performed some observations and an ECG. He was found to have a blood glucose of 3.6 and was given some GlucoGel and a biscuit. Other observations included a blood pressure of 90/60 mmHg, heart rate of 135/min which was irregular, irregular in character, respiratory rate of 16/min, afebrile.

The emergency department doctor reviewed the ECG and diagnosed atrial fibrillation with a fast ventricular response and prescribed digoxin in view of his asthma history and blood pressure readings. The patient had a normal QTc. Five minutes later the cardiac monitor showed a broad complex tachycardia and Michael became unresponsive.

What was the cause of the patient's collapse?

A. Hypertrophic cardiomyopathy (HCM)
B. MCAT related arrhythmia
C. Wolff-Parkinson-White syndrome
D. Alcohol induced atrial fibrillation
E. Torsades de pointes

C. Wolff-Parkinson-White syndrome

Wolff-Parkinson-White syndrome (WPW) is a disorder of the conduction system also known as a pre-excitation syndrome. The incidence of WPW is between 0.1% and 0.3% in the general population. Sudden cardiac death in people with WPW is rare (incidence of less than 0.6%).

In WPW there is an abnormal accessory pathway called the 'Bundle of Kent' found between the atria and ventricles. If this pathway is used signals may stimulate the ventricles to contract prematurely, resulting in atrioventricular re-entrant tachycardia.

Normally the AV node acts as a gatekeeper limiting the amount of electrical activity that can reach the ventricles. If a patient has an arrhythmia whereby the atria generate an excessively fast rhythm such as atrial flutter or fibrillation the AV node is able to reduce the amount of electrical activity that reaches the ventricles. However, the Bundle of Kent does not possess the ability to limit the electrical signals to the ventricles. If the person has an atrial arrhythmia the signals can pass down the bundle and cause the ventricles to contract at the same rate. In the extreme heart rates and when the accessory pathway is used the patient may develop dangerous cardiac arrhythmias which can trigger ventricular fibrillation and lead to death.

In WPW certain medications that can block the AV node or those that can enhance conduction down the accessory pathway by increasing the refractory period in the AV node should be avoided. These include digoxin, adenosine, diltiazem, verapamil, other calcium channel blockers and beta blockers. In this case, the patient's WPW was worsened by administration of digoxin and her arrhythmia developed into ventricular fibrillation.

People with WPW are usually asymptomatic. Symptomatic patients may complain of shortness of breath, palpitations, dizziness and syncope. Diagnosis is usually made by ECG as patients may have the characteristic 'delta wave'. Patients may also be found to be in atrial fibrillation or have SVT Treatment can include cardioversion in emergencies otherwise amiodarone. Definitive treatment would be ablation.

Question 54 of 129

A 65-year-old gentleman is reviewed in cardiology clinic with known cardiomyopathy. He has started to develop symptoms of progressive exertional shortness of breath and is concerned about having this treated. He has not had any other symptoms and on examination, there is no peripheral oedema or chest signs. A recent echocardiogram demonstrates a provoked left ventricular outflow gradient of 64mmHg.

What would be the most appropriate medical therapy?

A. Phosphodiesterase type 5 inhibitor
B. Beta-blocker
C. Nitrate
D. Digoxin
E. Ace-inhibitor

B. Beta-blocker

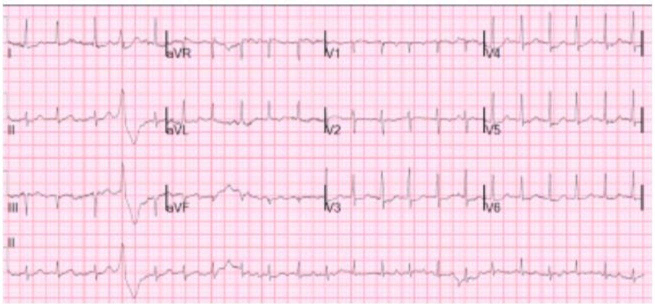
The correct answer is beta-blocker. Beta-blockers and verapamil can help with symptom management as they control the heart rate to the point where ventricular outflow obstruction is unlikely to occur. Nitrates and ace-inhibitors are contra-indicated as they lower blood pressure which can be very dangerous when combined with hypotension when the outflow is obstructed, whilst phosphodiesterase type 5 inhibitors and digoxin would offer no benefit. Phosphodiesterase type 5 inhibitors have a greater role in pulmonary hypertension whilst digoxin can be used to control the heart rate in AF when the patient is sedentary or there is coexisting heart failure.

Question 55 of 129

A 54-year-old man presents with a sensation of his heart racing. He has noticed this intermittently over the last several weeks. On examination, his heart sounds are normal with no added sounds. He has a heart rate of 90 beats per minute and a blood pressure of 124/66 mmHg.

His past medical history includes mild asthma only. He is otherwise fit and well and regularly cycles 30 - 40 miles at the weekend. He previously had electrical cardioversion 2 years ago which restored normal sinus rhythm at the time.

His ECG is 0shown below



As well as anticoagulation, what additional medication could be considered before electrical cardioversion?

A. Amiodarone
B. Aspirin
C. Digoxin
D. Flecainide
E. Ramipril

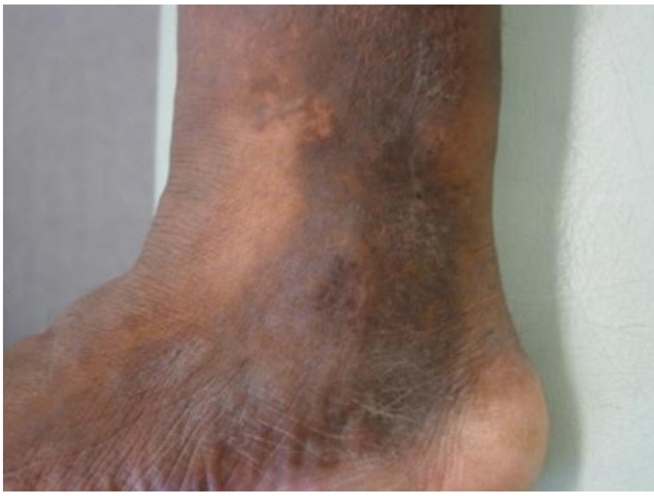
Not answered in the file

Question 56 of 129

A 69-year-old man visits his General Practitioner complaining of discolouration to his lower legs. He denies itch but complains of intermittent pain that is progressively worsening. He does not visit his doctor regularly and has not had a check-up in several years. He takes no regular medications and chooses to take herbal supplements daily.

Ankle brachial pressure index	1.1

His legs are examined, as shown below:



What is the recommended management for this patient?

A. Compression stockings
B. Low dose aspirin and statin
C. Oral flucloxacillin
D. Topical corticosteroids
E. Topical emollients

A. Compression stockings

This patient has evidence of discolouration to the lower leg, in keeping with haemosiderin deposition as seen in chronic venous insufficiency. It is likely that this patient has an underlying diagnosis of venous insufficiency and varicose veins. Risk factors for varicose veins include female sex, obesity, pelvic congestion (e.g. in pregnancy) which increases venous pressure in the lower limbs and increasing age. Other changes that can be seen in patients with varicose veins include lipodermatosclerosis (hardening of the skin of the lower limb) and varicose eczema. The management of choice consists of conservative measures in the first instance including exercise, weight loss and **compression stockings**.

Low dose aspirin and statin is incorrect. Although there is a history of pain, the normal ankle brachial pressure index is reassuring that this patient's pain is not secondary to arterial ischaemia. Therefore, aspirin and statin therapy is not indicated.

Oral flucloxacillin is incorrect. This is used in the management of cellulitis which typically appears as an erythematous and inflamed area of skin that is warm and tender to the touch. This is not in keeping with this patient's presentation.

Topical corticosteroids is incorrect. It is used in the management of some inflammatory skin disorders such as eczema, urticaria and psoriasis. However, it plays no role in the management of varicose veins.

Topical emollients is incorrect. This is used in the treatment of dermatitis which is visualised as dry and exfoliative skin that may show signs of excoriations and hyperpigmentation. This is not seen here.

Question 57 of 129

A 79-year-old woman is reviewed in cardiology clinic as part of the ongoing assessment for possible intervention for severe aortic stenosis. The patient had been diagnosed with severe aortic stenosis 4 months previously, after experiencing progressive exertional breathlessness and reduced exercise tolerance. At her initial review at cardiology clinic, the patient had expressed interest in undergoing intervention for aortic stenosis: either surgical aortic valve replacement (SAVR) or transcatheter aortic valve insertion (TAVI). Subsequently, the patient had undergone a variety of investigations to assess her suitability for the above procedures.

The patient had a good functional status, leaving independently with her daughter and still participating in a wide range of community activities. The patient had a long-standing diagnosis of hypertension and had suffered a left cortical stroke 3 years previously. In addition, the patient had chronic obstructive pulmonary disease, although she had stopped smoking 30 years previously. The patient's regular medications were amlodipine, ramipril, clopidogrel, simvastatin and an ipratropium inhaler. The patient used a salbutamol inhaler as required. The patient had no known drug allergies.

A summary of the investigations undergone by the patient is given below.

Haemoglobin	128 g / dL
Mean cell volume	87.1 fl
White cell count	6.3 x 10>3 / microlitre
Platelets	324 x 10>3 / microlitre
Urea	5.3 mmol / L
Creatinine	124 micromol / L
Sodium	136 mmol / L
Potassium	4.6 mmol / L

Investigation	Result
Transthoracic echocardiogram	Severe aortic stenosis (valve area 0.85 cm2); no other valve disease; normal systolic function; no anatomic contraindications to TAVI
Coronary angiography	No evidence of coronary artery disease
Iliofemoral angiography	Severe calcification and tortuosity of iliac arteries; unsuitable for transfemoral TAVI
Pulmonary function tests	Moderate obstructive lung disease

Following the above assessment, surgical aortic valve replacement was estimated to carry a 4.1 % risk of mortality and 3.7 % risk of permanent stroke (intermediate risk). No contraindications to transapical transcatheter aortic valve insertion were identified.

What is the recommended choice of intervention for the patient's aortic stenosis?

A. Surgical aortic valve replacement and transcatheter aortic valve
B. insertion inappropriate
C. Surgical aortic valve replacement with mechanical valve
D. Transapical transcatheter aortic valve insertion
E. Surgical aortic valve replacement with bioprosthetic valve
F. Transfemoral transcatheter aortic valve insertion

E. Surgical aortic valve replacement with bioprosthetic valve

The patient has severe, symptomatic aortic stenosis and without intervention is likely to have a poor prognosis. Given the patient's age, if she was to undergo surgical aortic valve replacement (SAVR) then a bioprosthetic valve would be preferred over a mechanical valve, freeing the patient from the need for lifelong anticoagulation. Typical risk stratification for SAVR defines the estimated risk of peri-operative death as low (< 4 %), intermediate (4-8 %) and high (> 8 %). Due to her comorbidities, the patient has an intermediate risk associated with SAVR, calculated using the STS risk calculator (http://riskcalc.sts.org/stswebriskcalc/#/).

Transcatheter aortic valve insertion (TAVI) was initially developed for patients considered unfit for SAVR due to high predicted mortality. However, a recent randomised controlled trial comparing outcomes for TAVI versus SAVR as an intervention for severe, symptomatic aortic stenosis has demonstrated that transfemoral TAVI can be a suitable intervention for some patients with a low or intermediate risk associated with SAVR. Transfemoral TAVI is increasingly favoured over SAVR as patient age increases.

In contrast, outcomes for transapical TAVI are inferior to SAVR, so this intervention is only appropriate for individuals with an unacceptably high surgical risk. For patients where both SAVR and transapical TAVI are possible, SAVR is strongly favoured at all patient ages.

Therefore, for this patient, bioprosthetic SAVR is the intervention of choice, favoured over transapical TAVI. Transfemoral TAVI is technically impossible in this patient due to the anatomy of her iliac arteries.

Question 58 of 129

A patient attends a cardiology clinic following a recent myocardial infarct (MI) which was successfully managed via percutaneous coronary intervention (PCI). The patient has been taking their secondary prevention medications regularly and reports no issues or symptoms.

Their examination is unremarkable and the patient's observations are as follows:

Heart rate 55 beats per minute Blood pressure 134/80 mmHg Respiratory rate 16 breaths per minute Oxygen saturations 98% on air Temperature 36.2 ºC

An ECG performed has widened QRS complexes and atrioventricular dissociation in keeping with accelerated idioventricular rhythm (AIVR) with a rate of 55 beats per minute.

What management should be advised?

A. Arrange for urgent repeat PCI
B. Arrange for urgent pacemaker insertion
C. No additional management is required
D. Stop the patient's beta blocker and continue all other medications
E. Urgent atropine

C. No additional management is required

Accelerated idioventricular rhythm is common and unconcerning following recent MI

AIVR is a benign ectopic rhythm of ventricular origin. It is common postMI following the reperfusion of an ischaemic myocardium. AIVR is usually self-limiting and therefore treatment is not necessary, especially as the patient is asymptomatic and haemodynamically stable with a normal heart rate and blood pressure.

Arranging for urgent repeat PCI is unnecessary as there is no indication of new/further ischaemic damage or an ischaemic event having occurred. AIVR is due to an ectopic rhythm and therefore PCI is of no value.

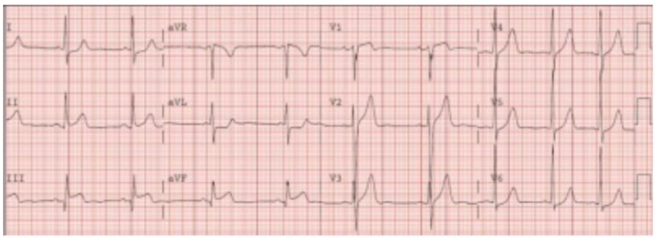
Pacemaker insertion is not required as AIVR is due to a benign ectopic rhythm and therefore pacemaker insertion would not remove the cause. As the patient is asymptomatic and haemodynamically stable no treatment is required.

Stopping the patient's beta-blocker is unnecessary as this will not eliminate the AIVR. Beta-blockers are an important part of secondary prevention post-MI and therefore should be continued.

Atropine could be considered to overcome AIVR via increase the sinus rate however this is rarely required. As the patient is symptom-free and haemodynamically stable the use of atropine is unnecessary.

Question 59 of 129

A middle-aged man is admitted to the resuscitation room of the Emergency Department with crushing central chest pain. His ECG is shown below:



Where is the lesion most likely to be?

A. Left circumflex
B. Right coronary
C. Left anterior descending
D. Posterior interventricular
E. Left main stem

B. Right coronary

Ischaemic changes in leads II, III, aVF - right coronary

There is inferior ST elevation (II, III and aVF) suggestive of a right coronary lesion. Some reciprocal ST depression in I and aVL is also seen.

Question 60 of 129

A 14-year-old female presented to her GP having collapsed at school. Her friends stated that whilst she was playing hockey she inexplicably collapsed and had lost consciousness for a few seconds. This was her first episode of collapse. No seizure activity was observed, and she made a full and spontaneous recovery a few moments later. She denied the presence of prodromal symptoms, and other than occasional palpitations upon exertion she was otherwise well. She had a cochlear implant inserted in early childhood for congenital hearing impairment but otherwise had no past medical history of note, and was not taking any medications. There was no family history of note.

Examination revealed the presence of a healthy athletic 14-year-old female. Her heart rate was 58bpm and regular, and her blood pressure 108/78 mmHg. Cardiovascular examination revealed a JVP of 3cm and was otherwise unremarkable with normal heart sounds. Gastrointestinal examination and neurological examinations were likewise unremarkable.

Initial investigations revealed the following results:

ECG: 57bpm normal, sinus rhythm QRS 112 ms, PR 122ms, QTc 502ms, normal ST and T wave morphology.

What is the most likely diagnosis?

A. Brugada syndrome
B. Romano Ward syndrome
C. Wolff Parkinson White syndrome
D. Jervell & Lange-Nielsen syndrome
E. Hypertrophic obstructive cardiomyopathy

D. Jervell & Lange-Nielsen syndrome

Inherited long QT syndrome, sensorineural deafness - Jervell and Lange-Nielsen syndrome

This female has long QT syndrome (LQTS), as per the findings of her ECG in combination with a history of collapse on exertion. The main differential diagnosis here is Romano-Ward syndrome, which is also a LQTS but is not associated with deafness, as opposed to Jervell & LangeNielsen syndrome, which is associated with deafness. A normal cardiac examination with no evidence of hypertrophy on ECG would make the diagnosis of hypertrophic obstructive cardiomyopathy less likely.

Question 61 of 129

A 59-year-old woman presents to the emergency department with shortness of breath. She has been progressively getting worse over two weeks and has now started to feel short of breath on rest. She is known to have mitral valve prolapse and is awaiting surgery but has so far not been given a date. She also has polycystic ovarian syndrome, type 2 diabetes and depression. She takes metformin, sertraline and furosemide.

On examination, she looks unwell. She has bilateral crepitations with no wheeze on auscultation of her chest, a raised JVP, and a systolic murmur. A chest X-ray shows pulmonary oedema. She is treated with IV diuretics but remains breathless and hypoxic.

What kind of ventilatory support would be most appropriate?

A. No ventilator support is appropriate
B. Negative pressure ventilation
C. Intubation
D. Bilevel positive airway pressure (BIPAP)
E. Continuous positive airway pressure (CPAP)

E. Continuous positive airway pressure (CPAP)

Acute heart failure not responding to treatment - consider CPAP

The correct answer is continuous positive airway pressure (CPAP). This is a patient with a known mitral valve prolapse presenting with decompensation. It can be assumed that the lesion is significant as she is due to have surgery to repair it. She has developed signs of pulmonary oedema and she is not responding to treatment with diuretics. Vasodilators and opiates could be a plan of further medical management, but CPAP could help reduce pulmonary oedema. BIPAP would be appropriate in ventilatory failure in COPD, whilst negative pressure ventilation is more of historical treatment for polio.

Mitral valve prolapse has a prevalence of 2-3% in the population and the majority of cases will be asymptomatic. Risk factors for progression the severe disease include:

- Comorbidities: atrial fibrillation, left sided cardiac failure, hypertension and obesity.
- Echocardiogram findings: mitral leaflet thickness >5mm, prolapse of the posterior leaflet, moderate or severe regurgitation.
- Stress echocardiogram findings: regurgitation during exercise but not at rest.

Question 62 of 129

Whilst covering medical receiving overnight, you are referred a 52-yearold man presenting to the Emergency Department with palpitations. He describes 'fluttering in the chest' for the last 48 hours. His past medical history is remarkable only for type 1 diabetes, adequately controlled with insulin. His admission ECG shows atrial fibrillation with a ventricular rate of 130-140 beats per minute. Examination reveals; blood pressure 88/60 mmHg, with capillary refill 3 seconds. His chest is clear to auscultation. He scores 15/15 on the Glasgow coma score. The patient feels light headed but is otherwise uncomplaining.

What is the most appropriate next step in management?

A. Monitor and observe the patient on the Coronary Care Unit
B. Load with 300mg, intravenous amiodarone
C. Attempt vagal manoeuvres
D. Give 5mg intravenous metoprolol as a slow bolus
E. Arrange DC cardioversion

E. Arrange DC cardioversion

In the context of a tachyarrhythmia, a systolic BP < 90 mmHg → DC cardioversion

The Resuscitation Council (UK) gives clear advice on the management of tachyarrhythmias (see link below for the relevant algorithm). Essentially patients with tachyarrhythmias should be categorised first by the presence or absence of adverse features, these are:

1) Shock - Systolic blood pressure of less than 90mmHg, cold extremities, prolonged capillary refill time etc.

2) Syncope

3) Heart failure pulmonary oedema plus or minus raised jugular venous pressure

Question 63 of 129

A 45-year-old man presents to the Emergency Department with shortness of breath, heavy chest pain and syncope. The chest pain and shortness of breath have been worsening over the last week. He is currently undergoing adjunct chemotherapy for a non-resectable soft tissue sarcoma. He has known metastasis in his thorax and mediastinum.

Hb	90 g/L	Male: (135-180)Female: (115 - 160)
Platelets	100 * 10 /L	(150 - 400)
WBC	12.3 * 10 /L	(4.0 - 11.0)
Na	131 mmol/L	(135 - 145)
K	3.1 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	8.0 mmol/L	(2.0 - 7.0)
Creatinine	145 µmol/L	(55 - 120)

On physical examination his JVP is raised at 6cm, there are no precordial thrills, and he has quiet S1 and S2.

Observations show:

- Heart rate of 115/min and regular
- Blood pressure 95/55mmHg
- Respiratory rate 28/min
- Temperature 36.5ºC
- AVPU - A

What is the more specific ECG finding associated with this diagnosis

A. Electrical alternans
B. RBBB
C. S1Q3T3
D. ST elevation in leads V1-4
E. Sinus tachycardia

A. Electrical alternans

Electrical alternans is suggestive of cardiac tamponade

Electrical alternans is the correct answer. The patient has metastatic disease within the thorax and mediastinum increasing his risk of a pericardial effusion. Electrical alternans is seen in massive pericardial effusions as an alternating height of QRS complex across the rhythm strip. Other ECG findings to look for are tachycardia and low voltage QRS. The website Life in the Fast Lane has a library of ECGs with examples of this.

RBBB is the incorrect answer because this is not a specific finding for massive pericardial effusion. There are a variety of causes of RBBB. Examples include congenital heart disease, cardiomyopathy, pulmonary embolus, right ventricular hypertrophy, ischaemic heart disease and others. In an acute PE setting, which is a differential, in this case, you would also look for right heart strain due to the sudden increase in right ventricular pressure caused by the obstruction to the pulmonary vasculature.

S1Q3T3 is the incorrect answer as this is associated with a pulmonary embolism (PE). However, this is only seen in approximately 15% of PEs. The more common ECG finding is sinus tachycardia.

ST elevation in leads V1-4 is the incorrect answer because this is seen in an anterior occlusive, or type 1, myocardial infarction. This typically affects the left anterior descending artery and confers a high risk of a ventricular arrhythmia. The patient requires urgent PCI or, if that is not available within 120 minutes, then thrombolysis.

Sinus tachycardia is the incorrect answer as it is a non-specific finding on ECG. You would expect a patient with a massive pericardial effusion to mount a tachycardic response. This is because a decrease in diastolic relaxation and the subsequent volume of ventricular filling decreases your stroke volume. To maintain an adequate cardiac output, the patient will increase HR. As CO = SV x HR. However, this is a non-specific finding and is seen in all types of shock; septic, cardiogenic, distributive and hypovolaemic. Answer 1 is a much more specific ECG finding.

Question 64 of 129

A 24-year-old man is brought in by ambulance to the emergency department after a witnessed collapse. He was unconscious for 10-15 seconds before quickly recovering. There were no preceding symptoms and no witnessed seizure activity. He has no past medical history and is not on any regular medications.

Observations:

Heart rate 82 beats per minute Blood pressure 120/80 mmHg Respiratory rate 16/minute Oxygen saturations 96% on room air Temperature 37C

The examination is unremarkable and his Glasgow coma scale is 15/15.

An ECG demonstrates possible coved ST elevation in leads V1-V3 without reciprocal changes.

Troponin	6 ng/L	(< 14)

Given the likely diagnosis, the administration of which anti-arrhythmic will make the ECG changes more apparent?

A. Dobutamine
B. Flecainide
C. Isoprenaline
D. Metoprolol
E. Quinidine

B. Flecainide

ECG changes in Brugada syndrome are more apparent following the administration of flecainide or ajmaline - this is the investigation of choice in suspected cases

Flecainide is the correct answer. The patient presents with syncope and ECG changes that raise the possibility of Brugada syndrome (coved ST elevation in leads V1-V3). Administration of flecainide can make these ECG changes more apparent and aid diagnosis.

Dobutamine is incorrect. This medication can be used in stress echocardiography to determine if there is any inducible ischaemia but is not used to make the ECG changes of Brugada syndrome more apparent.

Metoprolol is incorrect. Typically, a short-acting beta-blocker is administered prior to CT coronary angiography with the aim of reducing the heart rate to a level of approximately 60 to facilitate interpretation of this form of imaging. It is not used to unmask the ECG changes of Brugada syndrome.

Quinidine is incorrect. This has been suggested in some reports to be useful as an anti-arrhythmic in Brugada syndrome. It does not make the ECG changes more prominent.

Isoprenaline is incorrect. This has been shown to normalise the electrocardiographic pattern in Brugada syndrome.

Question 65 of 129

A 25-year-old male is brought to the emergency department with an episode of syncope, which occurred without warning. He has no past medical history and does not take any regular medications. There is no history of substance misuse.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 120/88 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air
- Temperature 37.1C

The examination is unremarkable.

An ECG demonstrates T wave inversion in leads V1-V3. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L	(150 - 400)
WBC	4.8 * 10 /L	(4.0 - 11.0)
Na	141 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	5.1 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Troponin	4 ng/L	(<14)

An echocardiogram demonstrates a dilated, hypokinetic right ventricle. A CT pulmonary angiogram excludes a pulmonary embolism.

Given the likely diagnosis, what is the most specific ECG finding suggestive of this condition?

A. Coved ST segment elevation in V1-V2
B. Delta wave
C. Epsilon wave
D. PR depression
E. Low voltage QRS and electrical alternans

C. Epsilon wave

The most characteristic ECG finding in arrhythmogenic right ventricular dysplasia (ARVD) is the epsilon wave (a small positive deflection at the end of the QRS complex)

Epsilon wave is correct. The patient presents with syncope without warning, suggesting a cardiogenic cause. T wave inversion in leads V1-V3 and an echocardiogram demonstrating a dilated, hypokinetic right ventricle is characteristic of arrhythmogenic right ventricular dysplasia (ARVD). The most specific finding for this condition is an epsilon wave, which is a small positive deflection at the end of the QRS complex).

Delta wave is incorrect. This is a slurred upstroke of the QRS complex and suggests Wolff-Parkinson-White (WPW) syndrome.

Coved ST segment elevation in V1-V2 is incorrect. This is characteristic of Brugada syndrome, which is another cause of sudden cardiac death.

PR depression is incorrect. The ECG finding, in the correct clinical context, is associated most specifically with pericarditis.

Low voltage QRS and electrical alternans is incorrect. This combination of ECG findings suggests a massive pericardial effusion.

Question 66 of 129

A 78-year-old man who is usually fit and well and takes levothyroxine for hypothyroidism presents to the acute medical take after two episodes of syncope. He recalls sitting at the dinner table and passing out with no dizziness prior. He can usually walk 100 metres at a time.

On examination, he has a loud systolic murmur heard over the 2nd intercostal space on the left side radiating to the carotid. He has a slow rising pulse and his chest is clear. No JVP is seen and there is no ankle oedema.

Chest xray	enlarged heart with calcification of the aortic knuckle
ECG	sinus, 75 beats per minute
ECHO	Aortic valve cross sectional area of 0.8mm^2 with a pressure gradient of 42mmHg, cusps appear calcified and poorly mobile

What other investigation should be performed?

A. Coronary angiography
B. Thyroid function test
C. CT chest
D. Treadmill ECG testing
E. HbA1c

A. Coronary angiography

Aortic stenosis co-occurs with atherosclerotic disease -> perform angiogram prior to surgical intervention

This gentleman meets the ECHO criteria for severe aortic stenosis and should be listed for aortic valve replacement (AVR) immediately. He shows no signs of failure or haemodynamic compromise and is therefore fit. Given that AVR involves opening the chest, it is a perfect time to perform coronary artery bypass grafting and since there is a correlation of aortic stenosis with atherosclerosis, it is beneficial to perform an angiogram prior to the AVR procedure. The patient effectively gets two procedures for one. CT chest would be important is he had respiratory disease. HbA1c and thyroid function tests are not essential unless there was a suspicion that these were abnormal. Treadmill testing is contraindicated in symptomatic and severe aortic stenosis where is can cause syncope.

Question 67 of 129

A 25-year-old male presents to the emergency department with palpitations. His observations are performed, heart rate 180/min, blood pressure 134/78 mmHg, respiratory rate 16/min. His past medical history includes asthma for which he takes salbutamol PRN and fluticasone BD. Examination reveals a clear chest. Heard sounds are too rapid to distinguish S1 and S2. ECG reveals a narrow complex tachycardia, consistent with supraventricular tachycardia (SVT). Multiple attempts at vagal manoeuvres have failed to cardiovert the patient. He remains symptomatic.

Bloods are taken:

Hb	135 g/l
Platelets	344 * 10 /l
WBC	10.1 * 10 /l
Na	141 mmol/l
K	4.2 mmol/l
Creatinine	65 µmol/l
CRP	2 mg/l

Arterial blood gases on room air:

pO2	12.1 kPa
PCO2	4.1 kPa
pH	7.39
Base excess	-0.2

Chest X-ray: No abnormality detected

Which pharmacological agent would be most appropriate for cardioverting this man?

A. Verapamil
B. Adenosine
C. Digoxin
D. Amiodarone
E. Bisoprolol

A. Verapamil

Use of adenosine is contraindicated in patients with asthma as it can cause bronchospasm. The next best option here is verapamil, which slows atrioventricular (AV) nodal conduction. The other options are not widely used to restore sinus rhythm in SVT.

Question 68 of 129

A 40-year-old male who is otherwise fit and well presents to clinic with dyspnoea on exertion. This has progressed over the last year to the point where he can only walk 0.5 miles before stopping. He denies having a cough. He has no chest pain. He has smoked 15 cigarettes per day for 25 years. He reports that his father had a myocardial infarction (MI) aged 54 years, but otherwise reports no cardiac-related family history. His body mass index (BMI) is 24 kg/m², heart rate 80/min, blood pressure 130/77mmHg, respiratory rate 18/min and he is saturating at 97% on air. Chest auscultation reveals occasional expiratory wheeze and he has no pedal oedema. Auscultation of the heart reveals a fixed split S2. His jugular venous pressure is not elevated.

Chest X-ray: dilated pulmonary vessels.

ECG: sinus rhythm, 78/min, right bundle branch block (RBBB)

What is the likely cause of his exertional dyspnoea?

A. Atrial septal defect
B. Ischaemic heart disease
C. Bronchial malignancy
D. Chronic obstructive pulmonary disease
E. Chronic pulmonary embolism

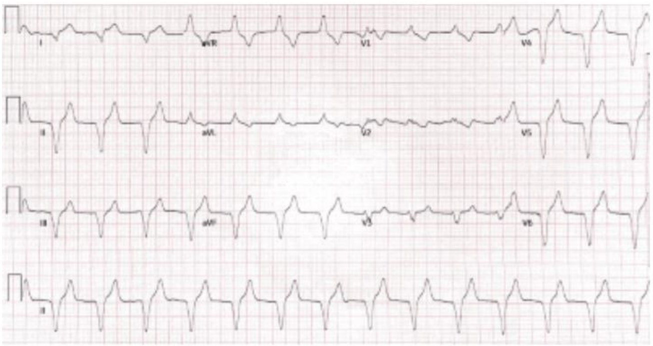
A. Atrial septal defect

The underlying cause here is likely to be an atrial septal defect. Presentation often occurs late in life with an incidental finding of RBBB. It may not be picked up in infancy as a murmur may not be audible. Presentation with symptoms occurs later in life as the right atrium becomes dilated and hence the cardiac efficiency decreases. A fixed-split S2 is a common finding in such patients

Question 69 of 129

A patient attends a cardiology clinic following a recent myocardial infarct (MI) which was successfully managed via percutaneous coronary intervention (PCI). The patient was stated on secondary prevention medications and has reports no further issues or symptoms. The patient is currently on aspirin, clopidogrel, bisoprolol, ramipril and atorvastatin.

Examination is normal and vital signs within normal range. An ECG performed is shown below.



What definitive management should be advised?

A. Arrange for urgent pacemaker insertion
B. Arrange for urgent repeat PCI
C. No additional management is required
D. Stop the patient's beta blocker and continue all othermedications
E. Arrange for urgent 24-hour Holter monitor

C. No additional management is required

The patient's ECG is a typical example of the benign ventricular ectopic rhythm, accelerated idioventricular rhythm (AIVR). It is associated with atrioventricular dissociation; P waves present but not associated with QRS complexes, wide QRS complexes (>120ms) and a rate between 50- 110 beats per minute. AIVR is common post-MI following the reperfusion of an ischaemic myocardium. It is usually self-limiting and therefore treatment is not necessary, especially as the patient is asymptomatic and haemodynamically stable.

Pacemaker insertion is not required as the atrioventricular dissociation and QRS complexes seen in AIVR does not affect the ventricular rate which is normally between 50-110 beats per minute. AIVR is due to a benign ectopic rhythm and so pacemaker insertion would not remove the cause. As the patient is asymptomatic and haemodynamically stable no treatment is required.

Arranging for urgent repeat PCI is unnecessary as there is no indication of new/further ischaemic damage or an ischaemic event having occurred. AIVR is due to an ectopic rhythm and therefore PCI is of no value.

Stopping the patient's beta-blocker is unnecessary as this will not eliminate the AIVR. Beta-blockers are an important part of secondary prevention post-MI and therefore should be continued.

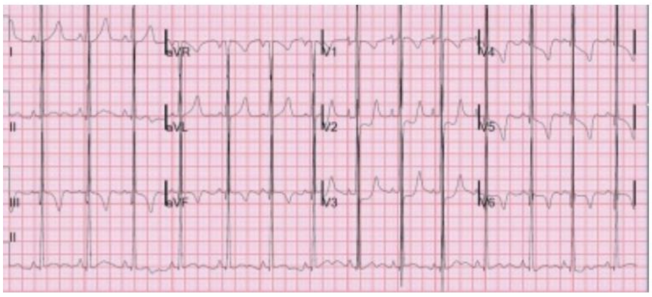
Arranging an urgent 24-hour Holter monitor is unnecessary as the patient's ECG is unlikely to change and there is no indication of any other underlying arrhythmia. The patient can be monitored in the outpatient setting as per any other post-MI patient.

Question 70 of 129

A 32-year-old female presents following a collapse whilst out jogging. The patient reports she experienced a subacute onset of chest discomfort that was quickly followed by symptoms of breathlessness and feeling faint. She thinks she 'blacked out' for a few seconds before recovering. Now she is feeling well with no symptoms.

On further questioning, she does not exercise regularly as she has experienced shortness of breath and chest discomfort in the past. She believes she has had a few episodes of feeling light-headed but has never fainted before. She is otherwise well with no recent illness or significant past medical history.

Observations are all within normal range and an ECG performed is shown below.



What is the patient's most likely diagnosis?

A. Brugada syndrome
B. Dilated cardiomyopathy
C. Hypertrophic obstructive cardiomyopathy
D. Wellen's syndrome
E. Arrhythmogenic right ventricular dysplasia

C. Hypertrophic obstructive cardiomyopathy

This patient has presented with features in keeping with hypertrophic obstructive cardiomyopathy (HOCM). The condition is due to a genetic defect causing a disorder of the cardiac muscle and, although patients can be asymptomatic, it is the commonest cause of sudden cardiac death in the young. Patients who do present with symptoms typically experience exertional dyspnoea, angina and syncope episodes, commonly during or following exertion. ECG findings, as seen in this case, are of left ventricular hypertrophy, non-specific ST-segment and Twave abnormalities, progressive T wave inversion and deep Q waves. The diagnosis can be confirmed via cardiac echo and management is dependent on the extent of obstruction and patient symptoms.

Brugada syndrome is another genetic cardiac disorder however unlike HOCM it results in electrical activity disorders and not structural issues. Features include syncope and sudden cardiac death however it is not always associated with exertion or exercise. There are several types of Brugada syndrome with variation seen on ECG however the only potentially diagnostic ECG abnormality is of coved ST-segment elevation in 2 or more of V1-3, followed by a negative T wave. This is classical of Brugada type 1 syndrome and is commonly known as Brugada sign.

Dilated cardiomyopathy is a disease of the myocardial and is characterised by progressive ventricular dilation and dysfunction. Presentation is normal with worsening biventricular failure including peripheral and pulmonary oedema. Syncope episodes are rare and symptoms are not fluctuant, as seen in this patient. ECG abnormalities are those associated with atrial and ventricular hypertrophy with conduction delays (e.g. LBBB), left axis deviation and poor R wave progression.

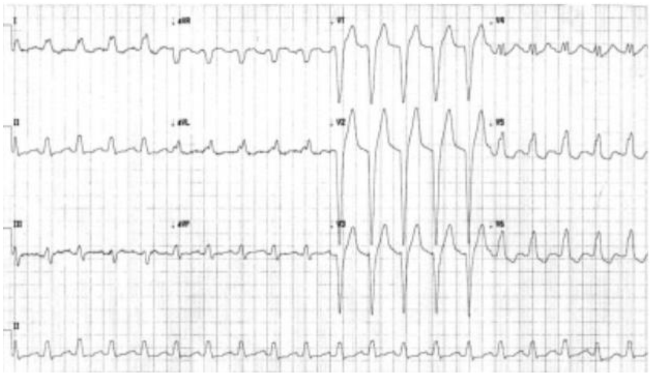
Wellen's syndrome is the ECG pattern of biphasic or deeply inverted T waves in the chest leads V2 and 3. It is highly specific for critical stenosis of the left anterior descending artery and therefore is normally seen in patients presenting with ischaemic-like symptoms.

Arrhythmogenic right ventricular dysplasia (ARVD), is due to a genetic defect affecting the desmosomes of the myocardium. ARVD results in a non-ischemic cardiomyopathy mainly affecting the right ventricle leading to areas of hypokinesia and myocardium replacement with fibrofat. These changes can results in associated arrhythmias. Patients typically present with palpitations, syncope, and potentially sudden cardiac death however ECG findings are of T wave inversion in leads V1 to V3 and of right bundle branch block which are not present in this case.

Question 71 of 129

A 72-year-old woman presents with palpitations. Her past medical history includes ischaemic heart disease and chronic obstructive pulmonary disease. Her pulse is 120/min, blood pressure 110/76 mmHg and the chest is clear on auscultation.

The ECG is shown below:



What is shown on the ECG?

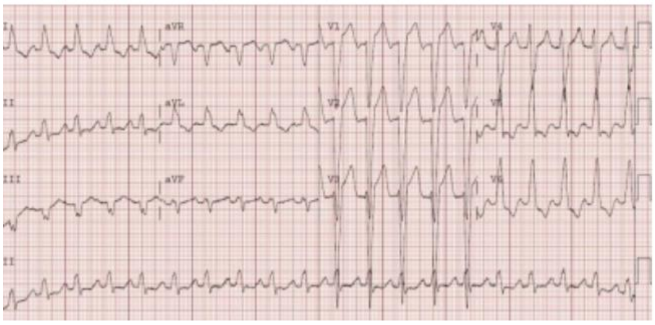
A. Left bundle branch block
B. Anterior ST elevation myocardial infarction
C. Right bundle branch block
D. Narrow complex tachycardia
E. Atrial flutter

A. Left bundle branch block

The morphology of the QRS complexes is diagnostic for left bundle branch block (LBBB). This finding can be associated with a wide variety of underlying problems but in an acutely unwell patient myocardial ischaemia needs to be excluded.

Question 72 of 129

A 58-year-old man presents with intermittent chest pains for the past two days. Whilst you are taking the history he complains of worsening pain and you arrange an ECG immediately:



He is tachycardic and sweaty with a blood pressure of 128/88mmHg.

What does the ECG show?

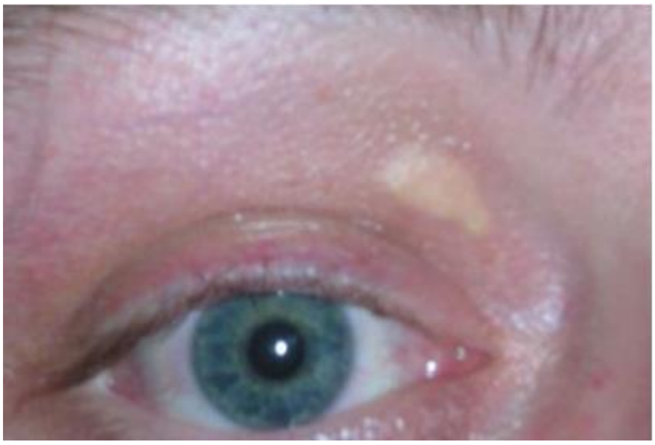
A. Narrow complex tachycardia with ST elevation
B. Right bundle branch block with ST elevation
C. Left bundle branch block with ST elevation
D. Ventricular tachycardia with ST elevation
E. Posterior myocardial infarction

C. Left bundle branch block with ST elevation

The ECG shows left bundle branch block (LBBB). The relationship between new LBBB and acute coronary syndrome (ACS) is complicated with many cardiologists ignoring the standard guidelines (both UK and US) to initiate reperfusion therapy due to the poor correlation seen in clinical practice between coronary lesions and standard LBBB. The Sgarbossa criteria have therefore been developed to evaluate whether new LBBB represents an ACS. In this particular ECG there is more ST elevation than is normally expected with LBBB indicating a likely ACS.

Question 73 of 129

A 40-year-old man presents to surgery as he has noted an abnormality around his right eye:



What is the most likely diagnosis?

A. Hypertriglyceridaemia
B. Hypercholesterolaemia
C. Hypothyroidism
D. Wilson's disease
E. Diabetes mellitus

B. Hypercholesterolaemia

The correct answer to this question is **Hypercholesterolaemia**. The image shows xanthelasma, which are yellowish plaques that commonly occur on or around the eyelids. Xanthelasma is often associated with hypercholesterolaemia, a condition characterised by high levels of cholesterol in the blood. Hypercholesterolaemia can lead to atherosclerosis and subsequently cardiovascular diseases.

Hypertriglyceridaemia is an incorrect option. While it is true that hypertriglyceridaemia can also cause xanthoma (fatty deposits under the skin), these usually present as eruptive xanthomas (small red-yellow bumps) or tuberous xanthomas (larger nodules), rather than xanthelasma.

Hypothyroidism, another incorrect option, can sometimes be associated with hypercholesterolaemia due to decreased metabolism of lipids. However, hypothyroidism itself would not directly cause xanthelasma. Hypothyroidism presents with symptoms such as fatigue, weight gain, cold intolerance, constipation, and dry skin.

The diagnosis of **Wilson's disease** does not fit the given scenario either. Wilson's disease is a rare inherited disorder causing copper to accumulate in vital organs like the liver and brain. The classic ocular manifestation in Wilson's disease is Kayser-Fleischer rings - copper deposition at the corneal limbus - rather than xanthelasma.

Lastly, **Diabetes mellitus** is also an incorrect answer for this case scenario. Diabetes could lead to various eye problems like diabetic retinopathy or cataracts but it does not cause xanthelasma. It's important for medical students to remember that while diabetes and hyperlipidemias often coexist due to their common risk factors, they are distinct conditions with different manifestations and complications.

Question 74 of 129

A 53-year-old Syrian refugee is referred to the cardiology clinic by her GP with dyspnoea and increasing peripheral oedema. Her past medical history is significant for rheumatic fever as a child. She gives a six month history of increasing dyspnoea on exertion. Her dyspnoea is now so severe that she has marked limitation in activity, being only able to walk 30 meters before stopping because of symptoms. She experiences no chest pain but tells you that she has taken to sleeping in a chair at night and has a chronic cough productive of pink sputum. More recently, she has awoken breathless from sleep terrified that she is going to die. On examination she has clinical evidence of severe mitral stenosis. She has an irregularly-irregular pulse and an ECG confirms atrial fibrillation at a rate of 89 bpm. Auscultation reveals a mid-diastolic murmur, an opening snap and a loud P2. She has bibasal crepitations and pitting oedema to below the knee. Her echo confirms severe mitral stenosis with a mitral valve area of 0.7cm2 and a mean gradient of 12mmHg. There is no evidence of mitral regurgitation and the sonographer comments that she has favourable mitral valve morphology.

Assuming a TOE excludes a left apical thrombosis, how should this lady be managed?

A. Diuresis, anticoagulate with one of the oral direct thrombin inhibitors/ factor Xa inhibitors and percutaneous mitral valve balloon valvotomy

B. Diuresis, anticoagulate with warfarin and refer for mitral valvereplacement
C. Diuresis, anticoagulate with warfarin and repeat echo in threemonths time
D. Diuresis, anticoagulate with one of the oral direct thrombin /factor Xa inhibitors and refer for mitral valve replacement
E. Diuresis, anticoagulate with warfarin and percutaneous mitralvalve balloon valvotom

E. Diuresis, anticoagulate with warfarin and percutaneous mitralvalve balloon valvotom

The correct answer is diuresis, anticoagulate with warfarin and percutaneous mitral valve balloon valvotomy.

The following is taken from the 2014 AHA/ACC consensus guidelines:

Percutaneous mitral balloon valvotomy is recommended for symptomatic patients with severe MS (mitral valve area 1.5 cm2) and favourable valve morphology in the absence of left atrial thrombus or moderate-to-severe MR.

Mitral valve surgery (repair, commissurotomy, or valve replacement) is indicated in severely symptomatic patients (NYHA class III to IV) with severe MS (mitral valve area 1.5 cm2) who are not high risk for surgery and who are not candidates for or who have failed previous percutaneous mitral balloon valvotomy.

Concomitant mitral valve surgery is indicated for patients with severe MS (mitral valve area 1.5 cm2) undergoing cardiac surgery for other indications.

With respect to anti-coagulation, the direct acting/ non-vitamin K antagonists are only indicated in non-valvular AF. Once adequate diuresis has been achieved, the addition of a beta-blocker should also be considered.

Question 75 of 129

A 48-year-old female presents with one day history of palpitation and shortness of breath. Her blood pressure is 150/90 mmHg, pulse is 190/min, respiratory rate is 21/min and oxygen saturation is 99% on air. ECG shows irregularly irregular rhythm and intermittent delta waves.

Which of the following drug should be used to control the heart rate?

A. Flecainide
B. Digoxin
C. Diltiazem
D. Verapamil
E. Adenosine

A. Flecainide

Delta waves suggest this patient has underlying Wolff-Parkinson-White syndrome in addition to atrial fibrillation. According to the NICE guidelines, in this condition, flecainide can be used as an alternative to electrical cardioversion for attempting pharmacological cardioversion. Atrialventricular node-blocking agents such as digoxin, diltiazem or verapamil should not be used. Adenosine is also an atrialventricular node-blocking agent.

Question 76 of 129

A 38-year-old man is referred to the pharmacology clinic for review. He is currently managed for hypertension with three anti-hypertensive agents, (ramipril, amlodipine and indapamide). His GP is concerned as he has still not achieved blood pressure target. On examination his blood pressure is 155/95 mmHg, pulse is 78 beats per minute and regular. There are no heart murmurs or bruits. Abdomen is soft and non tender with no masses and his body mass index is 24 kg/m².

Investigations:

Na +	142 mmol/l
K +	3.1 mmol/l
HCO3 -	30 mmol/l
Urea	7.0 mmol/l
Creatinine	90 µmol/l

Which of the following is the most likely diagnosis?

A. Bartter's syndrome
B. Conn's syndrome
C. Cushing's syndrome
D. Licorice overdose
E. Renal artery stenosis

B. Conn's syndrome

This patient has resistant hypertension in the presence of hypokalaemia and high bicarbonate, despite initiation of three different antihypertensive medications. Although the lack of symptoms or signs of cardiovascular disease doesn't rule out renal artery stenosis completely, it makes it less likely versus Conn's or licorice overdose as a cause of hypertension with hypokalaemia. Licorice overdose is made less likely by the fact that most licorice sold in shops in the UK now has glycyrrhizic acid removed, and this is the active agent which leads to hypokalaemia and hypertension. Conn's is the single most common cause of secondary hypertension, making up between 5 and 10% of cases of hypertension overall.

Bartter's syndrome leads to hypokalaemia with hypotension and is therefore not an appropriate answer here.

Question 77 of 129

A 28-year-old lady pregnant lady of 37 weeks gestation presented to the Emergency Department a few hours earlier with new onset chest pain. The pain was sharp and made worse with inspiration. She also complained of rapid onset progressively increasing shortness of breath, affecting her ability to complete sentences. She denied the presence of a cough or sputum production and did not suffer from haemoptysis or calf pain. Other than a successful external cephalic version for a breech presentation five days ago and a placenta praevia which spontaneously resolved, her pregnancy was unremarkable. She was in good health with an unremarkable past medical history and normal routine investigations throughout her pregnancy. She smoked 15 cigarettes per day and did not consume alcohol. Her mother suffered from an unexplained deep vein thrombosis when she was 42 years old but otherwise her family history was unremarkable.

Initial examination revealed a heart rate of 122bpm, respiratory rate 24/min, oxygen saturations of 98% on air, a temperature of 37.6ºC and a blood pressure of 112/72 mmHg. She was struggling to complete full sentences. Examination of her cardiorespiratory system revealed good air entry in both bases, a JVP of 3cm, the absence of pedal oedema and soft and non-tender calves. Examination of her gastrointestinal system was unremarkable and ultrasound auscultation revealed the presence of a fetal heartbeat.

As she was being tended to for initial investigations, her condition rapidly deteriorated. Her oxygen saturation dropped to 88% on air, and her blood pressure was recorded as 88/66mmHg. She appeared cool and clammy, and her respiratory rate increased to 32/min. The doctor tending to venepuncture noted the presence of oozing of blood from the wound. She was promptly transferred the intensive care unit and the following investigations were conducted:

Hb	101 g/l
Platelets	75 * 10 /l
WBC	12.2 * 10 /l
Na	136 mmol/l
K	4.8 mmol/l
Urea	14.1 mmol/l
Creatinine	158µmol/l
INR	3.9
APTT	84 s
D-Dimer	2920 ng/ml

Urinalysis: ketones ++, leucocytes/nit/prot/blood/glucose negative
Portable chest x-ray: normal appearance of heart and lung fields
ECG: sinus tachycardia 148bpm, T wave inversion leads V3-V6
Arterial blood gases on air:

pH	7.48
Pa02	5.9 kPa
PaC02	2.2 kPa
BE	1
HC03	24 mmol/l

She was commenced on 15 litres/min oxygen via non-rebreathe mask, and an arterial line and central venous line were sited, as well as the presence of two large bore peripheral cannulae. She was immediately commenced on 2 litres of Hartmann's solution stat.

What is the most likely diagnosis?

A. Pulmonary embolus
B. Septic shock
C. Peripartum cardiomyopathy
D. Aortic dissection
E. Amniotic fluid embolus

E. Amniotic fluid embolus

In this instance, pulmonary embolism would not account for the presence of DIC and there is no evidence of deep vein thrombosis clinically. Septic shock can follow a similar path to amniotic fluid embolus, but in this instance, there is little evidence for a focus of sepsis.

Question 78 of 129

A 77-year-old man has attended the Emergency Department as he is very concerned about a purple lacy rash that has appeared on his arms and legs over the past few days. It is not painful and does not itch. His past medical history includes hypertension, type 2 diabetes, diverticulitis and atrial fibrillation. He takes amlodipine, ramipril and metformin and was started on warfarin one week ago by his GP. Examination confirms a widespread purple mottled rash across all four limbs and the abdomen. His chest is clear, heart sounds are normal and the abdomen is soft, nontender.

Blood results on admission show:

Hb	119 g/l
MCV	85 fl
Platelets	142 * 10 /l9
WBC	10.1 * 10 /l9
Neuts	4.5 * 10 /l9
Lymphs	1.9 * 10 /l9
Eosinophils	1.5 * 10 /l9
Na +	142 mmol/l
K +	4.6 mmol/l
Urea	14.6 mmol/l
Creatinine	169 µmol/l

What is the most likely diagnosis?

A. Amyloidosis
B. Antiphospholipid syndrome
C. Cholesterol atheroemboli
D. Churg-Strauss syndrome
E. Focal segmental glomerulosclerosis

C. Cholesterol atheroemboli

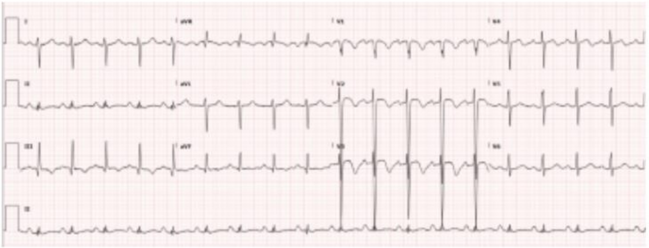
The purple, lacy, non-itchy rash described here is livedo reticularis. Antiphospholipid syndrome, Churg-Strauss syndrome and cholesterol atheroemboli can all cause livedo reticularis

Churg-Strauss and cholesterol atheroemboli could both result in raised eosinophils as seen here. However, this patient was started on warfarin a week ago by his GP which a recognised precipitant of cholesterol atheroemboli which makes it the most likely diagnosis here.

Question 79 of 129

A man in his 50's is brought to the emergency department by ambulance and was found collapsed in the street. His vital signs are as follows: Blood pressure 90/60 mmHg, pulse 120 bpm, respirations 25 bpm and temperature 37.9 ºC.

The 12 lead ECG showed:



What is the most likely cause of the patient's presentation?

A. Non-ST elevation myocardial infarction
B. Pulmonary embolism

C. ST elevation myocardial infarction
D. Severe hypokalaemia
E. Takotsubo cardiomyopathy

B. Pulmonary embolism

The ECG shows sinus tachycardia with right axis deviation, P pulmonale, Q waves in lead III and inverted T waves in the right precordial leads (V1- V3) and lead III.

Pulmonary embolism is the correct answer. Although the ECG is neither sensitive nor specific for pulmonary embolism, the classical findings of S1Q3T3 highly suggest right ventricular strain. Hence, the clinical picture is highly suspicious for pulmonary embolism, and the patient should promptly have an urgent CT pulmonary angiogram and thrombolysis if indicated. Other acute causes for right ventricular strain, like pneumothorax, upper airway obstruction and exacerbation of asthma/COPD, should also be considered in the differentials.

Non ST elevation myocardial infarction is incorrect. ECG changes like ST depression or T wave inversion in NSTEMI are often non-specific. If new, the T-wave inversions in this patient may suggest acute coronary syndrome, particularly right ventricular infarction, given the right ventricular strain pattern; however, NSTEMI is unlikely to cause collapse. The classical S1Q3T3 pattern in ECG, along with the clinical findings of tachycardia, tachypnoea and low-grade temperature, is more suggestive of pulmonary embolism in this patient.

ST elevation myocardial infarction is incorrect. Classically, STEMI is diagnosed if there is > 1-2 mm ST elevation in 2 contiguous leads or a new left bundle branch block (LBBB). Both of these are not found in this patient's ECG.

Severe hypokalaemia is incorrect. Although hypokalaemia may present with T-wave inversions in the precordial leads, there are no ST depression or U waves commonly seen in hypokalaemia. While hypokalaemia can cause muscle tetany, paralysis and respiratory failure, it is unlikely to cause collapse.

Takotsubo cardiomyopathy is incorrect. ECG changes like T wave inversion in Takotsubo cardiomyopathy are often non-specific. Moreover, the classical S1Q3T3 pattern in ECG, along with the clinical findings of tachycardia, tachypnoea and low-grade temperature, is more suggestive of pulmonary embolism in this patient.

Question 80 of 129

A 50-year-old woman was referred to the clinic with a 6-month history of shortness of breath. She gave a history of progressive exertional breathlessness and now could only walk a couple of hundred meters. In addition she also noted swelling of her ankles that started 3 weeks ago and had experienced 1 episodes of loss of consciousness. She had been a wheezy child but had grown out of it. She was a non-smoker and drank approximately 5 units of alcohol per week. She took no regular medications and had no known allergies. Her General Practitioner had prescribed salbutamol and beclomethasone inhalers for her but this had made no difference.

On examination her heart rate was 86 beats per minute, blood pressure 135/90 mmHg, respiratory rate 20 breaths per minute and oxygen saturations were 93% on room air.

Initial investigations are shown below:

Full blood count, urea and electrolytes, liver function tests: normal
Autoantibody screen: negative

Chest x-ray: clear lung fields, no cardiomegaly

Lung function tests:

- -forced expiratory volume in 1-second 2.8L (115% predicted) -forced vital capacity 3.2L (120% predicted)
- -total lung capacity 5.8L (120% predicted)
- -carbon monoxide diffusion in the lungs 92%

Transthoracic echocardiogram:

- -left ventricle: normal size, ejection fraction 65% (>55) -normal aortic and pulmonary valves
- -right ventricle dilated -tricuspid regurgitation (mild)
- -pulmonary artery systolic pressure: 55 mmHg

CT scan on chest: normal

Ventilation-perfusion (V/Q) scan: low probability for thromboembolic disease

What is the appropriate next investigation?

A. Bronchoscopy and bronchoalveolar lavage
B. Cardiac catheterisation
C. CT guided lung biopsy
D. CT pulmonary angiography
E. Genetic testing for cystic fibrosis

B. Cardiac catheterisation

The history and investigations in this case suggest a diagnosis of idiopathic pulmonary arterial hypertension (IPAH).

This condition is more common in women and commonly presents with progressive exertional breathlessness, lethargy, fatigue or syncope. On examination a loud pulmonary heart sound may be heard and eventually murmurs of pulmonary and tricuspid regurgitation may also be heard. As the disease progresses and right heart failure develops examination may reveal an elevated jugular venous pulse, hepatomaegaly, ascities and peripherial oedema.

Aside from idiopathic common causes include congenital/acquired cardiac lesions. Chronic obstructive pulmonary disease (COPD) of other lung pathology, pulmonary thromboembolic disease and vasculitic disorders.

ECHO is a good screening test but to confirming the diagnosis requires the gold standard investigation, which is cardiac catheterisation. Cardiac catheterisation will show the oxygen saturations in the veins and chambers of the heart and allow for accurate measurement of right atrial, ventricular and pulmonary artery pressures and pulmonary capillary wedge pressure, pulmonary vascular resistance and response to acute vasodilators (important implications for treatment).

The definition of IPAH includes: mean pulmonary artery pressure > 25 mmHg, pulmonary artery wedge pressure <= 15 mmHg and pulmonary vascular resistance > 3 Wood units.

Question 81 of 129

A 55-year-old man presents for review in cardiology clinic for his angina pectoris. He developed exertional chest pain two years ago and has been managed medically since that point with GTN, aspirin, atorvastatin and atenolol. He finds that he is unable to manage his angina and frequently needs the use of his GTN spray, which causes him headaches. He has a past medical history of gout and depression as well. He works as a paralegal and has quit smoking successfully five months ago. He is keen to better control the pain.

What is the most appropriate management option?

F. Add on nicorandil
G. Add on long-acting nitrite
H. Add on ivabradine
I. Refer for coronary arterial bypass graft
J. Add on calcium channel blocker

E. Add on calcium channel blocker

If angina is not controlled with a beta-blocker, a longer-acting dihydropyridine calcium channel blocker should be added

The correct answer is to add on a calcium channel blocker to his regular medications. He has been managed on monotherapy with a beta-blocker and prophylactic medication to prevent further ischaemic heart disease. Since first line monotherapy has failed, it should be combined with a calcium channel blocker following full up-titration of the monotherapy medication. If a combination of beta-blocker and calcium channel blocker fail to control symptoms then a long-acting nitrate, ivabradine, nicorandil or ranolazine can be added. Once medical management fails, surgery should be considered for further management.

Question 82 of 129

A 34-year-old woman comes to haematology clinic. She presented with a shortness of breath three days ago to a local emergency department. She underwent a CT pulmonary angiogram scan which demonstrated a pulmonary embolus. She was discharged with injections of low molecular weight heparin at treatment dose with a view of attending the anticoagulation clinic to start warfarin. She has no past medical history or allergies and only takes Microgynon as an oral contraceptive.

She is not pregnant and agrees to start warfarin.

What should be done with her heparin whilst starting warfarin?

A. Switch to prophylactic dose until INR is known to be above 2
B. Continue for one week whilst on warfarin
C. Stop same day as starting warfarin
D. Continue alongside warfarin for two weeks
E. Continue until INR is known to be above 2

E. Continue until INR is known to be above 2

The correct answer is to continue until INR is known to be above 2. This is a patient is started on warfarin whilst being covered with lowmolecular weight heparin for a pulmonary embolism. As she has not contraindications for warfarin, such as pregnancy or malignancy, warfarin should be started with a target INR of 2.5 (acceptable range 2-3). Starting warfarin can be variable and there are several protocols to achieve hospital induction, but whilst the patient has not yet been known to be at therapeutic anticoagulation, low-molecular weight heparin should be continued until a therapeutic INR is confirmed. Once this is achieved, the low-molecular weight heparin can be stopped.

Question 83 of 129

An 84-year-old female presents with a three-day history of constant chest discomfort associated with productive green sputum. On admission to the emergency department, a temperature of 38.2 degrees is recorded and she reports a recent history of 'shivering and shaking' over the past 24 hours. She reports no nausea or vomiting and was last well 72 hours ago, when she was living alone with BD carers. She has a known history of bronchiectasis, angina, hypertension, type 2 diabetes mellitus and hypertrophic obstructive cardiomyopathy.

On examination, you note bibasal coarse inspiratory crackles and an ejection systolic murmur. She has noted no deterioration in her exercise tolerance of 150 yards on flat ground. Her blood pressure is 140/85 mmHg heart rate 90/min and regular, Sats 94% on air, respiratory rate 26/min. Her ECG demonstrates ST depression and T wave inversion in V4 to V6, S wave in V1 and R wave in V5 add to 55 mm. You have no previous ECGs to compare this to. Her blood tests are as follows:

Hb	137 g/l
Platelets	402 * 10 /l
WBC	18.3 * 10 /l
Neutrophils	16.3 * 10 /l
Na	144 mmol/l
K	4.3 mmol/l
Urea	6.2 mmol/l
Creatinine	90 µmol/l
CRP	145 mg/l
Troponin < 0.03 (normal < 0.03)	

Her chest radiograph demonstrates left basal shadowing on a background of bibasal tramlining and fibrotic changes. Previous sputum cultures demonstrate pseudomonas colonisation. New sputum and blood cultures have been taken.

What is the most appropriate treatment?

A. Intravenous tazocin
B. Intravenous tazocin and acute coronary syndrome treatment
C. Acute coronary syndrome treatment only
D. Oral amoxicillin only
E. Oral amoxicillin and acute coronary syndrome treatment

A. Intravenous tazocin

The patient is elderly and has a number of comorbidities. The presenting condition is clearly infective exacerbation of bronchiectasis on a background of previous pseudomonal colonisation. As a result, oral amoxicillin is insufficient. The second question is regarding these abnormal ECG changes on a background of no cardiac chest pain and a negative first troponin. The key is to notice the history of HOCM with an ejection systolic murmur, suggesting a degree of left ventricular outlet obstruction. Her ECG demonstrates LV hypertrophy and the ST segment and T wave inversion are suggestive of LV strain, an expected pattern for patients with HOCM. No ACS treatment is thus necessary.

Question 84 of 129

A 54-year-old male business executive is referred to you after a heart murmur is detected at a medical examination he received after he transferred to a new company. He has no known past medical history or family history. He is well and leads an active lifestyle. On examination, you note a pansystolic murmur in the apex. Chest auscultation is unremarkable. An ECG demonstrates sinus rhythm at 64 beats/minute with no changes suggestive of ventricular hypertrophy. A transthoracic echocardiogram demonstrated good views with severe mitral regurgitation, preserved left ventricular function (EF 85%) and pulmonary arterial systolic pressure of 15 mmHg.

Which of the following is appropriate management?

A. Mitral valve replacement
B. Mitral valve repair
C. Percutaneous mitral valve repair (Mitraclip)
D. Infective endocarditis prophylaxis and 6 monthlyechocardiogram
E. 6 monthly echocardiogram

E. 6 monthly echocardiogram

The patient has severe chronic non-ischaemic mitral regurgitation that has not decompensated. The aetiology is unclear: primary causes include mitral valve prolapse, flail leaflet or rheumatic heart disease. Secondary causes include cardiomyopathy or coronary artery disease. The patient does not meet indications for intervention on the mitral valve, which include symptoms, left ventricular dysfunction, pulmonary hypertension, new atrial fibrillation and dilated left ventricle. It is uncommon for intervention to take place without any of the indications mentioned above. Instead, serial monitoring with 6 monthly echocardiograms is appropriate. Infective endocarditis prophylaxis is no longer indicated for patients in the absence of a prosthetic valve repair or replacement.

Percutaneous mitral valve repair is an emerging technique that is available to patients considered too high risk for mitral valve surgery, which uses a device to individually approximate the regurgitant leaflet. Comparing Mitraclip with mitral valve replacement or repair in severe mitral regurgitation patients with NYHA III/IV heart failure symptoms, one-year and four-year survival were similar with similar improvements in symptoms, LV size and function. However, Mitraclip patients demonstrated significantly higher incidence of requiring further surgery but significantly lower risks of major adverse events post-procedure.

Question 85 of 129

A 75-year-old male presents with increasing chest pain on exertion. He was first diagnosed with stable angina 7 years ago. His past medical history includes hypercholesterolaemia and hypertension. His drugs history includes bisoprolol and nifedipine, which he has been taking for the past 3 years. A recent angiogram was arranged as an outpatient by his GP, demonstrating stenoses in his left circumflex artery, distal right coronary artery and mid-left anterior descending artery.

What is the most appropriate long-term treatment of choice for his angina?

A. Coronary artery bypass graft
B. Percutaneous coronary intervention with 3 stents
C. Addition of ivabradine
D. Addition of nicorandil
E. Addition of ranolazine

A. Coronary artery bypass graft

NICE guidelines recommend the use of no more than 2 antianginals prior to consideration of reperfusion therapies. In the case of this gentleman, the consideration would be whether CABG or PCI would offer greater benefits: although the risks of recurrent MIs and stroke are similar for both PCI and CABG at one year, patients with complex anatomy, triple vessel disease or proximal left mainstem disease report better long-term survival and freedom from MI is greater with CABG. CABG is thus favoured to PCI in this patient according to American Heart Association and European Society of Cardiology guidelines.

Question 86 of 129

A 70-year-old male presents back to hospital 3 weeks after undergoing a primary percutenaous coronary intervention for anterior STEMI. He reports 24 hour history of increasing shortness of breath, fever over 39 degrees and pleuritic chest pain, different from the pain he reported when he initially presented with his ischaemic chest pain. On examination, his calves are soft, his heart sounds are normal with no added sounds and his lungs are clear on auscultation. His serum tests reveals a mildly raised troponin and ECG that demonstrates ST elevation in V2 to V4 but no reciprocal change. Angiography was performed again, demonstrating good radiological flow with no evidence of stent thrombosis. An transthoracic echocardiogram demonstrates a mild to moderate pericardial effusion with no tamponade.

What is the optimal initial treatment?

A. Aspirin, clopidogrel, low molecular weight heparin as per acute
B. coronary syndrome protocol
C. Fondaparinux
D. Bivaluridin
E. Oral prednisolone
F. Oral ibuprofen

F. Oral ibuprofen

The diagnosis is Dresslers syndrome, an inflammatory post-cardiac injury complication, characterised by high fever, chest pain with a possible pleural or pericardial rub and raised inflammatory markers. It is distinguished by late presentation compared to acute reperfusion injury, which normally occurs days to weeks after the acute MI. Dresslers syndrome is thus thought to be immune mediated instead. Most patients symptoms resolve completely with oral NSAIDs but a few refractory cases require corticosteroid therapy.

Question 87 of 129

A 43-year-old gentleman who is admitted and found to have a STEMI has chest pain on the ward. He is currently recovering from his percutaneous coronary intervention the day before and has felt well until now. The pain is over the left side of the chest and severe if he breathes. He has no cough or fevers and his observations are within normal limits.

On examination, he has normal heart sounds and a clear chest. He is mildly tender over the chest wall. His femoral puncture sites are clean with no haematoma. He is in sinus rhythm on the cardiac monitor and has soft non-oedematous calves. No JVP is seen.

Na	156 mmol/l
K	3.4 mmol/l
Urea	5.6 mmol/l
Creatinine	78 µmol/l
CRP	45 mg/l
Hb	134 g/l
Platelets	398 * 10 /l
WBC	13.0 * 10 /l
ECG	sinus rhythm, T wave inversion in V1-V3, PR 180ms and flat in most leads
Chest xray	clear lung fields, heart is at the upper limit of normal for size

What is the likely diagnosis?

A. Hospital acquired pneumonia
B. Pericarditis
C. Pulmonary embolism
D. Coronary artery dissection
E. Pleurisy

B. Pericarditis

Pleuritic chest pain at <48hrs after MI -> pericarditis

This gentleman develops chest pain in the first 24-48hrs after an MI. A hospital-acquired pneumonia would usually take longer to develop. A coronary artery dissection can be a complication of PCI but there would most likely be ischaemic changes seen on the ECG. Pleurisy is usually a post inflammatory condition after a lower respiratory tract infection. Pulmonary embolism is possible but patients with MI are anticoagulated and this is early for a PE to develop. It is recognised that a number of MI patients develop and acute pericarditis in the first 48hrs. Treatment is supportive and it is key to rule out other complications first.

Question 88 of 129

A 63-year-old female patient attends the Emergency Department with crushing central chest pain and 3mm ST segment elevation in leads II, III and aVF. She is taken to the cardiac catheter laboratory where she has a primary PCI with a satisfactory angiographic result.

Six hours later, whilst on CCU, she develops complete heart block. The patient is asymptomatic and her haemodynamic parameters are as follows:

Pulse 44bpm, regular

Blood pressure - 123/75mmHg

What is the most appropriate course of action?

A. Synchronised direct current cardioversion (DCCV)
B. Continue close monitoring and observation of the patient
C. Start an infusion of isoprenaline
D. Insertion of a permanent pacemaker
E. Insertion of a temporary pacing wire

B. Continue close monitoring and observation of the patient

In the description of the patient's presentation, it is stated that her ECG showed ST elevation in leads II, III and aVf, indicating an inferior STEMI. Complete heart block soon after an inferior MI is not uncommon, and usually resolves without the need for intervention. The key to this question is the fact that the patient is asymptomatic and haemodynamically stable. In view of this fact, it is sensible to closely monitor and observe on the assumption that given enough time postreperfusion she will return to sinus rhythm. If she was haemodynamically unstable, a temporary pacing wire would be the best option in the first instance, with an upgrade to a permanent system if she did not recover to sinus rhythm in due course.

Question 89 of 129

A 28-year-old man presented with heart palpitations. He states that he has had a a couple of episodes each week for the past 3 months. He describes the palpitations as a rapid beating of his heart. He has no past medical history and takes no regular medicines.

An ECG is performed:

P waves	Normal morphology. Inverted in lead I
PR interval	130ms
QRS	110ms. Loss of R wave progression in chest leads
QTc	410ms
Axis	Right axis deviation

What is the most likely explanation of the ECG results?

A. Torsades de pointes
B. Wolff-Parkinson-White (WPW) syndrome
C. Misplacement of the limb lead
D. Dextrocardia
E. AV nodal reentrant tachycardia (AVNRT)

D. Dextrocardia

Dextrocardia is associated with an inverted P wave in lead I, right axis deviation, and loss of R wave progression

The inverted P wave in lead I, right axis deviation, and loss of R wave progression should alert you to dextrocardia. Misplacement of the limb leads can cause a similar picture with inverted P wave in lead I and right axis deviation (RAD), however we would not expect loss of R wave progression, making dextrocardia the best answer in this question.

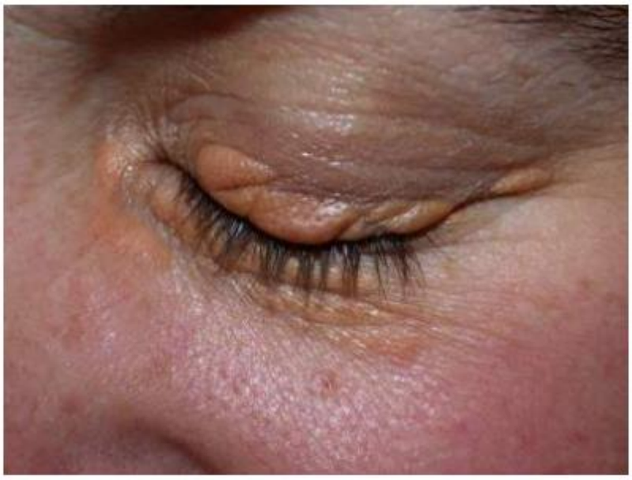
The PR interval is not short, and there is no delta waves present, making Wolff-Parkinson-White (WPW) unlikely.

The QTc is normal making Torsades de pointes unlikely

Question 90 of 129

A 56-year-old woman presents to her GP with discolouration around her eyes which has been present for some months. She feels very conscious about its appearance but denies any pain, itch or discomfort.

On examination, she appears well. The area in question appears as follows:



Given the likely diagnosis, which of the following would be an appropriate management option?

A. Topical emollient
B. Topical hydrocortisone
C. Topical ketoconazole
D. Topical trichloroacetic acid
E. Urgent referral to secondary care

D. Topical trichloroacetic acid

The photo above demonstrates xanthelasma - high lipid levels leading to soft yellow/orange plaques, periorbitally. They are not of clinical concern except for the underlying lipid profile which should be investigated and treated accordingly. They can be left alone, but if patients are keen for treatment, a commonly used option is topical trichloroacetic acid.

Topical emollient is unnecessary. This will not help to alleviate the appearance of the xanthelasma.

Topical hydrocortisone is inappropriate here. As a steroid, this would not help to reduce the appearance of xanthelasma.

Topical ketoconazole is also inappropriate. This is an antifungal and may be used for seborrhoeic dermatitis, which would instead present with dry, flaky skin and erythema - not yellow/orange plaques.

An urgent referral to a hospital is also unwarranted. Xanthelasma is of no clinical concern and requires no further investigation.

Question 91 of 129

A 32-year-old woman presented to the emergency department with a 2- hour history of acute shortness of breath. Helical CT pulmonary angiography shows no evidence of pulmonary embolus but reveals dilatation of her ascending aorta to 4.4 cm.

On examination, she is afebrile and has a heart rate of 102 beats/min, respiratory rate of 19 breaths/min, and a BP of 132/46mmHg. Her cardiac examination reveals a normal S1 with an end-diastolic murmur over the aortic valve.

Which of the following physical examination findings are most likely to be present in this patient?

A. De musset's sign
B. Presence of atrial fibrillation
C. Pulsus bigeminus
D. Pulsus paradoxus
E. Pulsus parvus et tardus

A. De musset's sign

De Musset's sign (head bobbing) is a clinical sign of aortic regurgitation

The typical presentation of severe acute aortic regurgitation includes sudden, severe shortness of breath; rapid development of heart failure and chest pain. Heart sounds usually reveal a decrescendo diastolic murmur over the aortic area. The likely diagnosis here is severe aortic regurgitation as the patient has sudden shortness of breath with an enddiastolic murmur and wide pulse pressure and the dilatation of the aorta in CT angiography.

Wide pulse pressure is due to an incompetent aortic valve that allows the diastolic pressure to fall significantly often below 60mmHg.

Some of the important aortic regurgitation clinical signs are

- Corrigan pulse - A 'water hammer' or 'collapsing' pulse is characterised by a rapidly rising and falling arterial pulse during late systole and diastole with wide pulse pressure. This finding is best appreciated by palpation of the radial or brachial arteries (exaggerated by raising the arm) or the carotid pulses.
- De Musset's sign - A head bob occurring with each heartbeat.
- Traube's sign - A pistol shot pulse (systolic and diastolic sounds) heard over the femoral arteries.
- Duroziez's sign - A systolic and diastolic bruit heard when the femoral artery is partially compressed.
- Quincke's pulses - capillary pulsations in the fingertips or lips.
- Mueller's sign - systolic pulsations of the uvula.

Pulsus paradoxus is described as a drop in systolic blood pressure of >10mmHg during the inspiratory phase, seen mostly in pericardial tamponade or severe COPD.

Pulses bigeminus occur in premature ventricular beats following a low volume pulse after a normal beat.

Pulsus parvus et tardus is more commonly known as a slow-rising pulse is a sign where on palpation of the pulse, it is late (tardus) relative to contraction of the heart and weak/small (parvus), found classically in severe aortic stenosis.

The presence of atrial fibrillation is usually present in enlarged left atrial like severe mitral stenosis or mitral regurgitation.

Question 92 of 129

A 77-year-old man with known atrial fibrillation is admitted following an upper gastrointestinal haemorrhage. His atrial fibrillation is managed using bisoprolol and warfarin. Since his admission, he has had four large episodes of haematemesis. You, the emergency department doctor, request the patient's INR to be checked as one of a series of investigations. The haematology laboratory phone through and inform you his INR is 8.5. He is currently hypotensive (90/45 mmHg) and tachycardic (120 beats per minute). You begin resuscitation using 0.9% saline, and send a cross match, group and save.

What is the most appropriate treatment of this patients INR?

A. Fresh frozen plasma + stop warfarin
B. Vitamin K + stop warfarin
C. Prothrombin complex concentrates
D. Prothrombin complex concentrates + vitamin K + stop warfarin
E. Stop warfarin

D. Prothrombin complex concentrates + vitamin K + stop warfarin

Major bleeding - stop warfarin, give intravenous vitamin K 5mg, prothrombin complex concentrate

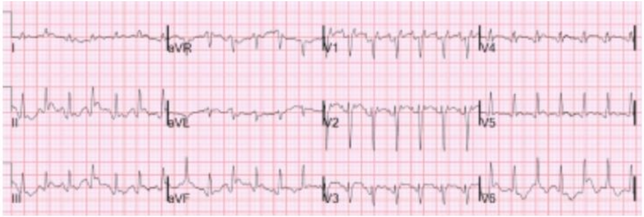
The nub of this question is the emergency management of haemorrhage in patients on warfarin. This patient has an INR greater than 8 and is actively bleeding. Therefore the answer is 4.

Patients on warfarin have reduced levels of Factor X, IX, VII and II. Rapid correction is most effectively achieved through administration of prothrombin complex concentrates.

The British Journal of Haematology states that: 'Emergency anticoagulation reversal in patients with major bleeding should be with 2550 u/kg four-factor prothrombin complex concentrate and 5 mg intravenous vitamin K

Question 93 of 129

A 70-year-old man is admitted with fever, chills and dysuria. He has a medical history of ischaemic heart disease, hypertension, hyperlipidaemia and diabetes. His current medications include aspirin, ramipril, bisoprolol, atorvastatin, metformin and dapagliflozin. He is an ex-smoker and requires assistance with personal care. He is started on cefuroxime for urosepsis. His admission ECG shows:



What is the most likely diagnosis?

A. Atrial fibrillation
B. Atrial flutter
C. Sinus tachycardia
D. Ventricular tachycardia
E. Wolff Parkinson White syndrome

B. Atrial flutter

The ECG shows an atrial rate of 300 bpm and ventricular rate of 150 bpm suggesting atrial flutter with a 2:1 AV block (regular p waves seen as notched t waves can be better appreciated in lead III, V1 and V2).

Atrial flutter is the correct answer. There are regular saw-toothed P waves at 300 bpm. There are regular QRS complexes at 150 bpm. Thus, this is atrial flutter with a rapid ventricular response and 2:1 AV block.

Atrial fibrillation is incorrect. Atrial fibrillation, unlike atrial flutter, is irregular with fibrillatory p waves caused by disorganised and chaotic atrial electrical activity. Contrary to atrial fibrillation, atrial flutter is more amenable to cardioversion than medications.

Sinus tachycardia is incorrect. In sinus tachycardia, every P wave is followed by a QRS complex and the PR interval is <200 ms. However, in this patient's ECG, not every p wave is followed by a QRS complex suggesting a 2:1 AV block. Moreover, the saw-toothed P waves at 300 bpm and prolonged PR interval is suggestive of atrial flutter.

Ventricular tachycardia is a broad complex tachycardia. The QRS complex here is narrow measuring < 120 ms and regular at 150 bpm suggesting an Atrial Flutter with 2:1 block.

Wolff Parkinson White syndrome is incorrect. WPW is a pre-excitation syndrome characterised by PR interval <120 ms, delta wave and QRS >110 ms which are absent in this patient's ECG.

Question 94 of 129

A 77 year old woman is brought to the Emergency Department by blue light ambulance in acute respiratory distress. She has a background history of congestive cardiac failure (NYHA II) due to hypertension and a previous anterior myocardial infarction which was treated medically. She is also a type 2 diabetic and has chronic kidney disease stage 2. She takes aspirin 75mg od, simvastatin 40mg od, ramipril 5mg od, bisoprolol 5mg od, furosemide 40mg bd and vildagliptin 5mg od.

On assessment her airway is patent. Respiratory rate is 32 per minute. Fingertip oxygen saturations are 90% on 15L/min oxygen. There are bilaterally crackles in the chest to above the midzones. Heart rate is 112bpm. Blood pressure is 125/75mmHg. ECG shows sinus tachycardia with no acute ischaemic change. There is peripheral oedema to the mid thigh and the JVP is elevated 6cm.

Which medical therapy is most appropriate immediately?

A. 3mg bumetanide orally
B. 80mg furosemide intravenously
C. 300mg aspirin, 300mg clopidogrel and 2.5mg subcutaneousfondaparinux
D. 50mg glycerol trinitrate infusion, commencing at 1mg/hr
E. 5mg metoprolol intravenously

B. 80mg furosemide intravenously

IV loop diuretic is the treatment for acute pulmonary oedema

This question concerns the pharmacological management of acute decompensation of left ventricular failure. It is important to point out that a patient presenting with symptoms of acute heart failure does not automatically imply an acute ischaemic event. Cardiac failure can be precipitated by changes in medication, intercurrent illness, worsening of other medical conditions or even dietary changes and it is wrong to assume a patient presenting with symptoms of cardiac failure have an acute coronary syndrome de facto. These patients should not routinely be given anticoagulant triple therapy unless there is also evidence of coronary ischaemic disease since this is unnecessary and significantly increases risk of haemorrhage. Prophylaxis against thromboembolic disease in cardiac failure is important however.

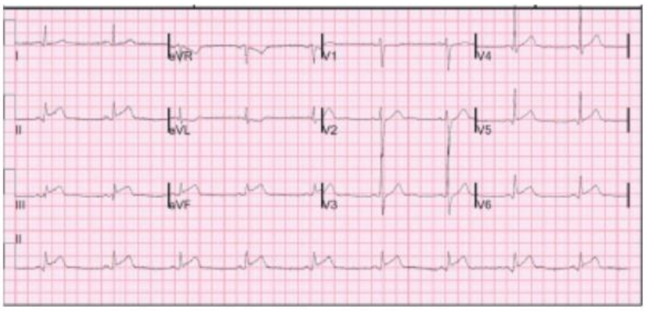
Current guidelines issued by the European Society of Cardiology and echoed by NICE guidance in the UK recommend diuretic therapy as first line medical intervention in acute cardiac failure. Intravenous administration is suggested rather than oral since this route is more rapid, there is a higher bioavailability and gut absorption can be hampered by gastrointestinal oedema in severe heart failure. Even pending the results of renal function, if pulmonary oedema is so severe to be impeding gas exchange, a bolus of furosemide is recommended to commence offloading. In patients with pre-existing renal disease, higher doses of diuretics will be needed to achieve adequate diuresis. Renal disease in itself it not a reason to avoid diuretics in heart failure, however diuretic use will result in a deterioration in renal function. Diuretic use will cause a rapid depletion in intravascular volume but the aim is to reduce tissue fluid by reducing hydrostatic pressure and a balance must be struck between deteriorating renal function due to intravascular loss and failure of therapy. Careful fluid balance monitoring is required.

Other options for fluid offloading include positive pressure ventilation which has a good evidence base behind it but patients find it uncomfortable and claustrophobic. Pressure ventilation causes an increase in intrathoracic pressure so venous return to the heart is reduced which in turn reduces cardiac output; care must be taken in hypotensive patients. Similarly glycerol trinitrate (GTN) can be used to offload pulmonary fluid by dilating arteries and to a lesser extent veins. This reduces both afterload and preload respectively reducing pulmonary oedema. Evidence demonstrates that this effect is negligible however when compared to standard diuretic therapy and should not be used first line. Indeed, it is usually only recommended in hypertensive patients with heart failure; neither GTN nor opioids are considered appropriate initial treatment of heart failure any longer, despite ongoing ubiquitous use. Side effects of GTN include hypotension, rapid tolerance, headache and complete cardiovascular collapse in cardiac outflow tract obstructions; GTN should never be given to patients with severe aortic stenosis for this reason.

Question 95 of 129

A 64-year-old man presents to the emergency department with a 2-hour history of chest pain. He has never experienced pain like this before. There is no history of shortness of breath and he reports to have been well in himself prior to today. His past medical history includes hypertension and hyperlipidaemia.

An ECG is taken, as shown below:



What is the most likely diagnosis?

A. Anterior myocardial infarction
B. Anterolateral myocardial infarction
C. Inferior myocardial infarction
D. Inferolateral myocardial infarction
E. Septal myocardial infarction

D. Inferolateral myocardial infarction

Inferolateral myocardial infarction is correct. This patient's ECG shows ST elevation in leads II, III, aVF, V5 and V6 along with ST depression in aVL. This is indicative of an inferolateral myocardial infarction. The inferior wall of the myocardium is supplied by both the right coronary artery (medial inferior wall) and left circumflex artery (lateral inferior wall). Given the ST elevation in the inferior and lateral leads, the left circumflex artery is more likely to be the occluded vessel.

Anterior myocardial infarction is incorrect. This presents with ST elevation in leads V1-V2 (septal) and V3-V4 (anterior). This is not seen here.

Anterolateral myocardial infarction is incorrect. This presents with ST elevation in the anterior leads (V3 and V4) +/- the septal leads (V1 and V2) in addition to ST elevation in the lateral leads (I, aVL, V5 and V6). Although there is ST elevation in V5 and V6, there are no ST segment changes in the anterior leads.

Inferior myocardial infarction is incorrect. Although there is ST elevation in the inferior leads (II, III and aVF), there is also ST elevation in V5 and V6 which makes an inferolateral myocardial infarction the diagnosis.

Septal myocardial infarction is incorrect. A septal myocardial infarction presents with ST elevation in leads V1 and V2 which is not seen here.

Question 96 of 129

An 82-year-old lady presented with shortness of breath and palpitations. These came on suddenly whilst she was watching television. She had a sedentary lifestyle and recently had been confined to bed with an upper respiratory tract infection. After this she had noticed that her ankles and legs were more swollen than usual, in particular her left leg. On further questioning she said that she had always needed three pillows to sleep but had recently required an extra pillow.

Her past medical history included hypertension, hypothyroidism, asthma and known coronary artery disease.

On examination her pulse was irregularly irregular. The jugular venous pressure was 6cm above the manubriosternal angle. Heart sounds were normal with no added sounds. On auscultation of the lung fields there were coarse crepitations at both bases. There was bilateral pitting oedema to the knees more marked on the left. The circumference of the left leg was 2cm greater than the right.

Observations:

- Heart rate: 128 beats per minute
- SaO2: 92% on room air
- Respiratory rate: 22 breaths per minute Temperature: 36.8 degrees Celsius Blood pressure: 110/68 mmHg

Investigations:

- 12-lead electrocardiogram: atrial fibrillation with a fast ventricular response, left ventricular hypertrophy
- Chest X-ray: cardiomegaly, Kerley B lines, small bilateral pleural effusions, pulmonary oedema
- Echocardiogram: poor biventricular function with an ejection fraction of 35%
- Computed Tomography Pulmonary Angiogram: small segmental pulmonary embolus

This lady was anticoagulated appropriately. Following this acute episode she improved clinically but remained in atrial fibrillation.

Given the clinical information available which of the following is the most appropriate drug to control her heart rate in the long term?

A. Metoprolol
B. Digoxin
C. Diltiazem
D. Flecainide
E. Warfarin

B. Digoxin

Digoxin is a good choice as this patient also has evidence of congestive cardiac failure which may also benefit from digoxin therapy. It is important to note that NICE recommends the use of digoxin only in sedentary patients and not those with an active lifestyle.

Metoprolol, a beta blocker, is not an appropriate choice here given the past medical history of asthma.

Warfarin is not a drug that is used for rate control; it is an anticoagulant.

Diltiazem is a rate-limiting calcium channel blocker and unlike digoxin does not have the added benefits in congestive cardiac failure.

Flecainide, a class 1c anti-arrhythmic drug, is used for chemical cardioversion in patients with no underlying structural heart disease as part of a pill-in-the-pocket regimen.

Question 97 of 129

A 68-year-old lady, who is a retired teacher, is admitted with lightheadedness. She has a history relevant for depression, osteoarthritis and sciatica. Her medication history includes codeine 30mg QDS, ibuprofen 400mg TDS, pregabalin 50mg TDS and amitriptyline 100mg ON. She is also on nitrofurantoin 50mg OD for recurrent urinary tract infections. Electrocardiogram (ECG) confirms normal sinus rhythm with a heart rate of 80bpm. There are no dynamic ST/T changes. PR interval is 140ms and QTc is prolonged at 526ms.

Which medication is most likely to be implicated?

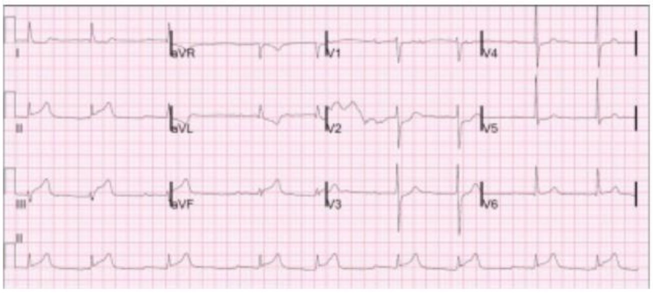
A. Nitrofurantoin
B. Pregabalin
C. Amitriptyline
D. Ibuprofen
E. Codeine

C. Amitriptyline

The correct answer is amitriptyline. Tricyclic anti-depressants are associated with prolongation of QTc interval. Other medications that can cause this include quinidine, erythromycin, digoxin, amiodarone and lithium. Prolongation of QTc interval, if marked, can result in R on T phenomenon, whereby a ventricular stimulus causes premature depolarisation of cells that have not completely repolarised. This may result in ventricular tachycardia or ventricular fibrillation. This lady is presenting with dizziness, and one should be concerned that this is a result of dysrhythmia secondary to pharmacotherapy. Any implicated medications should be temporarily discontinued, with alternatives sought.

Question 98 of 129

A 67-year-old man presents to the Emergency Department with central crushing chest pain. His ECG is shown below:



What is shown on the ECG?

A. Anterior non-ST elevation MI + atrioventricular block
B. Inferior ST elevation MI + atrioventricular block
C. Inferior ST elevation MI + left bundle branch block
D. Inferior ST elevation MI + right bundle branch block
E. Anterior non-ST elevation MI + complete heart block

B. Inferior ST elevation MI + atrioventricular block

There is ST elevation in the II, III and aVF diagnostic of an inferior myocardial infarction. The PR interval is significantly prolonged (first degree heart block) suggestive that the AV node may have been affected by the infarction.

Question 99 of 129

A 54-year-old woman presents to the emergency department with shortness of breath. She has slight associated pleuritic chest pain, but no cough and denies coughing up any blood and denies feeling hot or cold. Her symptoms started four hours ago and came on suddenly whilst at rest. She was well prior to today.

She has a past medical history of hypothyroidism and underwent a wide local excision for ductal carcinoma in situ one year ago. Her observations are all within normal range except for oxygen saturations which are at 93%. She has never smoked. Chest examination reveals few scattered crepitations heard over the right lower zone. Blood tests, including a Ddimer, are pending.

What is the most appropriate next step?

A. Warfarin
B. Chest X-ray
C. CT pulmonary angiogram
D. Ventilation-Perfusion scan
E. Treatment dose low molecular weight heparin

B. Chest X-ray

A chest xray is an essential investigation when investigating a PE

The correct answer is chest X-ray. This is a patient presenting with a typical history of a pulmonary embolism (PE). Whilst a CT pulmonary angiogram should be arranged urgently, a chest X-ray should be done first to exclude alternative pathologies such as a chest infection or pneumothorax. If a chest X-ray was done and a definitive scan such as a CT pulmonary angiogram or ventilation-perfusion scan was not available immediately then starting treatment with low molecular weight heparin would be appropriate.

'Venous thromboembolic diseases: diagnosis, management and hrombophilia testing' Clinical guideline [CG144]. The National Institute for Health and Care Excellence, June 2012.

Question 100 of 129

A 69-year-old gentleman is reviewed in cardiology clinic. He has been suffering from angina for five years and despite optimal medical management he finds that his symptoms are worsening. He has a past medical history of type 2 diabetes mellitus, gout and hypertension. He is currently taking felodipine, atenolol, atorvastatin, aspirin, ramipril and metformin. He has recently undergone an angiogram which has delineated triple vessel disease. He is very keen to optimise his survival chances as he is concerned about dying of a heart attack.

What intervention would have the greatest survival advantage?

A. Aggresive control of blood pressure, cholesterol and diabetes
B. Percutaneous coronary intervention (PCI) with insertion of stents
C. Coronary arterial bypass graft (CABG)
D. No intervention will give a further survival advantage
E. Heart transplant

C. Coronary arterial bypass graft (CABG)

The correct answer is coronary arterial bypass graft (CABG). This is a gentleman with severe ischaemic heart disease and angina. The greatest benefits are in either PCI or CABG as they address the underlying problem; reduced coronary artery blood flow. CABG is favoured over PCI in the case of people who are over 65 years old, have diabetes or have triple vessel disease. This patient has all three and therefore is a better option, but both options should be discussed in an MDT setting and with the patient.

Question 101 of 129

A 64-year-old woman presents to the emergency department with breathlessness. She has been feeling progressively breathless over the last two weeks with marked reduction in her exercise tolerance. She now finds that even a few steps make her short of breath whilst normally she would be able to walk to her local shops and back. She finds that she cannot lie down as it makes her feel worse. She has a past medical history of hypertension, previous myocardial infarction and asthma.

On examination, she has a raised JVP, bilateral crepitations on auscultation, reduced air entry in both bases and dull percussion. On her chest X-ray, there is evidence of pulmonary oedema and bilateral pleural effusions.

What is the most appropriate management plan?

A. Treat medically with diuretics
B. Pleural aspirate and if exudate insert chest drain
C. Insert chest drain on one side
D. Insert chest drain on both sides
E. Non-invasive ventilation

A. Treat medically with diuretics

The correct answer is to treat medically with diuretics. The history, examination and imaging all strongly suggest the underlying cause for her shortness of breath to be due to heart failure. The presence of the pleural effusions are therefore most likely to be transudates and it is reasonable to first treat the underlying cause before attempting to drain one or both of the effusions. If medical management with diuretics and nitrates failed to control this acute exacerbation of heart failure then non-invasive ventilation would be appropriate.

Question 102 of 129

A 45-year-old gentleman is advised by his GP to attend hospital following a routine blood test demonstrating an increase in creatinine two weeks following a dose increase in his ramipril. His ramipril was increased from 5mg daily to 5mg twice a day.

He has a letter which demonstrates investigation results, shown below. He reports no new symptoms. He reports that home monitoring of blood pressure has shown his control to be better.

21/11/2016	6/11/2016	
Na +	140 mmol/l	138 mmol/l
K +	4.5 mmol/l	4.1 mmol/l
Urea	5.5 mmol/l	5.4 mmol/l
Creatinine	110 µmol/l	92 µmol/l

How should his ramipril be managed and monitored?

A. Continue ramipril and repeat U&Es in 1-2 weeks
B. Reduced the dose of ramipril and repeat U&Es in 1-2 weeks
C. Stop ramipril and repeat U&Es in 1-2 weeks
D. Stop ramipril and arrange for an urgent out-patient imaging toexclude renal artery stenosis
E. Continue ramipril and repeat U&Es within 48 hours

A. Continue ramipril and repeat U&Es in 1-2 weeks

The correct answer is to continue ramipril and repeat U&**Es** in 1-2 weeks. Up to an increase in creatinine of 30% can be tolerated following the start or increase in an ACE-inhibitor such as ramipril, but U&Es should be repeated in 1-2 weeks. If the increase is greater than 30% then the ACEinhibitor should be stopped.

Question 103 of 129

A 75-year-old gentleman with a background of type II diabetes mellitus, ischaemic heart disease (IHD) and New York Heart Association (NYHA) III heart failure presents to your clinic with continuing fatigue and shortness of breath on minimal exertion. He currently takes Aspirin 75mg, Bisoprolol 10mg, Ramipril 5mg, Furosemide 40mg twice daily and Spironolactone 25mg. His electrocardiograph demonstrates left bundle branch block (old) and his ejection fraction is 32% measured by echocardiography at the clinic today. His chest x-ray shows an enlarged cardio-thoracic ratio but no obvious pulmonary oedema. Blood tests taken with his general practitioner this week are as follows:

Haemoglobin	110g/l
White cell count	11.0 *10^9
Neutrophils	7.2 *10^9
Platelets	240 *10^9
Na+	137 mmol/l
K+	4.2 mmol/l
Urea	9 mmol/l
Creatinine	125 µmol/l

What evidence-based treatment, if any, is available to treat this gentleman's cardiac failure?

A. Increase dose of Spironolactone to 50mg once daily
B. Increase dose of Furosemide to 80mg twice daily
C. Cardiac-resynchronisation therapy
D. Angiography +/- coronary stenting
E. He is already on maximal treatment

C. Cardiac-resynchronisation therapy

NICE guidance has recommended that cardiac resynchronisation therapy can be offered to patients who fulfil all of the following criteria:

- NYHA III or IV heart failure
- Ejection fraction of <35%
- The heart is beating regularly with evidence of electrical conduction disease\
- They are medication that is most effective for them

This patient is on appropriate doses of secondary-prevention and heart failure medications and there is no evidence of an acute coronary syndrome but the previous IHD is likely the cause of his cardiac failure. He satisfies all of the above criteria for cardiac resynchronisation and this has a good evidence-base.

Question 104 of 129

A 76-year-old woman is brought into the Emergency Department following an episode of loss of consciousness. On more detailed review, she reveals that she has been suffering increasingly with shortness of breath on exertion, with great difficulty in managing her shopping and cleaning.

Her past medical history include right hip fracture 6 years ago after a fall walking down the stairs; this required a total hip replacement.

She takes no regular medication and has no drug allergies.

On examination, her pulse was 80 beats per minute, blood pressure 104/89 mmHg, and respiratory rate 16 breaths per minute. She had a slow rising pulse, and on auscultation of the chest there was an ejection systolic murmur heard loudest at the aortic area, and radiating to the carotid arteries.

Electrocardiogram (ECG) shows sinus rhythm and criteria for left ventricular hypertrophy.

Chest x-ray shows clear lung fields. Transthoracic echocardiogram:

Aortic valve area	0.8 cm² (3-4)
Transvalvular gradient	55 mmHg (0)

The diagnosis of aortic stenosis is explained to the patient, and she opts for open surgical valve replacement.

What other investigation is warranted before proceeding to aortic valve replacement?

A. Exercise tolerance testing
B. Dopamine stress echocardiogram
C. 24 hour holter ECG
D. Transoesophageal echocardiogram
E. Coronary angiography

E. Coronary angiography

The valve area <1 cm² and transvalvular gradient >50 mmHg on transthoracic echocardiogram confirm the diagnosis of severe aortic stenosis, and the patient has opted for open surgical valve replacement.

Patients undergoing open surgical valve replacement should first undergo coronary angiography to exclude any coronary stenosis that could simultaneously be treated with bypass grafting.

This patient has undergone an 12 lead ECG and transthoracic echocardiogram. Further ECG or echocardiogram studies are not usually necessary.

Question 105 of 129

A 50-year-old man is recovering 12 hours after a stent placement for a ST elevation myocardial infarction in which there was a small stenosis of the circumflex artery. He has returned to the coronary care unit and you are called to see him due to changes on the cardiac monitor.

There are runs of broad complexes lasting 3-10 seconds at a rate of 80 per minute. He is asymptomatic and on waking is able to tell you that he has no chest pain or palpitations.

Na +	135 mmol/l
K +	3.2 mmol/l
Urea	5.3 mmol/l
Creatinine	89 µmol/l
Magnesium	0.61mmol/l (normal range 0.6-1.0)
Troponin	3000pg/ml (normal range <20)
ECG	Broad complexes at 73 beats per minute running in sets of 3-15 with normal sinus rhythm between. PR 150ms, QTc 450ms. No ST elevation at present

What action should be taken?

A. Reassure
B. IV magnesium sulfate
C. Transcutaneous pacing
D. DC cardioversion
E. Amiodarone

A. Reassure

Accelerated idioventricular rhythm is common and unconcerning following recent MI

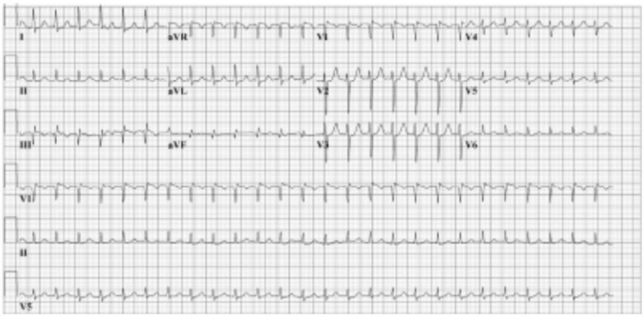
This gentleman has an MI that has been successfully treated and is recovering well. He is at risk of malignant arrhythmias like ventricular tachycardia during this time. However these broad complexes are not tachycardic. This phenomenon is accelerated idioventricular rhythm which commonly follows an MI in which ventricular ectopic tissue take over the pacemaker role. This usually resolves with time but can be helped by atropine if the patient is symptomatic. In this case, there are no symptoms and so the best action is to reassure the patient and continue monitoring. All other options would not be appropriate given the benign nature of this rhythm.

Question 106 of 129

A 41-year-old woman attends the emergency department with a 6-hour history of palpitations and breathlessness. She denies chest pain or recent illness. Her past medical history includes type 1 diabetes and she smokes 15 cigarettes/day.

On examination, she has a heart rate of 140bpm with a blood pressure of 122/77mmHg. Peripheral pulses are present bilaterally with a capillary refill of < 2 seconds. On auscultation, her heart sounds are normal with vesicular breath sounds throughout.

An ECG is taken, as shown below:



What is the most likely diagnosis?

A. Atrial flutter
B. Sinus tachycardia
C. Supraventricular tachycardia
D. Ventricular tachycardia
E. Wolff-Parkinson White syndrome

C. Supraventricular tachycardia

This patient's ECG shows a regular, narrow-complex tachycardia in keeping with supraventricular tachycardia (SVT). Given the absence of clear P waves, it is likely that the cause of this SVT is an atrioventricular nodal re-entry tachycardia (AVNRT) secondary to a re-entry circuit causing premature ventricular contraction. SVT is more common in women with a heart rate varying from between 140-280bpm. Symptoms include palpitations and breathlessness, as seen here, and may occur spontaneously or following provocation with caffeine, drugs or alcohol.

Atrial flutter is a form of supraventricular tachycardia caused by a reentry circuit into the right atrium. This typically causes an atrial rate of 300bpm. The ventricular rate is determined by the degree of the atrioventricular block at the atrioventricular node e.g. a 2:1 block would result in a heart rate of 150bpm, whilst a 3:1 block would give a rate of 100bpm. Symptoms include palpitations or shortness of breath, whilst common ECG findings include a narrow complex tachycardia with inverted flutter waves in leads II, III and aVF, giving rise to a saw-tooth appearance on the baseline of the ECG. These are not seen here, making it a less likely diagnosis.

Sinus tachycardia is a common ECG finding in patients presenting with palpitations. However, the absence of discernable P waves makes sinus tachycardia less likely.

Ventricular tachycardia presents as a broad-complex tachycardia with widened QRS complexes. This ECG shows a narrow-complex tachycardia, making ventricular tachycardia unlikely.

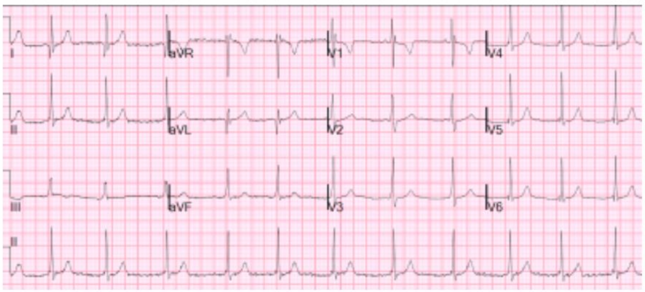
Wolff-Parkinson White (WPW) syndrome causes a tachyarrhythmia secondary to an accessory excitatory pathway stimulating premature ventricular contraction. WPW syndrome may present as palpitations, as seen in this patient. However, the ECG findings in Wolff-Parkinson White include a shortened PR interval and a slurred upstroke of the QRS complex (delta wave) causing QRS interval prolongation which is not seen here

Question 107 of 129

A 40-year-old woman presents to the emergency department with a 10- day history of intermittent palpitations. She reports that her symptoms have worsened over the last 8 hours and her palpitations are now persistent and are associated with lightheadedness. She has no past medical history of note and takes no regular medications.

On examination, she appears clammy and warm to the touch. Her heart rate is 72 beats/min with a blood pressure of 125/83mmHg.

An ECG is taken (as shown below):



What is the most likely diagnosis?

A. Accelerated junctional rhythm
B. Atrial flutter
C. Normal sinus rhythm
D. Supraventricular tachycardia
E. Wolff-Parkinson white syndrome

E. Wolff-Parkinson white syndrome

This patient has **Wolff-Parkinson White syndrome** a pre-excitation syndrome that causes clinical features of palpitations, shortness of breath, chest pain and in severe cases collapse and shock, including cardiac arrest. Wolff-Parkinson White is caused by an accessory pathway conducting impulses from the sinoatrial node to the ventricles giving rise to an atrioventricular re-entry tachycardia. ECG features include a shortened PR interval, left axis deviation or right axis deviation (depending on the location of the accessory pathway) and a widened QRS complex from the 'delta' wave (a slurred upstroke of the QRS complex). The delta wave can be seen in this patient's ECG, along with a shortened PR interval.

Accelerated junctional rhythm is incorrect. Accelerated junctional rhythm is when the atrioventricular node conducts at a faster rate than the sinoatrial node. This gives rise to an ECG with appearances of a narrow complex rhythm, with a ventricular rate between 60-100 beats/min. Retrograde P waves can be seen. Causes include digoxin toxicity, beta-blockers and myocardial ischaemia.

Atrial flutter is incorrect. Atrial flutter is an irregular supraventricular arrhythmia. Although it can cause similar symptoms to those experienced by the patient, a characteristic ECG finding is a saw-tooth appearance of the baseline of the ECG which is not seen here.

Normal sinus rhythm is incorrect. Although the patient's rhythm is sinus with QRS complexes following a P wave. There are clear delta waves preceding the QRS complexes that are consistent with Wolff-Parkinson White syndrome.

Supraventricular tachycardia (SVT) is incorrect. SVT is caused by a reentry circuit within the atrioventricular node. This is in contrast to atrioventricular re-entry tachycardia which is caused by an accessory conducting pathway (e.g. Wolff-Parkinson White syndrome). Symptoms are similar to this patient's presentation with palpitations, shortness of breath and chest pain that may be exacerbated by caffeine or alcohol. However, the presence of a delta wave is more suggestive of an accessory conducting pathway, making supraventricular tachycardia.

Question 108 of 129

You are asked to see a 64-year-old woman in the emergency department who has presented with a 3-day history of pleuritic chest pain and smallvolume haemoptysis.

She has a past medical history of hypertension, stage 4 chronic kidney disease, previous deep venous thrombosis (DVT), and a newly diagnosed primary breast cancer awaiting multidisciplinary team discussion.

You note crackles at the right lung base. There are no added heart sounds and no limb swelling is noted.

Her observations are as follows:

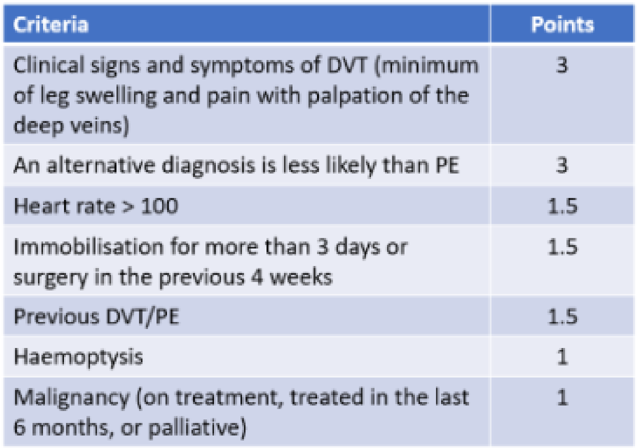
- Oxygen saturation: 98% on room air
- Respiratory rate: 18 per minute
- Heart rate: 104bpm
- Blood pressure 110/57 mmHg

Her blood results return as below.

Hb	116 g/L	Male: (135-180)Female: (115 - 160)
Platelets	181 * 10 /L	(150 - 400)
WBC	6 * 10 /L	(4.0 - 11.0)
Na	137 mmol/L	(135 - 145)
K	6.1 mmol/L	(3.5 - 5.0)
Urea	13.6 mmol/L	(2.0 - 7.0)
Creatinine	382 µmol/L	(55 - 120)
CRP	34 mg/L	(< 5)

Chest x-ray shows no obvious abnormality.

2-level PE Wells test



Criteria	Points
Clinical signs and symptoms of DVT (minimum of leg swelling and pain with palpation of the deep veins)	3
An alternative diagnosis is less likely than PE	3
Heart rate > 100	1.5
Immobilisation for more than 3 days or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Haemoptysis	1
Malignancy (on treatment, treated in the last 6 months, or palliative)	1

Of the options given, which is the most appropriate next step?

A. Arrange for CT pulmonary angiogram
B. Arrange for Doppler ultrasound
C. Arrange for V/Q Scan
D. Arrange for d-dimer
E. Arrange for echocardiography

C. Arrange for V/Q Scan

This patient has a Wells score of 8, given that it is the most likely diagnosis, she has active malignancy, a history of previous DVT, a heart rate >100, and is presenting with haemoptysis. As they have scored more than four, pulmonary embolism (PE) would be considered likely in this patient, and therefore merits further imaging to further evaluate this, without the need for a d-dimer.

A **V/Q Scan** would be the investigation of choice for confirming a diagnosis of PE given this patient's renal function.

A **CT pulmonary angiogram** would have been the recommended initial lung-imaging modality for non-massive PE if not for being contraindicated by the patient's renal function.

Echocardiogram can be used in patients who are haemodynamically unstable, but as this is not the case here, it is not the initial investigation of choice.

Arranging for Doppler ultrasound is incorrect given there are no symptoms suggesting a current DVT.

D-dimer would be the appropriate next step for risk stratification if the patient had a Wells score of less than four.

Question 109 of 129

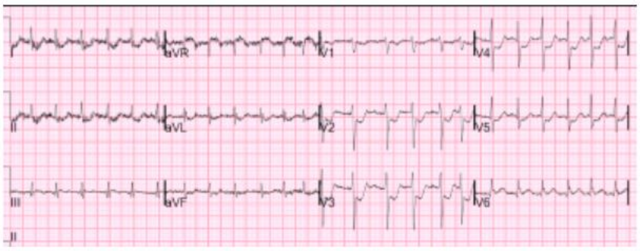
A 34-year-old male is brought in from a nearby bar having collapsed. His friends who accompany him tell you that the patient had been moderately intoxicated but had not reported any symptoms prior to his collapse.

On arrival, the patient is conscious but reports feeling generally weak and light-headed. He has never had an episode like this before but has had episodes of palpitation with associated shortness of breath previously.

The patient states he smokes 20 cigarettes/day, often binge drinks consuming 10 plus pints of beer most weekends and occasionally uses cocaine.

On examination, the patient is conscious and reports some lightheadedness and palpitation but feels otherwise ok when lying down. He has a fast, thready pulse between 130-150bpm and a blood pressure of 89/65mmHg. He has a mildly raised respiratory rate but his chest is clear and peripheral saturations are 94% on room air. Heart sounds are normal and examination is otherwise unremarkable.

An ECG is performed as below



What is the most appropriate management?

A. IV adenosine
B. IV metoprolol
C. Cardioversion
D. Pacemaker insertion
E. Percutaneous coronary intervention

C. Cardioversion

This patient has presented with a tachyarrhythmia and is haemodynamically unstable with an acute collapse, most likely syncope induced, and shock, demonstrated by the hypotension and cool extremities, etc. As seen on the ECG the patient's rhythm is fast and irregular with a varied rate of between 100 and 150 bpm. The QRS complexes are narrow and clear 'p' waves cannot be seen before each complex. This is in keeping with a tachyarrhythmia, most likely secondary to atrial fibrillation however the specific cause is not relevant as urgent synchronised cardioversion is required in any unstable patient presenting with a tachyarrhythmia. Cardioversion should be carried out in a resuscitation setting, with procedural sedation if possible. Other indications of instability in arrhythmias include evidence of myocardial ischaemia and heart failure. Following cardioversion, further management is based on the QRS complexes (narrow vs broad) and the rhythm (regular vs irregular).

Adenosine is the treatment of choice in patients presenting with supraventricular tachycardias (SVT), which may be the underlying diagnosis in this case, however, it should be used in hemodynamically stable patients only. As the patient is unstable cardioversion is required.

Metoprolol is an IV beta-blocker and, although it can be used in some tachyarrhythmias, this patient is unstable and requires urgent electrical cardioversion. IV beta-blockers can be used in stable patients with tachyarrhythmias (e.g. atrial fibrillation) for rate control as so long as they have an adequate systolic blood pressure and there are no other contraindications (e.g. asthma).

Pacemaker insertion is used in the management of bradycardia arrhythmias and does not have a role in acute arrhythmias causing compromise.

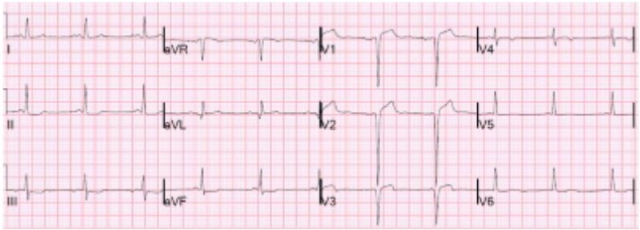
Percutaneous coronary intervention is used in the management of myocardial infarction (MI). Although the patient has some risk factors, and cocaine use can induce an MI, it is unlikely to be the underlying issue in this case with the patient not reporting chest pain **symptoms** and no clear evidence of ST-elevation seen on the ECG.

Question 110 of 129

A 55-year-old man presents to the emergency department with a 1-day history of central chest pain. He also complains of progressive shortness of breath on exertion over the last 2 weeks. He was discharged from the cardiology ward 21 days ago after having a drug-eluting stent inserted following an anterolateral myocardial infarction. His past medical history includes diet-controlled type 2 diabetes mellitus and hypertension.

On examination, he is afebrile with a temperature of 36.4ºC. His heart rate is 88 beats/min and regular with a blood pressure of 139/82mmHg. On auscultation, there are bibasal crepitations with saturations of 90% on air. There is pitting oedema to his mid-shins with soft and non-tender calves.

An ECG is taken, as shown below:



What is the most likely diagnosis?

A. Anterior myocardial infarction
B. Left ventricular aneurysm
C. Papillary muscle rupture
D. Pericarditis
E. Pulmonary embolism

B. Left ventricular aneurysm

This patient has a diagnosis of a **left ventricular aneurysm**, a rare but serious complication of an anterior myocardial infarction. The complication tends to present more than 2 weeks after a myocardial infarction and symptoms may include chest pain or congestive heart failure (e.g. shortness of breath and fluid overload). This patient's ECG shows ST elevation in V1-V3 with QS waves and upright T waves. Persistent ST elevation after a myocardial infarction is suggestive of a left ventricular aneurysm. However, in a patient with a recent history of ischaemia, it is also important to exclude another ischaemic event. A left ventricular aneurysm is much more likely if there are absent reciprocal ST changes, dynamic ST changes and well-formed Q or QS waves.

Acute coronary syndrome is an important diagnosis to consider following a myocardial infarction. However, ECG findings that are more typical of acute coronary ischaemia include new ST changes with dynamic and reciprocal changes, which are not seen here. Furthermore, the more gradual onset of symptoms is more suggestive of an alternative diagnosis such as a left ventricular aneurysm.

Papillary muscle rupture is incorrect. An anterolateral myocardial infarction causes rupture of the anterolateral papillary muscle, producing symptoms of mitral regurgitation. Although symptoms of congestive cardiac failure are evident in such cases, the onset of symptoms is usually more acute compared to a left ventricular aneurysm. Furthermore, it does not explain this patient's ECG changes or normal heart sounds (where a pansystolic murmur of mitral regurgitation may be seen).

Pericarditis is incorrect. Unlike Dressler's syndrome, post-MI pericarditis is an acute complication within the first 48 hours. The presentation is also similar to acute pericarditis with pleuritic chest pain worse on lying flat.

Pulmonary embolism is incorrect. ECG findings consistent with a pulmonary embolism include sinus tachycardia, RAD, RBBB or S1Q3T3. It does not explain this patient's ST elevation.

Question 111 of 129

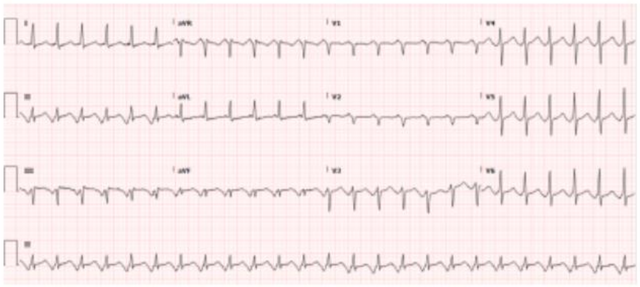
A 26-year-old woman has attended the emergency department with palpitations and shortness of breath. She has a background of asthma for which she has beclometasone and salbutamol inhalers.

On further questioning, she denies chest pain, dizziness, and loss of consciousness.

Observations are as follows:

Heart rate	200 bpm
Blood pressure	102/56 mmHg
Oxygen saturations	98%
Respiratory rate	28 /min
Temperature	36.8ºC

Her ECG is shown below:



Of the following options, what is the most appropriate management?

A. Direct current (DC) cardioversion
B. Intravenous adenosine 12mg
C. Intravenous adenosine 6mg
D. Intravenous metoprolol
E. Intravenous verapamil

E. Intravenous verapamil

The above ECG shows a narrow complex tachycardia of approximately 200bpm. This is also associated with an absence of P waves, except for P wave inversion in the inferior leads, otherwise known as retrograde conduction. These findings are in keeping with atrioventricular nodal reentry tachycardia, or AVNRT, the most common form of supraventricular tachycardia.

The correct management option in the above scenario is **intravenous verapamil**. All five of the above options can be used in patients with supraventricular tachycardia, however, verapamil is the most appropriate given the patient's clinical state and past medical history of asthma.

Following advanced life support algorithms, **DC cardioversion** should be used in narrow complex tachyarrhythmias when the patient is unstable. The above scenario does not describe evidence of heart failure, syncope, chest pain, or haemodynamic instability (shock). This option is therefore incorrect.

Intravenous adenosine 12mg is used in chemical cardioversion of narrow complex tachyarrhythmias, however, should only be used when 6mg of adenosine has failed to cardiovert. Furthermore, adenosine is contraindicated in patients with asthma. For these reasons, this option is incorrect.

Intravenous adenosine 6mg is often the initial medical management in narrow complex tachyarrhythmias. Although this would normally be the next option in management, adenosine is contraindicated in patients with asthma, making this option incorrect.

Intravenous metoprolol is also an option in the management of supraventricular tachycardias. Cardioversion is caused by heart rate reduction leading to self-termination of the tachyarrhythmia. However, due to the patient's asthma history, beta-blockers should be avoided.

Question 112 of 129

A 55-year-old Afro-Caribbean man visits his general practitioner for a follow-up of his hypertension management. He was diagnosed with hypertension 5 years ago, and his past medical history is significant for hypercholesterolemia. His hypertension has been treated with ramipril and amlodipine. Over the past 6 months, his blood pressure chart shows consistently high readings. He has already tried decreasing salt intake and exercising more. He does not smoke or consume alcohol.

On examination, his blood pressure is 156/97 mmHg, and pulse is 80/min. His BMI is 32 kg/m² with an increased waist-to-hip ratio.

Which of the following is the next best step in the management of this patient's hypertension?

A. Add benazepril
B. Add chlortalidone
C. Change ramipril to losartan
D. Refer to bariatric surgery
E. Advise lifestyle changes and reassess in 6 months

B. Add chlortalidone

In black individuals who are already taking a calcium channel blocker and ACE-inhibitor, and who continue to have blood pressure that is difficult to control, adding a thiazide-like diuretic is the next most appropriate step

This patient has primary hypertension that is not controlled by an ACEinhibitor and calcium channel blocker. The addition of another antihypertensive drug is the most appropriate management in this case. The choice of drug depends on the race of the patient. For black individuals, the recommendation is to add a thiazide-like diuretic, like chlortalidone or indapamide.

This patient is already taking an ACE inhibitor, ramipril. The guidelines recommend adding a drug with a different mechanism of action. Adding another ACE inhibitor, like benazepril, is inappropriate.

In some patients, ACE inhibitors may cause side effects. In such patients, it is suggested to replace the ACE-inhibitor with angiotensin-receptor blockers, like losartan. This patient does not report any side effects associated with ACE inhibitors.

Bariatric surgery is a treatment option for people with obesity if all of the following criteria are fulfilled:

- A BMI of 40 kg/m or more, or
- BMI between 35 kg/m and 40 kg/m and another significant disease (for example, type 2 diabetes or high blood pressure) that could be improved if they lost weight.

With a BMI of 32 kg/m , this patient does not fulfil the criteria for bariatric surgery.

This patient has already tried lifestyle changes. Although he should continue these lifestyle changes, he also needs a change in his drug regimen.

Question 113 of 129

A 32-year-old woman presents to the emergency department with palpitations. Her past medical history includes type 2 diabetes mellitus and acne vulgaris. She is currently taking Yasmin (a combined oral contraceptive pill) and has no known allergies.

Examination reveals a strong radial pulse, which is tachycardic and regular. She has a raised body mass index. Her cardiopulmonary system is unremarkable.

Observations:

- Heart rate: 168/min
- Blood pressure: 138/88 mmHg
- Oxygen saturations: 98% on room air
- Temperature: 37ºC

An ECG shows a supraventricular tachycardia.

The foundation year two doctor has already tried vagal manoeuvres and has just given 6mg of adenosine to no effect.

What is the most appropriate next step in management?

A. Amiodarone IV infusion
B. 12mg adenosine IV
C. Beta blocker IV
D. Cardioversion
E. Further 6mg adenosine IV

B. 12mg adenosine IV

Supraventricular tachycardia follows the narrow complex, regular tachycardia ALS guidelines.

If the patient is haemodynamically stable with no adverse features, such as shock, myocardial ischaemia or heart failure:

- Start with vagal manoeuvres. Carotid sinus massage or the Valsalva manoeuvre
- 2. Adenosine 6 mg rapid IV bolus; if unsuccessful give 12 mg; if unsuccessful give further 12 mg
- 3. If unsuccessful, seek specialist help

Use a large cannula to administer the adenosine and give a rapid bolus. A history of asthma is an important contraindication to adenosine, as it can cause bronchospasm. Instead, a calcium channel blocker should be used.

If the patient in unstable, they should the electrically cardioverted start with 70-120 J biphasic (100 J monophasic).

Question 114 of 129

A 72-year-old man presents to the emergency department with dizziness. There is no chest pain, palpitations or shortness of breath. He has a past medical history of hypertension. He takes amlodipine. He does not smoke or drink alcohol.

His observations are as follows:

- Heart rate 48 beats per minute
- Blood pressure 125/84 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air
- Temperature 37.1C

On examination, he is now asymptomatic. His heart rate is irregular. There are no murmurs. Chest auscultation is normal. His jugular venous pulse is not elevated. His Glasgow coma scale is 15/15.

An ECG demonstrates intermittently non-conducted P waves associated with a prolonged PR interval that is constant and not progressive. The QRS is broad. There are no ischaemic changes.

Bedside echocardiography reveals an approximately normal ejection fraction.

Given the likely diagnosis, what is the most appropriate management?

A. Atropine
B. Biventricular implantable cardioverter defibrillator (ICD) insertion
C. Dual chamber pacemaker insertion
D. Monitoring
E. Single chamber pacemaker insertion

C. Dual chamber pacemaker insertion

In patients with Mobitz type II AV block, or complete heart block, a DDD or DDDR pacemaker is indicated

Dual chamber pacemaker insertion is the correct answer. The patient has high grade atrioventricular (AV) block (2nd degree, Mobitz type II). This is characterised by intermittent non-conduction of P waves associated with a prolonged PR interval. In contrast to Mobitz type I, the PR interval is constantly prolonged and does not progressively lengthen. Mobitz type II is typically caused by significant structural damage to the conducting system. Mobitz II is much more likely than Mobitz I to degenerate to haemodynamic compromise and progress to complete heart block. Pacemaker insertion is warranted. It should be a dual chamber pacemaker on setting DDD or DDDR. DDD pacing means that the pacemaker can record both atrial and ventricular rates and can pace either chamber as necessary. DDDR is the same but can adjust the heart rate to account for the need for higher cardiac output.

Atropine is incorrect. 2nd degree AV block is typically not responsive to atropine. Additionally, while this patient certainly needs a pacemaker, he is now asymptomatic with no adverse features and therefore does not need atropine urgently.

Biventricular implantable cardioverter defibrillator (ICD) insertion is incorrect. This is typically indicated in patients with an ejection fraction of < 35% and symptomatic heart failure. It is not strictly inserted for high risk bradyarrhythmias.

Monitoring is incorrect. He is at risk of sudden deterioration and needs definitive management.

Single chamber pacemaker insertion is incorrect. Single chamber pacemakers are predominantly used for the management of atrial arrhythmias and are not indicated in those with AV block.

Question 115 of 129

A 58-year-old woman was referred to the acute medical unit with headaches and hypertension. She had no history of fever, neck stiffness, limb weakness, seizures or blurring of her vision. Her pulse rate was 70 beats per minute and blood pressure was 200/110 mmHg. Her heart sounds, chest examination, abdominal and neurological examination were normal. Fundoscopy was also normal.

Hb	138g/l
Platelets	238 * 10 /l9
WBC	6.2 * 10 /l9
Na +	135 mmol/l
K +	3.8 mmol/l
Urea	6.4 mmol/l
Creatinine	75 µmol/l
ECG	normal sinus rhythm
Chest x-ray	normal
CT Head	normal
Urinalysis	normal

What is the best initial management?

A. Intravenous labetalol
B. Intravenous glyceryl trinitrate
C. Oral amlodipine
D. Intravenous sodium nitroprusside
E. Sublingual nifedipine

C. Oral amlodipine

In an hypertensive urgency, treatment aims to lower blood pressure with the use of oral anti-hypertensive medication like a calcium channel blocker

This woman has hypertensive urgency, which is a severe increase in blood pressure (>180 mmHg systolic or >110 mmHg diastolic) not associated with target organ damage. This may be associated with headache, shortness of breath, or nosebleeds. The treatment is to lower the blood pressure within 24-48 hours and oral antihypertensive medications are recommended. Hospitalisation is not required. Amlodipine is a dihydropyridine calcium channel antagonist and a potent antihypertensive that can be used in this situation.

Intravenous antihypertensives like labetalol, glyceryltrinitrate are used in hypertensive emergencies which require lowering of blood pressure within minutes to hours e.g hypertensive encephalopathy, aortic dissection. Sublingual nifedipine is not recommended for treatment of hypertensive crises.

Question 116 of 129

A 72-year-old female presents with a 6-month history of gradual onset, progressive exertional dyspnoea associated bilateral increased lower limb pitting oedema. She has no previous cardiac history and prior to 6 months ago, had no limitations to exercise tolerance. Her past medical history includes B cell lymphoma diagnosed four years ago and in remission one course of chemotherapy. On examination, the jugular venous pulse is raised at 6cm above the angle of Louis. A soft systolic murmur and bibasal inspiratory crackles can be heard on auscultation. Abdominal examination demonstrates a pulsatile 3cm liver edge. Her blood pressure is 125/77 mmHg, heart rate 68/min and sinus, saturations 92% on 2l, respiratory rate 22/min. ECG reveals sinus rhythm of low voltage. Chest radiography demonstrates bibasal alveolar shadowing with prominent upper lobe vasculature.

Urine dip is as follows: blood -ve, leucocytes -ve, nitrates -ve protein 3+ pH 5.5.

Blood tests are as follows:

Hb	111 g/l
Platelets	275 * 10 /l
WBC	8.3 * 10 /l
Na	139 mmol/l
K	4.9 mmol/l
Urea	7.4 mmol/l
Creatinine	140 µmol/l
CRP	3 mg/l
Trop	<0.03 (normal range < 0.03)
Bilirubin	6 µmol/l
ALP	32 u/l
ALT	260 u/l

A transthoracic echocardiogram is performed, reported as significant increase in echogenicity, symmetrical left ventricular wall thickening, impaired bilateral diastolic ventricular dysfunction, bilaterally enlarged atria, pulmonary artery systolic pressure 45 mmHg, a 5mm pericardial effusion

What is the most likely underlying diagnosis for this patient?

A. Amyloid cardiomyopathy
B. Non-ST elevation myocardial infarction (NSTEMI)
C. Idiopathic dilated cardiomyopathy
D. Chemotherapy induced cardiomyopathy
E. Viral pericarditis leading to tamponade

A. Amyloid cardiomyopathy

A clinical picture of decompensated congestive cardiac failure is described with subtle details of hepatomegaly (possible congested, possibly related to the underlying diagnosis), associated heavy proteinuria, echogenic TTE and low voltage criteria ECG, on a background of previous B-cell lymphoma. The unifying diagnosis is amyloid cardiomyopathy, likely secondary to AL amyloid from B-cell dyscrasia, with cardiac, renal and possibly liver involvement. There is no evidence of a sudden onset cardiac event suggestive of an ischaemic cause. Echocardiogram does not demonstrate ventricular dilation, only impaired function. A 5mm pericardial effusion is not sufficiently significant to cause tamponade. Although chemotherapy-induced cardiomyopathy is possible, it is difficult to tie in the delayed onset from the end of treatment with renal involvement. It also does not explain the echogenic pictures on transthoracic echo.

Question 117 of 129

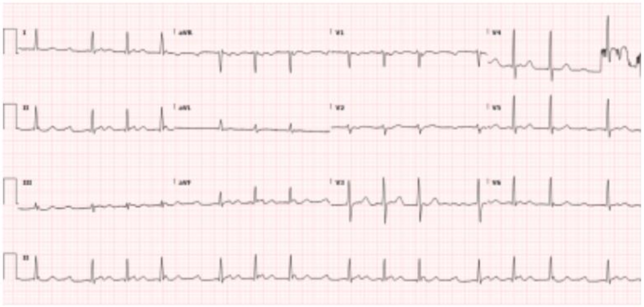
A 68-year-old man presents with occasional lightheadedness over the past few weeks. During his morning walk today, he experienced a brief spell of dizziness. He denies experiencing chest pain, breathlessness, or any other significant complaints.

His medical history includes diabetes, hypertension, and myocardial infarction for which he underwent coronary artery bypass grafting (CABG) seven years ago. He is currently on medications including aspirin, bisoprolol, lisinopril, atorvastatin, and vildagliptin.

Observations are as below:

- BP 140/85 mmHg
- Heart rate 74 bpm
- Respiratory rate 16/min
- Oxygen saturation 98% on room air

An ECG was subsequently carried out.



What is the most appropriate management option?

A. Discharge him and recommend a follow up ECG
B. Give atropine
C. Intravenous infusion of isoproterenol
D. Refer for cardiac resynchronisation therapy
E. Review his medications

E. Review his medications

The correct answer is **review his medications**.

The ECG findings demonstrate a progressive prolongation of the PR interval until a beat is dropped. This is characteristic of a 2nd-degree Mobitz 1 or Wenckebach-type block. This is usually a relatively benign rhythm with a low risk of progression to higher-degree blocks. This patient has symptoms of lightheadedness and dizziness, coupled with stable vital signs. As long as there is no hemodynamic compromise, there is no need for urgent intervention. Searching for a reversible cause should be the first step. This patient is on bisoprolol, a known cause of AVN block, and should be reviewed.

Discharge him and recommend a follow up ECG is incorrect. It is indicated if the patient is asymptomatic with a first or 2nd-degree Mobitz 1 heart block. This patient has symptoms of light-headedness and dizziness, which require intervention.

Give atropine is incorrect. Atropine is generally indicated for acute symptomatic AVN block with bradycardia and adverse features (heart failure, shock, syncope, myocardial ischaemia). There are no adverse features in this case.

Intravenous infusion of isoproterenol is also an incorrect answer. Reviewing any potential causes should be the initial approach for symptomatic hemodynamically stable patients. IV isoproterenol is indicated for hemodynamically unstable patients who fail to respond to transcutaneous pacing. Given the patient's history of coronary artery disease, it is important to avoid it if possible, due to the potential development of ischemic chest pain.

Refer for cardiac resynchronisation therapy is incorrect. Cardiac resynchronisation can be beneficial if there is heart failure with an ejection fraction of less than or equal to 35% and a widened QRS (e.g. left bundle branch block) complex on the ECG. It has no role in the management of the AVN block.

Question 118 of 129

A 23-year-old man presents with 2 days of chest pain to the emergency department. The pain is moderate and made worse if he breathes in. He is usually well but did have a few days off work for 'flu' last week.

On examination, he is sitting forward and groans in pain when asked to lie flat. His heart sounds are normal and his chest is clear. He is tender in his trapezius and scapular muscles but able to flex his neck .

Na +	135 mmol/l
K +	4.9 mmol/l
Urea	4.2 mmol/l
Creatinine	86 µmol/l
Hb	130 g/l
Platelets	354 * 10 /l9
WBC	4.5 * 10 /l9
Lymphocytes	0.1* 10 /l9
Chest X-ray	clear lung fields, normal heart contour

What ECG finding would be most specific in the likely diagnosis?

A. S1Q3T3
B. ST elevation
C. Sinus arrhythmia
D. Sinus tachycardia
E. PR depression

E. PR depression

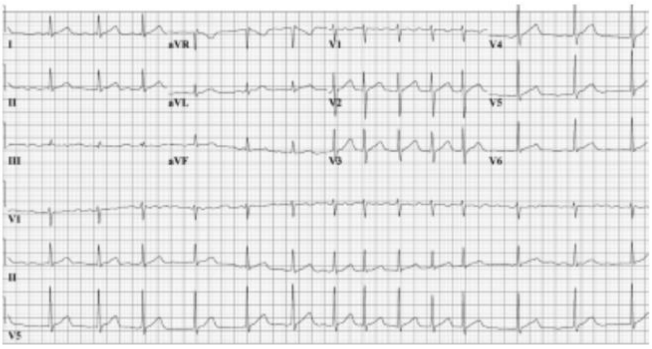
The most specific ECG finding in acute pericarditis is PR depression

The chest pain that is worse on lying flat in a person with a recent viral illness is due to pericarditis. ST elevation and PR depression are seen with the latter being the most specific. Sinus tachycardia and S1Q3T3 pattern are more commonly seen in pulmonary embolism. Sinus arrhythmia is a normal phenomenon in which the heart rate varies with the respiratory cycle.

Question 119 of 129

A 68-year-old man presents to hospital with left-sided upper and lower limb weakness that was present on waking that morning. The symptoms continue to persist in hospital. On examination, he has homonymous hemianopia. He has no significant medical history and is not on any regular medications.

A CT head is performed which is unremarkable. An ECG is performed, which is shown below.



How would you manage this patient's anti-thrombotic medication?

A. Apixaban for life
B. Aspirin 300mg once daily for 14 days, then apixaban for life
C. Aspirin 300mg once daily for 14 days, then clopidogrel 75mgonce daily for life
D. Clopidogrel 75mg once daily for life
E. Thrombolysis with alteplase, then apixaban for life

B. Aspirin 300mg once daily for 14 days, then apixaban for life

Aspirin 300mg once daily for 14 days, then apixaban for life is the correct answer. This patient has symptoms in keeping with a partial anterior circulation stroke. The CT head excludes an intracranial haemorrhage. Note, a normal scan is not sufficient to exclude a stroke, and stroke diagnosis should be based on clinical signs. The ECG shows atrial fibrillation which is the likely cause of the stroke. His CHA DS - VASc score is 3 due to age (+1) and stroke (+2). As such, he should receive two weeks of single anti-platelet treatment (aspirin 300mg once daily) as with all ischaemic strokes, followed by lifelong anticoagulation with a direct-acting oral anticoagulant (DOAC) such as apixaban, to prevent further strokes secondary to atrial fibrillation. Initiation of apixaban is delayed by two weeks post-stroke to prevent haemorrhagic transformation.

Apixaban for life is the incorrect answer. Therapeutic anticoagulation with a DOAC should not be initiated until after two weeks to avoid hemorrhagic transformation of an ischaemic stroke.

Aspirin 300mg once daily for 14 days, then clopidogrel 75mg once daily for life is the incorrect answer. This would be the correct answer if this patient did not have atrial fibrillation. Clopidogrel is insufficiently anti-thrombotic to prevent strokes secondary to atrial fibrillation and therefore a lifelong DOAC is required.

Clopidogrel 75mg once daily for life is the incorrect answer. A higher dose of antiplatelet is required to initially treat an ischaemic stroke (aspirin 300mg) and a DOAC is required long-term to reduce the atrial fibrillation-associated stroke risk.

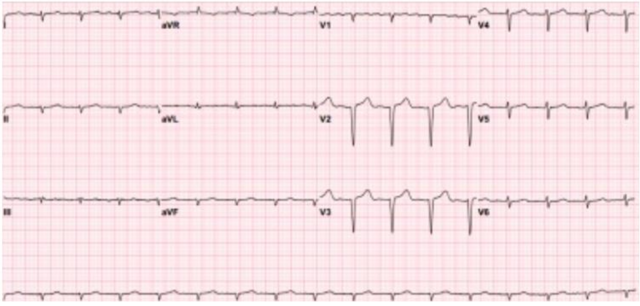
Thrombolysis with alteplase, then apixaban for life is the incorrect answer. This patient does not meet the criteria for thrombolysis as he awoke with the symptoms - thrombolysis requires symptom onset within the past four hours.

Question 120 of 129

An 81-year-old man is referred to the cardiology clinic due to worsening heart failure. Over the past 12 months he has become increasingly shortof-breath, particularly upon exertion or when lying flat. He has also suffered from ankle swelling which his GP has treated with large doses of furosemide. Around 6 months ago a clinical diagnosis of heart failure was made and he is already taking bisoprolol, ramipril and atorvastatin. He was diagnosed with multiple myeloma around 3 years and has been treated with melphalan to date.

On examination his pulse is 72/min and blood pressure 98/62 mmHg. The JVP is elevated at 6cm above the angle of Louis. There are crackles in both bases and pitting oedema to his knees.

An ECG accompanies the referral:



What is the most likely diagnosis?

A. Constrictive pericarditis
B. Infective endocarditis
C. Chronic pulmonary embolism
D. Cardiac amyloidosis
E. Hypercalcaemia-induced heart failure

D. Cardiac amyloidosis

This patient is likely to have AL amyloidosis secondary to his myeloma. This has resulted in cardiac amyloidosis as evidenced by the low voltage QRS complexes asssociated with poor R wave progression in the chest leads (a pseudoinfarction pattern).

Question 121 of 129

A 52-year-old lady was admitted with sudden onset central chest pain and breathlessness. Her past medical history included hypertension, atrial fibrillation and she was a smoker of 20 cigarettes a day. She lived alone after having recently split up with her husband which had been a difficult few weeks. Her friend had been staying with her occasionally during this difficult period.

She had a family history of ischaemic heart disease. She had recently complained to her friend of a cold that was now passing. Medications included aspirin 75mg OD and bisoprolol 5mg OD. Her friend called 999 and she was admitted directly to the angiogram suite as the paramedics noticed that her ECG showed ST elevation in the anterior chest leads.

Her angiogram showed mild coronary atherosclerosis but an akinetic left ventricle. Her troponin T was significantly elevated at 7800ng/L (normal < 14).

What is the most likely diagnosis?

A. Pericarditis
B. Myocardial infarction
C. Embolic event
D. Takotsubo cardiomyopathy
E. Pneumothorax

D. Takotsubo cardiomyopathy

Takotsubo cardiomyopathy (also known as broken heart syndrome, apical ballooning syndrome, acute stress cardiomyopathy) is nonischaemic cardiomyopathy where there is a temporary weakening of the heart muscle. This is often triggered by emotional stress or physical stress. Takotsubo cardiomyopathy is more commonly seen in postmenopausal women Patients most commonly present with chest pain and shortness of breath. Sudden onset congestive cardiac failure may also occur.

On initial presentation diagnosis of Takotsubo cardiomyopathy may be difficult and patients are often treated as an acute myocardial infarction. ECGs classically mimics ST-segment elevation myocardial infarction. Patients often proceed acutely to an angiogram which shows the absence of significant heart disease. Cardiac enzymes are significantly raised.

An echocardiogram may demonstrate pathognomonic wall motion abnormalities, in which the base of the left ventricle is contracting normally or is hyperkinetic while the remainder of the left ventricle is akinetic or dyskinetic. This coupled with the lack of significant coronary artery disease that would explain the wall motion abnormalities allows the diagnosis to be made.

Treatment of Takotsubo cardiomyopathy is generally supportive. Patients may be hypotensive, however, treatment with inotropes often worsens the disease. Patients may require intra-aortic balloon pump, fluids, beta blockers or calcium channel blockers. Aspirin is also commonly used in the management. Once over the initial event outcomes are favourable. Even when ventricular systolic function is heavily compromised at presentation, it typically improves within the first few days and normalises within the first few months

Question 122 of 129

A 71-year-old gentleman is reviewed in hospital prior to discharge after having received treatment for an exacerbation of COPD. His systolic blood pressure has been recorded as measuring between 138mmHg to 156mmHg. He has a background of ischaemic heart disease, gout, gallstones and a fractured neck of femur which was repaired with a dynamic hip screw. He is found to have ACR of 31mg/mmol. He normally takes allopurinol, aspirin, tiotropium, Symbicort, salbutamol.

What is the most appropriate pharmacological management for his hypertension?

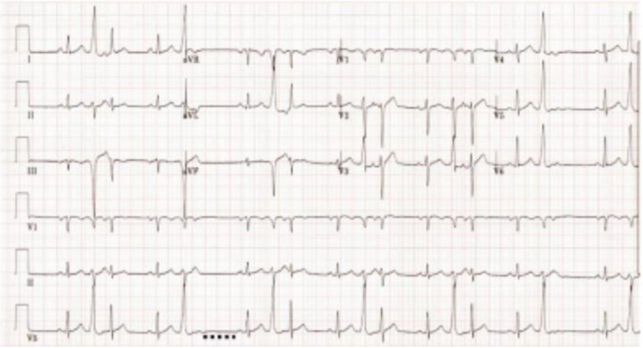
A. ACE-inhibitor
B. Calcium channel blocker
C. Thiazide-like diuretic
D. Beta-blocker
E. Alpha-blocker

A. ACE-inhibitor

The correct answer is ACE-inhibitor. This is an elderly man with hypertension and proteinuria. A calcium channel blocker would have been appropriate if he did not have proteinuria, whilst a thiazide-like diuretic and alpha-blocker feature at later stages in the NICE guidelines. Beta-blockers can provoke bronchospasms in COPD.

Question 123 of 129

A 58-year-old woman presents to the emergency department complaining of palpitations for half an hour. She has been diagnosed with diabetes, heart failure and depression and is on metformin, dapagliflozin, losartan, digoxin and sertraline. She reports experiencing abdominal cramps and loose stools over the last two days, which began following dinner at a restaurant. Her heart rate is 103 beats per minute, her BP is 100/70 mmHg, and respiratory rate is 20 breaths/min. An ECG was taken:



What is the most likely cause of the findings on the ECG?

A. Anxiety
B. Dapagliflozin
C. Digoxin
D. Metformin
E. Sertraline

C. Digoxin

The correct answer is **digoxin**. The electrocardiogram (ECG) presented demonstrates premature ventricular complexes (PVCs), which are characterised by abnormally large QRS complexes that disrupt the underlying sinus rhythm. A typical PVC is identifiable on an ECG as a broad QRS complex, exceeding 120 milliseconds in duration, with an abnormal morphology. It presents prematurely and is associated with discordant ST segment and T wave changes, followed by a compensatory pause prior to the next normal sinus impulse. Digoxin toxicity is recognised for inducing a spectrum of arrhythmias that may be lifethreatening. Arrhythmias associated with digoxin toxicity include paroxysmal atrial tachycardia, atrioventricular (AV) blocks, junctional rhythms, and ventricular arrhythmias such as PVCs and ventricular tachycardia. Notably, PVCs are often the initial indicator of digoxin toxicity and represent the most frequent arrhythmia linked to elevated serum digoxin levels. In this case, it is probable that hypokalaemia induced by diarrhoea has precipitated the digoxin toxicity.

Anxiety can lead to the emergence of PVCs; however, it is not deemed the primary cause in this clinical scenario. Anxiety-related PVCs are thought to originate from sympathetic nervous system overactivity. Nonetheless, given the circumstances described above, digoxin toxicity remains a more plausible explanation for this patient's presentation.

Metformin is not associated with arrhythmias when used within therapeutic dosages. Metformin toxicity might arise in contexts such as renal impairment or intentional overdose and could result in severe lactic acidosis that may precipitate arrhythmias. Despite this possibility, hypokalaemia secondary to diarrhoea resulting in digoxin toxicity appears to be a more convincing cause for the observed PVCs.

Sertraline, an selective serotonin reuptake inhibitor (SSRI), is utilised primarily in managing depression and does not align with this clinical picture as a causative agent for arrhythmia. Although sertraline is among the preferred antidepressants following myocardial infarction (MI), there exists no direct association between sertraline use and arrhythmic events. It should be noted that certain psychiatric medications such as clozapine, chlorpromazine and thioridazine have been implicated in arrhythmic side effects.

Dapagliflozin stands incorrect for this question. As an SGLT-2 inhibitor prescribed for heart failure and diabetes management, dapagliflozin has been reported to reduce incidents of significant ventricular arrhythmias including cardiac arrest or sudden death; thus it would be improbable for dapagliflozin to account for the clinical findings described here.

Question 124 of 129

An 86-year-old female presents to the diabetic ulcer clinic for regular foot care when regular observations note her heart rate to be 42 beats per minute. Her blood pressure is 142/55 mmHg and she reports no recent episodes of syncope. A 12 lead ECG demonstrates Mobitz type 1 rhythm at 42 beats/ minute. A 24 hours tape performed as an outpatient demonstrates bradycardia with up to 2.7 second pauses. Her past medical history includes type 2 diabetes mellitus, hypertension and angina. Her medications include ramipril, furosemide, verapamil, metformin and GTN on an as-required basis. During this second encounter, her heart rate is 41 beats/min and her blood pressure is 115/ 57 mmHg. She informs you that she is guided by you in terms of the most appropriate treatment.

What do you advise?

A. Temporary pacing wire
B. Permanent pacemaker insertion
C. Stop verapamil
D. Regular digoxin
E. Stop furosemide

C. Stop verapamil

The question focuses on the management of bradycardia and indications for pacemaker insertion. The patient is asymptomatic and sustains a reasonable blood pressure, there is no indication for a temporary pacing wire. Digoxin would only further the atrioventricular node block. Stopping furosemide is unlikely to affect the heart rate. Indications for pacemaker insertion is dependent on whether the patient has recently suffered a myocardial infarction. For patients post-MI, complete heart block, Mobitz type II, trifascicular block, symptomatic bradycardia or bilateral bundle branch block. For a patient not post-MI, symptomatic second and third-degree heart block or with haemodynamic compromise or VT secondary to bradycardia are indications. In this case, the patient is not post-MI and asymptomatic with no haemodynamic compromise. There are no indications for a pacemaker, stopping verapamil, an AV node blocker should be sufficient.

Question 125 of 129

A 50-year-old gentleman presented feeling dizzy and generally unwell for the last 3 days. He denied any chest pain, cough or fever but complained of increased fatigue and breathlessness. His past medical history included ischaemic heart disease, heart transplant, hypertension and diabetes. He takes the following medications: ramipril 5mg od, metformin 500mg bd, simvastatin 40mg od, amlodipine 5mg od and various immunosuppressive agents.

On examination his heart sounds were normal and chest was clear. There was only mild leg oedema. His vital signs show heart rate = 35 beats per minute, blood pressure = 90/40, SaO2 = 95% on air, T= 36.5ºC and respiratory rate = 20 breaths per minute. His ECG shows sinus bradycardia and CXR is clear. The following blood tests were obtained:

Hb	10.5 g/dl
Platelets	190 * 10 /l9
WBC	10.4 * 10 /l9
Na +	135 mmol/l
K +	3.6 mmol/l
Urea	8 mmol/l
Creatinine	100 µmol/l
CRP	15 mg/l

What is the next best management plan?

A. Glucagon intravenous
B. Atropine intravenous
C. Theophyline intravenous
D. Adrenaline 0.5mg intravenous
E. Adrenaline 0.5mg intramuscular

C. Theophyline intravenous

This question aims to raise awareness about the treatment of bradycardia and some potential pitfalls.

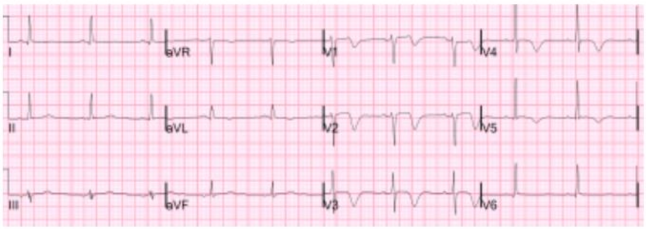
According to ALS protocol any bradycardia has to be assessed according to the ABCDE principle. In the presence of shock, syncope, myocardial ischaemia or heart failure further treatment is needed as soon as possible. Atropine is usually the first line treatment for bradycardia and if that fails then consider transcutaneous or transvenous pacing. However, in patients with heart transplant atropine is contraindicated. The hearts of these patients are denervated and do not respond to vagal blockade by atropine, which might precipitate paradoxical sinus arrest of highgrade block. In these cases, theophyline intravenously is indicated.

Glucagon is indicated if the bradycardia is due to beta-blockers or calcium channel blockers. Adrenaline is a potential option but the dose mentioned is wrong and certainly use of intravenous adrenaline outside the cardiac arrest scenario requires expert help (intramuscular in the anaphylaxis scenario.

Question 126 of 129

A 55-year-old man presents to the emergency department with a 2-hour history of central chest pain and dizziness. He has tried taking paracetamol and ibuprofen but has seen little improvement. His past medical history includes hypertension, for which he takes amlodipine 10mg once daily. He smokes 20 cigarettes/day and drinks 12 units of alcohol per week.

An ECG is taken (as shown below):



What is the most likely diagnosis?

A. Brugada syndrome
B. Hypertrophic obstructive cardiomyopathy
C. Posterior myocardial infarction
D. Pulmonary embolus with right heart strain
E. Wellen's syndrome

E. Wellen's syndrome

This patient has **Wellen's syndrome**. Wellen's syndrome is the critical ischaemia of the left anterior descending artery. Patients typically have a history of chest pain and ECG findings include biphasic T waves in the anterior leads or deep symmetrical T wave inversion in leads I and aVL associated with 1mm ST elevation in the chest leads. These can be seen in this patient's ECG.

Brugada syndrome is incorrect. Brugada syndrome is an autosomal dominant inherited cardiovascular disease. It can be asymptomatic and lead to sudden cardiac death. ECG changes consistent with Brugada syndrome include convex ST-segment elevation > 2mm in at least 1 of V1-V3 that is followed by T wave inversion. A partial right bundle branch block may also be seen. Sometimes, a patient may have an appearance of a normal electrocardiogram (ECG). However, following the administration of flecainide, these ST-segment changes may appear.

Hypertrophic obstructive cardiomyopathy (HOCM) is incorrect. HOCM is an autosomal dominant inherited condition resulting in left ventricular hypertrophy with decreased cardiac compliance and ultimately decreased cardiac output. Most cases can be asymptomatic. However, symptoms include exertional dyspnoea or chest pain, syncope and sudden cardiac death. Given the family history of sudden cardiac death, HOCM is a reasonable differential. However, ECG features of HOCM include features of left ventricular hypertrophy (eg increased R wave height), deep Q waves and non-specific ST segment changes that are not seen in this patient's ECG.

Posterior myocardial infarction is incorrect. A posterior myocardial infarction causes ECG findings such as a dominant R wave in V2, and horizontal ST depression and broad R waves in V1-V3. Although the patient has cardiac-sounding chest pain, their ECG findings do not match those that we see here, making this answer incorrect.

Pulmonary embolus with right heart strain is incorrect. Classic findings of a pulmonary embolus include sinus tachycardia and the less common S1Q3T3 finding. However, in more significant disease, patients may exhibit features of **right heart strain** secondary to pulmonary hypertension. Right heart strain appears as ischaemic changes (including deep T wave inversion) in the right-sided leads of the heart. The history here is not suggestive of a pulmonary emboli and does not explain the biphasic T waves seen in V1 and V2.

Question 127 of 129

A 48-year-old man is brought in by ambulance to the Emergency Department after experiencing sudden onset crushing central chest pain radiating down his arm. His ECG showed an inferior STEMI and he undergoes successful PCI with 2 stents inserted into his right coronary artery. He is transferred to CCU and started on secondary prevention medication.

24 hours after his presentation he becomes bradycardic at 34bpm and his blood pressure falls to 80/47 mmHg. He denies chest pain but feels dizzy and light headed. His cardiac monitor shows 3rd-degree heart block. He is given atropine but his heart rate does not raise and his blood pressure remains low.

What is the most appropriate next step in his management?

A. Isoprenaline infusion
B. Temporary pacing wire
C. Permanent pacemaker
D. Repeat angiography
E. Adrenaline

B. Temporary pacing wire

This gentleman has suffered an inferior STEMI. Complete heart block is a recognised complication of both inferior and anterior STEMI. Inferior STEMI CHB is usually more transient and they only require treatment if they become symptomatic. Anterior STEMI CHB is a more serious complication and they are more likely to need a permanent pacing system. In this case, as he has not responded to atropine then isoprenaline infusion is unlikely to work. There is no suggestion of repeat infarction so angiography is not indicated. He will require a temporary pacing wire to be placed.

Question 128 of 129

A 70-year-old woman with a history of type 2 diabetes mellitus and hypertension is reviewed in clinic. You can see from the records their is no evidence of diabetic retinopathy, chronic kidney disease or cardiovascular disease.

Her current medication is as follows:

- simvastatin 40mg on
- ramipril 10mg od
- amlodipine 5mg od
- metformin 1g bd

Recent blood results are shown below:

Na +	142 mmol/l
K +	4.4 mmol/l
Urea	7.2 mmol/l
Creatinine	86 µmol/l
HbA1c	45 mmol/mol (6.3%)

Urine dipstick shows no proteinuria. Her blood pressure today in clinic is 134/76 mmHg.

What is the most appropriate course of action?

A. Add gliclazide
B. Increase amlodipine
C. Increase ramipril
D. Add losartan
E. No changes to medication required

E. No changes to medication required

Newly diagnosed patient of black African or African-Caribbean origin with hypertension - add a calcium channel blocker

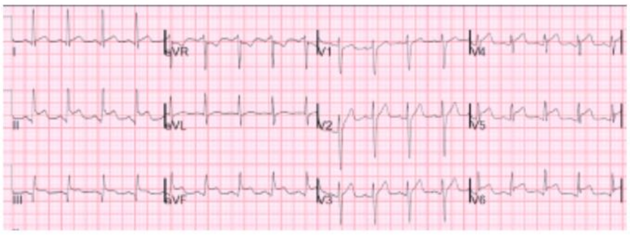
Her diabetic control is good - NICE do not advocate changing treatment at this stage unless the HbA1c is >= 6.5%.

As she has no complications from her diabetes the blood pressure target is < 140/80 mmHg. No changes are therefore required to her antihypertensive regime.

Question 129 of 129

A 45-year-old man is referred to the ambulatory care team with a 4-day history of left-sided chest pain and dyspnoea. He describes the chest pain as feeling sharp in nature and is associated with occasional shortness of breath and palpitations, particularly on exertion. He reports that his daughter has just recovered from scarlet fever and he has also been affected by coryzal symptoms over the past 2 weeks. His past medical history includes hypertension for which he takes ramipril 10mg OD.

An ECG is taken, as shown below:



Given the likely diagnosis, what is the most appropriate management?

- A. Calcium gluconate
- B. Colchicine
- C. Dual antiplatelet therapy
- D. Intravenous broad-spectrum antibiotics
- E. Simple analgesia and reassurance

B. Colchicine

Colchicine is correct. This patient has a likely diagnosis of pericarditis given the history of pleuritic chest pain after a recent coryzal illness. This patient's ECG shows widespread ST elevation with PR depression, both of which are characteristic signs of pericarditis. The treatment of pericarditis is with NSAIDs and colchicine, particularly for idiopathic or viral pericarditis.

Calcium gluconate is incorrect. ECG findings consistent with hyperkalaemia include tall tented T waves, PR interval prolongation and QRS widening. It does not cause widespread ST elevation or PR depression, as shown here.

Dual antiplatelet therapy is incorrect. Although this patient's ECG does demonstrate ST elevation, the ST elevation is widespread and not specific to one coronary artery territory. Furthermore, the nature of the ST depression is concave and is associated with PR depression, making pericarditis much more likely.

Intravenous broad-spectrum antibiotics is incorrect. This would be indicated for infective endocarditis which is a condition that typically presents with fevers, constitutional symptoms (e.g. malaise, weight loss, night sweats) and fatigue as the predominant features, in contrast to pleuritic chest pain that is being described here. Infective endocarditis does not explain this patient's ECG findings.

Simple analgesia and reassurance is incorrect. This would be indicated for musculoskeletal chest pain or perhaps even costochondritis which is characterised by pleuritic chest pain that may follow a recent viral illness. However, unlike pericarditis, costochondritis is the inflammation of the costochondral joints and does not produce ECG changes, as seen in this presentation.

PASSMEDICINE PART 2 NEUROLOGY OPHTHALMOLOGY, and PSYCHIATRY 2024

Question 1 of 409

A 68-year-old man is admitted to the unit with an exacerbation of severe pain around his abdomen. He describes it as a tight band like pain which is burning in character. He has a past medical history of metastatic prostate cancer. His drug history includes morphine modified release (100mg, twice daily), duloxetine (60mg, twice daily), pregabalin (200mg, three times per day). He states that the pain initially responded well to the analgesics he is on however over the past few weeks it has got progressively worse and culminated in a severe attack of pain today.

After discussion with the palliative care consultant, you elect to start the patient on an NMDA receptor antagonist.

What medication will you start?

A. Fentanyl
B. Codeine
C. Paracetamol
D. Gabapentin
E. Ketamin

E. Ketamin

Ketamine can be used as a third line agent in the management of neuropathic pain which is poorly responsive to titrated opioids and oral adjuvant analgesics

The patient describes classic radicular pain associated with thoracic radiculopathy. It is described as a tight band like pain which may be burning, tingling, or shooting in character. He is on a large dose of opioids and two neuropathic agents which act on different pathways.

He is already on a strong opioid so it would be inappropriate to use a middle strength opioid (e.g. codeine, dihydrocodeine, or buprenorphine). Fentanyl would only be used in stable pain, or with specific other indications such as renal disease. In this case it is unlikely to control his pain.

He is already on two neuropathic agents so it would be inappropriate to start gabapentin.

Ketamine can be used for neuropathic pain poorly responsive to titrated opioids and oral adjuvant analgesics (e.g. antidepressant and/or anticonvulsant) particularly when there is abnormal pain sensitivity (e.g. allodynia, hyperalgesia or hyperpathia). Ketamine is an NMDA receptor antagonists.Side effects to be aware of include hypertension, raised intracranial pressure and hallucinations.

Gabapentin was designed to mimic the neurotransmitter GABA. It does not, however, bind to GABA receptors. Its mechanism of action is to block voltage-gated calcium channels.

Question 2 of 409

A 34-year-old female presents to the clinic. She states that she sometimes has difficulties leaving the house due to fear of being in situations where she cannot escape. Some examples she gives includes being in busy places such as shopping malls and public transport. She states that when she he is at home and in her place of work she functions well, with regards to both productivity and interpersonal relationships.

What is the most likely diagnosis?

A. Panic disorder
B. Generalized anxiety disorder
C. Agoraphobia
D. Depression
E. Social phobia

C. Agoraphobia

Agoraphobia describes a fear of open spaces. It may or may not be associated with panic disorder

The clinical features are suggestive of agoraphobia which is described as fear of open spaces and being trapped in situations which are difficult to escape from.

Agoraphobia may or may not be associated with panic disorder. However, there is no evidence that this patient is having panic attacks.

Generalized anxiety disorder describes a syndrome where patients feel anxiety in a range of different situations including work and personal life. Social phobia describes a condition in which patients have a fear of being in social situations e.g. a fear of embarrassing themselves. The patient functions well with others both at work and home suggesting an alternative diagnosis.

There is nothing to suggest that the patient is depressed.

Question 3 of 409

A 64-year-old man presents to the endocrinology clinic with a palpable neck mass. He has noticed this incidentally. He denies any problems in swallowing, speaking or breathing. On more detailed history he does admit to a 3kg weight loss over the last 4 months which he cannot explain but is happy with as he has always been overweight. He has a past medical history of appendicectomy, hypertension, high cholesterol. He takes aspirin and atorvastatin. Thyroid function tests are normal. On examination, he has a roughly 3cm mass in the anterior neck triangle on the left side. It is firm and non-tender.

What is the most appropriate next investigation?

A. CT neck
B. US neck

Question 6 of 409

A 37-year-old man presents to the emergency department with a six-hour history of an acutely painful right eye associated with photophobia and reduced visual acuity. He has had no previous episodes. He has no relevant past medical history and occasionally takes codeine for back pain.

On examination, diffuse redness is noted throughout the right eye. The right pupil is smaller than the left and he is unable to count fingers in the right eye although visual acuity in the left eye is unimpaired.

What is the most likely diagnosis?

A. Acute angle closure glaucoma
B. Anterior uveitis
C. Bacterial conjunctivitis
D. Cluster headache
E. Scleritis

B. Anterior uveitis

Anterior uveitis presents with acutely painful red eye, photophobia, small pupil, reduced visual acuity. It is often associated with pus in the anterior chamber (a hypopyon)

This man has presented with a case of anterior uveitis, as confirmed by the typical findings on examination. Note that anterior uveitis can be both unilateral or bilateral, largely dependant on the cause. Although this condition is associated with a hypopyon, this is only sometimes present. A further clue is the presence of back pain in a young man which points towards a history of ankylosing spondylitis, a condition closely associated with anterior uveitis.

Acute angle-closure glaucoma does present with an acutely painful red eye however is commonly associated with a headache, nausea, and vomiting, and seeing halos. It is also more likely in the older population and particularly people with a history of presbyopia or chronic open-angle glaucoma.

Bacterial conjunctivitis does cause redness but is usually associated with itching and purulent discharge. Additionally, it is unlikely to be associated with the additional features this man has exhibited (miosis, photosensitivity, and reduced visual acuity).

Scleritis again is another cause of an acutely painful red eye however is unlikely to cause photophobia and miosis. Although scleritis is related to autoimmune conditions (such as systemic lupus erythematosus and rheumatoid arthritis), it is less associated with ankylosing spondylitis.

A cluster headache causes pain behind the eye and can be associated with redness and watering of the eye as well as miosis however attacks are more likely to be frequent and short-lived rather than persisting for six hours.

Question 7 of 409

A 20-year-old woman presents to a general neurology clinic. Over the last year, she has noted that she is becoming increasingly clumsy with heavy objects. She describes struggling to wash her hair and complete certain house hold chores such as hanging washing up.

Neurological examination findings of the upper limbs have been summarised below. Power has been recorded as per the Medical Research Council (MRC) grading system.

	Left arm	**Right arm**
Tone	normal	normal
Power:		
shoulder abduction	3/5	3/5
shoulder adduction	4/5	4/5
elbow flexion	4/5	5/5
elbow extension	5/5	5/5
wrist flexion	5/5	5/5
wrist extension	5/5	5/5
Reflexes:		
Biceps	normal	normal
Triceps	normal	normal
Supinator	normal	unable to elicit
Sensation	intact	intact

When examining her cranial nerves it is noted there is drooping of her eyelids and decreased facial expression. Tests for fatigability were unremarkable. There were no other abnormal findings.

What is the most likely diagnosis?

A. Myasthenia gravis
B. Facioscapulohumeral dystrophy
C. Multiple sclerosis
D. Miller-Fisher syndrome
E. Becker's muscular dystrophy

B. Facioscapulohumeral dystrophy

Facioscapulohumeral muscular dystrophy: facial weakness (e.g. difficulty closing eyes, smiling, blowing), winged scapula and weakness of the shoulderm upper arm and hip girdle muscles

The history here is typical of facioscapulohumeral dystrophy, the diagnosis is confirmed by the examination findings which confirm a proximal weakness affecting the limb girdle and subtle signs of weakness in the face.

The absence of fatigability in muscle power excludes myasthenia gravis. The clinical picture is not of Miller-Fisher syndrome which often presents as a triad of ophthalmoplegia, ataxia, and areflexia. Becker's muscular dystrophy is excluded as it typically affects the limb girdles in males who carry the X-linked gene. The presentation is also atypical of MS.

Question 8 of 409

A 43-year-old woman presents to the emergency department with fevers and confusion. She has no past medical history and does not take any regular medications.

On examination, her Glasgow coma scale is 13/15 (E3V4M5). There is no localizing neurological signs. Cardiovascular, respiratory and abdominal assessment is unremarkable. Her temperature is 38.8ºC.

An urgent MRI brain is organized, which demonstrates oedema of both temporal lobes. A lumbar puncture is arranged.

What set of results is most likely to be found?

A. Normal white cell count / elevated protein
B. Normal white cell count / normal protein
C. Raised lymphocytes / elevated protein
D. Raised lymphocytes / normal protein
E. Raised neutrophils / elevated protein

A. Raised lymphocytes / elevated protein

Herpes simplex encephalitis - the CSF usually shows a lymphocytosis amd elevated protein

Raised lymphocytes / elevated protein is the correct answer. The patient presents with fever and confusion and is pyrexial with a low GCS on examination. In this context, the MRI findings of bilateral temporal lobe oedema are highly suggestive of herpes simplex encephalitis. A lumbar puncture would typically demonstrate lymphocytosis and elevated protein.

Normal white cell count / elevated protein is incorrect. The normal white cell count points away from infection. Protein content in the CSF is usually raised either due to either an increased permeability of the blood brain barrier or synthesis of proteins within the spinal canal due to inflammatory cells. The differential for this set of results is broad and includes numerous inflammatory causes. It is however, a less likely set of results in HSV encephalitis.Raised lymphocytes / normal protein is incorrect. This set of results may be compatible with a viral infection but in HSV encephalitis the protein is more likely raised than normal.

Raised neutrophils / elevated protein is incorrect. This set of results is more consistent with a bacterial infection.

Normal white cell count / normal protein is incorrect. This is a normal result and unlikely in HSV encephalitis.

Question 9 of 409

A 47-year-old woman was admitted from a rehabilitation unit after appearing unwell. She has a past medical history of a road traffic accident 1 year prior and spinal cord injury at the C5 level which has left her quadriplegic.

Her regular medications include laxido, codeine and paracetamol.

On examination from the end of the bed, there is marked flushing of the skin across the face and shoulders and she appears diaphoretic and extremely agitated. Her temperature is 37.6ºC, oxygen saturation 97% on air, heart rate 102 beats per minute, respiratory rate 21 breaths per minute and blood pressure 206/130 mmHg. Auscultation of the chest reveals good bilateral air entry and vesicular breath sounds. Her heart sounds are normal with no added murmurs. There is a bounding pulse peripherally and central capillary refill time of 2 seconds. There is no swelling of the lower legs and the abdomen is soft with a rounded supra-pubic mass. There is a long term catheter in-situ connected to an empty catheter bag.

Initial investigations are displayed below:

ECG	Sinus tachycardia

Hb	126 g/L	Male: (135-180) Female: (115 - 160)
Platelets	368 * 10 /L	(150 - 400)
WBC	9.3 * 10 /L	(4.0 - 11.0)
Na	141 mmol/L	(135 - 145)
K	4.3 mmol/L	(3.5 - 5.0)
Urea	5.3 mmol/L	(2.0 - 7.0)
Creatinine	84 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Troponin T	5ng/L	(<14)

Chest X-ray	no focal consolidation or collapse

What would be the next most appropriate management step given the likely diagnosis?

A. Treatment dose of low molecular weight heparin followed by a CTPA
B. IV co-amoxiclav and gentamicin
C. Antihypertensives
D. Abdominal X-ray
E. Antihypertensives and bladder scan

E. Antihypertensives and bladder scan

Management of autonomic dysreflexia involves removal/control of the stimulus and treatment of any life-threatening hypertension and/or bradycardia

Patients with a high cervical spinal cord injury are at risk of autonomic dysreflexia which can be distressing and potentially cause life-threatening hypertension. The management of autonomic dysreflexia would be to identify and remove the offending stimulus - in this case, a blocked catheter causing urinary retention - while treating extreme hypertension.

Although the patient is at risk of venous thromboembolism given her immobility. The clinical picture is more in keeping with autonomic dysreflexia secondary to urinary retention and therefore option 1 is incorrect.

The clinical picture and investigation results are not consistent with urinary sepsis and therefore option 2 is incorrect.

Antihypertensives alone do not address the underlying cause and therefore option 3 is incorrect.

An abdominal X-ray may be an appropriate further down the line if you are suspecting faecal impaction as a cause for the urinary retention or for the autonomic dysreflexia. In this case, the clinical picture is more suggestive of acute urinary retention due to a blocked catheter. To confirm and manage this retention would be the immediate priority and therefore option 4 is incorrect

Question 10 of 409

A 60-year-old female presents to the Emergency Department with altered sensation in both hands and reduced visual acuity in the left eye. She states that these symptoms have slowly worsened over a week. She has no issues with bladder or bowel activity.

On examination, she is haemodynamically stable. Of note, she has a sensory loss throughout her arms and legs, but no clear sensory level. Additionally, she has brisk reflexes in both the upper and lower limbs. She also has a visual acuity of 6/36 in the left eye, but normal vision in the right eye, with normal visual fields.

Her MRI scan reveals multiple continuous segments of inflamed spinal cord throughout the cervical region and left optic nerve inflammation. There are no cerebral lesions. Her cerebrospinal fluid (CSF) studies are negative for oligoclonal bands.

Which of the following tests will confirm the diagnosis?

A. dsDNA antibodies
B. Aquaporin-4 antibodies
C. ACh receptor antibodies
D. NMDA receptor antibodies
E. Neuronal antibodies

B. Aquaporin-4 antibodies

Neuromyelitis optica is associated with aquaporin 4 positive serum antibody

The description of a patient with optic neuritis and longitudinal extensive cervical transverse myelitis with a CSF negative for oligoclonal bands is highly suggestive of neuromyelitis optica (NMO). The classic antibody associated with this disease is NMO-IgG or antibodies against aquaporin-4.

The 2006 diagnostic criteria for NMO are as follows:

Transverse myelitis and optic neuritis with at least 2 of the following features:

- MRI brain negative/nondiagnostic for multiple sclerosis
- MRI spinal cord lesion extending over 3 vertebral segments (LETM)
- NMO-IgG/Aquaporin-4 antibody seropositivity.

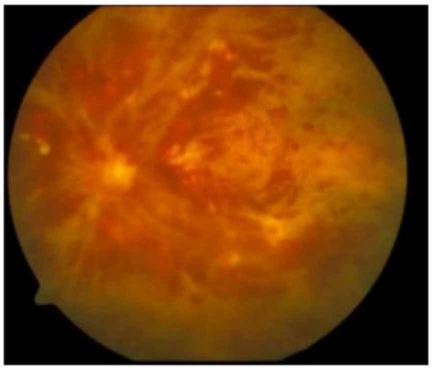
Question 11 of 409

A 62-year-old woman presents with sudden loss of vision in her left eye. Fundoscopy reveals the following:-

What is the diagnosis?

A. Retinal detachment
B. Ischaemic optic neuropathy
C. Vitreous haemorrhage
D. Central retinal vein occlusion
E. Central retinal artery occlusion

D. Central retinal vein occlusion



Central retinal vein occlusion - sudden painless loss of vision, severe retinal haemorrhages on fundoscopy

This appearance is sometimes compared to a cheese and tomato pizza.

Question 12 of 409

A 74-year-old man presents to the emergency department via ambulance with a sudden onset of speech difficulty, numbness and weakness. The symptoms started eight hours previously but he was initially reluctant to come to hospital due to fears regarding the coronavirus pandemic. He has a past medical history of hypertension, hypercholesterolemia and ischaemic heart disease. He is on regular aspirin, atorvastatin, bisoprolol and amlodipine. He does not smoke and drinks minimal alcohol. He is usually independent and lives with his wife.

His observations are heart rate 88 beats per minute, blood pressure 158/64 mmHg, respiratory rate 18/minute, oxygen saturations 96% on room air and temperature 37.1ºC.

On examination, an expressive dysphasia is noted in addition to right-sided hemisensory loss affecting his face, arm and leg. There is evidence of facial weakness and power is 3/5 in his right upper limb and 4/5 in his right lower limb. Chest auscultation is normal. Heart sounds are audible with no murmurs and his pulse is irregular. There are no carotid bruits.

Urinalysis is unremarkable and bedside testing demonstrates a glucose level of 7.1 mmol/L. An ECG demonstrates atrial fibrillation.

Urgent CT angiography demonstrates occlusion of the proximal anterior circulation.

Approximately one hour later, the patient undergoes a diffusion-weighted MRI that shows limited core infarct volume.

What is the most appropriate management?

A. Anticoagulation
B. High dose aspirin
C. Intravenous thrombolysis
D. Intravenous thrombolysis and thrombectomy
E. Thrombectomy

A. Thrombectomy

For thrombectomy in acute ischaemic stroke, an extended target time of 6-24 hours may be considered if there is the potential to salvage brain tissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume.

Anticoagulation is incorrect. This patient has had an ischaemic stroke likely secondary to new atrial fibrillation and will need anticoagulation in due course. However, anticoagulation is not a treatment for acute stroke and is usually delayed for two weeks after the initial event.

High dose aspirin is incorrect. This patient is outside the typical thrombolysis window of 4.5 hours but is already established on aspirin treatment and there is another more suitable option in this circumstance i.e. thrombectomy.

Intravenous thrombolysis is incorrect. This treatment needs to be administered with 4.5 hours of the onset of an ischaemic stroke. We are outside the thrombolysis window and therefore this is not an appropriate option.

Intravenous thrombolysis and thrombectomy is not the right answer. The combination of thrombectomy and intravenous thrombolysis is still time-limited by the thrombolysis window of 4.5 hours. The decision to offer thrombectomy alone is dependent on different criteria. This patient is outside the thrombolysis window.

Thrombectomy is the correct answer. An extended target time of 6-24 hours for thrombectomy alone may be considered if there is confirmed proximal occlusion of the anterior circulation by CT angiography and the potential to salvage brain tissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume. Our patient underwent a diffusion-weighted MRI demonstrating limited infarct core volume within 9 hours of symptom onset and has a confirmed proximal anterior circulation occlusion and therefore is an eligible candidate.

Question 13 of 409

A previously well 69 year old patient presents to the A+E department with a sudden onset of weakness. This was noticed by his wife who immediately called 999.

Neurological examination: CN I-IV normal

CN V ophthalmic and maxillary divisions normal with reduced sensation in mandibular division on left side

CN VI normal

CN VII reduced power to left lower facial musculature

CN VIII normal

CN IX, X and XII weakness in swallow

CN XI weakness on turning the head to the left.

Right upper limb normal tone, power 5/5, normal reflexes and sensation. Normal finger pointing. Left upper limb markedly increased tone, power 1/5 globally in all muscle groups, brisk reflexes and reduced sensation to light touch. Unable to move limb to determine ability to finger pointing.

Right lower limb normal tone, power 5/5, normal reflexes and sensation. Heel-knee-shin test normal.

Left lower limb slightly increased tone, power 3/5 globally, brisk reflexes and reduced sensations. Reduced ability to heel-knee-shin test when compared to right side.

Gait - not assessed due to weakness. Romberg's test - not done due to weakness.

Where is the lesion most likely to be?

A. Left middle cerebral artery
B. Right middle cerebral artery
C. Posterior cerebral artery
D. Left anterior cerebral artery
E. Right anterior cerebral artery

A. Right middle cerebral artery

Contralateral hemiparesis and sensory loss with the upper extremity being more affected than the lower, contralateral homonymous hemianopia and aphasia - middle cerebral artery

The understanding of stroke territories is important both in clinical practice but also in the MRCP! In terms of limb weakness it must be remembered that an ischaemic event in the anterior cerebral territory caused contralateral hemiparesis (leg>arm) and the middle cerebral territory causes contralateral hemiparesis (face/arm>leg).

A posterior cerebral artery lesion causes contralateral homonymous hemianopia with amnesia and sensory loss.

Question 14 of 409

A 56-year-old man presents to the neurology clinic with a 6-month history of loss of dexterity and new-onset dysphagia. The patient reports a history of hypertension for which he takes amlodipine 5mg once daily with no family history of note, he is a non-smoker and drinks 3 glasses of wine per week. Systems review reveals no history of rashes, joint pain, swelling or stiffness, no fevers, and no weight loss. A recent endoscopy showed no obvious abnormalities to explain the patient's dysphagia.

Physical examination demonstrates asymmetrical wasting of the deltoids with noticeable weakness of wrist flexion bilaterally (MRC grading 4/5).

Co-ordination is normal on the assessment of the upper and lower limbs, which decreased ankle jerk relaxes bilaterally. Plantars are downgoing bilaterally. Cranial nerve assessment is unremarkable, however, a bedside swallow assessment is suggestive of a delayed oropharyngeal phase.

Bloods tests ordered by the neurologist demonstrate:

Hb 140 g/L	Male: (135-180) Female: (115 - 160)
Platelets 220 * 10 /L	(150 - 400)
WBC 5.0 * 10 /L	(4.0 - 11.0)

Calcium 2.26 mmol/L	(2.1-2.6)
Phosphate 1.04 mmol/L	(0.8-1.4)

Magnesium 0.9 mmol/L	(0.7-1.0)
Thyroid stimulating hormone (TSH) 0.6 mU/L	(0.5-5.5)
Free thyroxine (T4) 10.1 pmol/L	(9.0 - 18)
Creatine kinase 1000 U/L	(35 - 250)

What is the most likely diagnosis?

- A. Inclusion body myositis
- B. Dermatomyositis
- C. Motor neuron disease
- D. Multiple sclerosis
- E. Myasthenia gravis

A. Inclusion body myositis

Older man + quadriceps and finger/wrist flexors weakness + raised CK → inclusion body myositis

Inclusion body myositis is characterized by frequently asymmetrical muscle weakness, with a mixed proximal and distal distribution of weakness. Dysphagia affects approximately 9% of patients at presentation.

Dermatomyositis usually features symmetrical muscle weakness with a characteristic rash. This patient has neither.

Motor neuron disease presents with upper motor neuron signs, with hyperreflexia and extensor plantars. This patient has neither.

Multiple sclerosis could possibly explain the patient's symptoms, however, it would be very unlikely in a male patient of late middle age.

Myasthenia gravis usually presents with symmetrical muscle weakness which is fatiguable. This patient has an asymmetrical weakness with no mention of fatiguability.

Question 15 of 409

A 24-year-old male presents to the acute medical unit with confusion. His mother states that over the past day he has been behaving very strangely. His past medical history includes epilepsy, asthma, and depression. His drug history includes salbutamol, sertraline, and sodium valproate. On examination, you note myoclonus and his Glasgow coma score is reduced at 13 (M6, V4, E3).

Blood results are as follows:

Hb	132 g/l	Na	142 mmol/l	Bilirubin	18 µmol/l
Platelets	328 * 10 /l	K	4.1 mmol/l	ALP	72 u/l
WBC	8.7 * 10 /l	Urea	6.8 mmol/l	ALT	184 u/l
Neuts	7.4 * 10 /l	Creatinine	72 µmol/l	INR	1.1
Lymphs	1.2 * 10 /l	Albumin	42 g/l	Plasma ammonia	72 µmol/L (normal range 11-32 µmol/L)

What is the most likely cause of this presentation?

- A. Hepatic encephalopathy
- B. Sertraline
- C. Small intestinal bacterial overgrowth
- D. Sodium valproate
- E. Intracerebral hemorrhage

D. Sodium valproate

Sodium valproate is a well known cause of hyperammonemic encephalopathy

The patient has features of encephalopathy and raised serum ammonia levels. Valproate-induced hyperammonaemic encephalopathy (VHE) is an unusual complication characterised by a decreasing level of consciousness, focal neurological deficits, cognitive slowing, vomiting, drowsiness, and lethargy. Asymptomatic hyperammonaemia occurs in 15-50% of patients on valproate.

Treatment with L-carnitine may be beneficial in reducing ammonia levels.Although the ALT is raised, this is a fairly common finding and may be entirely explained as a side effect of valproate therapy. The true liver function is normal as demonstrated by normal albumin, INR, and bilirubin. Therefore hepatic encephalopathy is an incorrect answer.

Small intestinal bacterial overgrowth can lead to acquired hyperammonaemia, however, there is nothing to suggest that this is the diagnosis in this case.

Question 16 of 409

A 48-year-old man is reviewed in psychiatry clinic after a referral from his general practitioner with eccentric behaviour. He has no past medical history and does not take any regular medications. There is no history of drug or alcohol abuse.

On examination, he appeared unkempt and dressed exclusively in black clothing. He was accompanied by his mother.

During the course of the interview, it transpires that others have always felt he was 'odd' and he has difficulty forming social relationships. He becomes anxious in social situations. He is obsessed with ghosts and has sought to purchase ghost-hunting equipment. He occasionally feels the spirits of ghosts in his home as a cold breeze.

His affect is inappropriate throughout, avoiding eye contact while laughing at unusual points in conversation.

What is the correct description of this type of personality disorder?

- A. Antisocial
- B. Avoidant
- C. Borderline
- D. Schizoid
- E. Schizotypal

E. Schizotypal

Schizotypal personality disorder is characterised by social isolation and odd beliefs

Schizotypal is the correct answer. This personality disorder is characterized by social isolation, odd or eccentric behaviour, inappropriate affect, unusual perceptual disturbances (the cold breeze in this scenario) and odd beliefs and magical thinking (ghost-hunting in this scenario). This patient demonstrates most of these characteristics.

Avoidant is incorrect. While this personality disorder can also result in social isolation, it is characterized by a craving for others that is absent in this context. Most of the avoidant behaviors in this disorder are as a consequence of fears of embarrassment or ridicule.

Borderline is incorrect. This is characterized by fear of abandonment, unstable interpersonal relationships, impulsivity and chronic feelings of emptiness. Patients often demonstrate recurrent suicidal behaviour.

Schizoid is incorrect. While there is also a preference for solitude in this condition and few friends or confidants other than family, abnormal perceptions and magical thinking are absent. Coldness is predominant rather than eccentricity.

Antisocial is incorrect. The key characteristics of this personality disorder are repeated failure to respect lawful behaviours, deception, irritability and aggressiveness, which are not mentioned in this case.

Question 17 of 409

A 16-year-old female is brought to the general practitioner by her mother, who is concerned about the difficulties her daughter has in forming successful friendships and personal relationships. The patient herself denies this is a problem and reports that she has many 'best friends'.

During the course of the consultation, the GP becomes aware that she is inappropriately sexually seductive and seems to use her physical appearance to seek attention. In addition, she tends to dramatize events and stories and always places herself as the central protagonist. Many of her stories seem to involve emotional overreaction her part.

What is the most accurate description of this personality disorder?

A. Antisocial
B. Borderline
C. Dependent
D. Histrionic
E. Narcissistic

D. Histrionic

Histrionic personality disorder is characterised by excessive attention-seeking and emotional overreaction

A histrionic personality disorder is correct. This personality disorder is characterized by inappropriate sexual seductiveness, self-dramatization, attention-seeking behaviour and emotional overreaction. Additionally, relationships are considered to be more intimate than they are in reality., In this case, the patient considered herself to have many 'best friends', while her mother disagrees with that assessment.

An antisocial personality disorder is incorrect. This personality disorder is characterized by repeatedly breaking the law, deception, irresponsibility and a lack of remorse.

A borderline personality disorder is incorrect. This personality disorder is characterized by an unstable self-image and efforts to avoid abandonment. Impulsivity is common, along withdifficulties in controlling temper and recurrent suicidal behaviour.

A dependent personality disorder is incorrect. People with this personality disorder have difficulty making everyday decisions without excessive reassurance from others and have unrealistic fears about being left to care for themselves. They often commence an urgent search for another relationship as a source of care when a close relationship ends.

A narcissistic personality disorder is incorrect. This personality disorder is characterized by a grandiose sense of self-importance and a sense of entitlement. People who exhibit these features often take advantage of others to achieve their own needs and lack empathy.

Question 18 of 409

A 25-year-old woman is reviewed in the neurology outpatient clinic. She has a past medical history of idiopathic intracranial hypertension and she reports a recurrence of headaches. She takes regular acetazolamide.

On examination, fundoscopy reveals papilloedema. Her body mass index is 31 kg/m². Her visual acuity is normal.

A decision is made to perform a therapeutic lumbar puncture in the left lateral position. The opening pressure is 29 €‰25 cm CSF and 10 ml of cerebrospinal fluid is removed. The patient subsequently develops a headache.

What intervention could have reduced the likelihood of developing this complication?

A. Bed rest following procedure
B. Decreased quantity of CSF removal
C. Increased fluid intake post procedure
D. Performing the procedure in a sitting up position
E. Re-insertion of the stylet prior to removing the needle

E. Re-insertion of the stylet prior to removing the needle

Lumbar puncture: Re-insertion of the stylet prior to removing the needle reduces the incidence of post-LP headaches

Re-insertion of the stylet prior to removing the needle is the correct answer. This is an intervention that has been shown to decrease the incidence of post LP headaches.

Bed rest following procedure is not the correct answer. This has not been shown to decrease the incidence of post-LP headaches.

Decreased quantity of CSF removal is incorrect. This patient has had a standard amount of CSF removed (10ml). It has not been shown that varying the amount of CSF removed has any effect on the incidence of post LP headaches.

Increased fluid intake post-procedure is incorrect. This has not been shown to reduce the incidence of post-LP headaches.

Performing the procedure in a sitting up position is incorrect. This has now been shown to reduce the incidence of post-LP headaches. Additionally, we cannot measure an opening pressure in this position so it would be unsuitable in this context.

Question 19 of 409

You have been referred a 45-year-old man by the Accident and Emergency doctors with a severe headache. The headache woke him up at 3am, and he describes it as the worst headache he's ever had. He has had two episodes like this over the past three days that have followed a very similar pattern, each lasting around 70 minutes before going. The pain is mainly around the left eye and temple and is sharp in nature. On examining him you note that his left eye is watering and swollen, and there's some redness and mild bruising just above the eye. When you ask him about this bruising he says that the pain was so bad he bashed his head against the fridge door to try and help take it away.

How would you treat his headache?

A. Oral triptan
B. Indometacin
C. 100% oxygen and indometacin
D. 100% oxygen
E. 100% oxygen and nasal triptan

E. 100% oxygen and nasal triptan

Cluster headache - acute treatment: subcutaneous sumatriptan + 100% O2

What is described above is the classical cluster headache. NICE guidelines characterise cluster headaches as one-sided headache in or around the eye or temporal region associated with signs of autonomic dysfunction on the same side.

Attacks of pain:

- Usually last for 15-180 minutes
- Almost always described as the most severe pain known
- Tend to recur at the same time each day
- Often wake the person shortly after falling asleep

Signs of symptoms of autonomic dysfunction include:

- Rhinorrhoea or nasal congestion
- Red eye and/or lacrimationFacial or forehead sweating or flushing
- Constriction of the pupil and/or ptosis
- Eyelid oedema
- A sense of aural fullness

The suggested first line treatment for cluster headaches is 100% oxygen at a flow rate of at least 12 litres per minute and a subcutaneous or nasal triptan. Evidence from one small study suggests that subcutaneous sumatriptan provides faster relief of symptoms than intranasal sumatriptan.

Indometacin is used in paroxysmal hemicrania which has similar characteristics to cluster headaches, but attacks tend to be shorter (2-45 minutes) and more frequent (up to 40/day) and more common in women.

Oral triptans have no evidence base in cluster headaches.

Question 20 of 409

A 16-year-old boy attends GP with their parents for a review of constipation. They have improved well and are taking regular movicol with a soft motion every 1-2 days. The parents asked about a rash across the face. He has a background of autism and learning difficulty.

On examination, the boy has raised papules across the nose and cheeks with a warty appearance that measure 1-2mm. This does not extend across the back or chest. He has 2 patches of hypopigmentation on his lower back that are 3cm x 2cm and 1cm x 5cm. There are three hyperpigmented patches over the abdomen.

These have not resolved despite using over the counter treatments for acne.

Hb	134	Na	139 mmol/l	Bilirubin	5 µmol/l
Platelets	456	K	4.2	ALP	100 u/l
WBC	4.5	Urea	4.21	ALT	24 u/l
Neuts	2.2 *	Creatinine	78	γGT	78 u/l
Lymphs	0.1	Albumin	35 g/l		

What treatment would you start for the facial lesions?

A. Sirolimus
B. Retinoid
C. Lymecycline
D. Benzoyl
E. peroxide Excision

A. Sirolimus

Acne and hyperpigmentation -> tuberous sclerosis

This patient has autism, unusual pigmented patches on the skin and acne. This collection of signs should prompt thoughts of neurocutaneous syndromes and particularly of tuberous sclerosis. The acne that occurs is called acne sebaceum and these are angiofibromas. Compared to acne vulgaris, these do not respond to typical therapies and the first line treatment is sirolimus cream. They aretoo small and numerous to be excised. This boy should be referred to genetics to confirm the diagnosis and screen for further malignancies that he will be at risk of.

Question 21 of 409

An 18-year-old female is admitted to hospital with worsening lower limb weakness. She states that it started in her ankles, but now she is unable to stand from a squatting position which is abnormal for her. On examination, she has reduced power in ankle plantar and dorsiflexion bilaterally as well as some mild weakness in her hip extensors. Her hand grip strength is normal.

A cerebrospinal fluid (CSF) study is carried out and based on the clinical syndrome and the result she is diagnosed with Guillain-Barre Syndrome (GBS).

Which of the following treatments should be commenced in the acute setting?

A. Intravenous methylprednisolone
B. Intravenous immunoglobulin
C. Oral prednisone
D. Rituximab
E. Pyridostigmine

B. Intravenous immunoglobulin

IVIG is generally used first-line for Guillain-Barre syndrome

Immunomodulatory treatment has been proven to hasten recovery in GBS. Intravenous immunoglobulin (IVIG) and plasma exchange have proved equally effective, however, IVIG is often the initial treatment for practical reasons.

Corticosteroids (oral and intravenous) have not been found to have a clinical benefit in GBS. Consequently, this class of drugs is not currently employed in the treatment of the syndrome.

Question 22 of 409

You are working in a neurology outpatient clinic seeing a patient referred from a local GP clinic. He's a 42-year-old man who has been troubled by severe headaches over the past half a year. These headaches are the worse that he's ever had in his life, describing them as far worse that the compound fracture he sustained three years ago. These headaches tend to happen most nights at around 2am just after he falls asleep. He often paces around his kitchen for a couple of hours and often resorts to bashing his head against the fridge the pain is so bad. When probed further he mentioned that he gets a sense of fullness in his right ear (which is the side that the headache most often occurs on). He remembers having a similar problem a couple of years ago that lasted a few months before resolving on their own.

What medication is most likely to prevent these headaches?

A. Oral triptan
B. Home oxygen
C. Pizotifen
D. Propranolol
E. Verapamil

E. Verapamil

Verapamil is used for long-term prophylaxis of cluster headaches

NICE guidelines suggest that one should diagnose a cluster headache if:

- Pain lasts 15 minutes to 3 hours and is associated with intense restlessness and agitation.
- Episodes occur with a frequency between one every other day and eight times a day.
- Commonly wakes the person from sleep within 2 hours of going to sleep.
- At least five episode of pain have occurred.
- Headache is associated with at least one autonomic feature occurring on the same side as the pain.

Acute treatment for cluster headaches:

- Subcutaneous or nasal triptan
- High flow oxygen 12L/min - this should be set up at home

Prophylactic treatment:

- Verapamil

Question 23 of 409

A 20-year-old man presented to his general practitioner following an episode of collapse. He reported that he was attending a comedy night when he suddenly collapsed to the floor. He denied loss of consciousness and had a quick recovery from the event. He is normally fit and well, though reports that he is having difficulty at university as he is struggling to stay awake.

On examination, his pulse was regular at 60bpm and ECG demonstrated normal sinus rhythm. Blood pressure was 134/70mmHg on sitting and 125/65mmHg on standing.

What is the most likely cause of his collapse?

A. Transient ischemic attack (TIA)
B. Neuromuscular dystrophy
C. Cataplexy
D. Conversion disorder
E. Stokes-Adams syndrome

C. Cataplexy

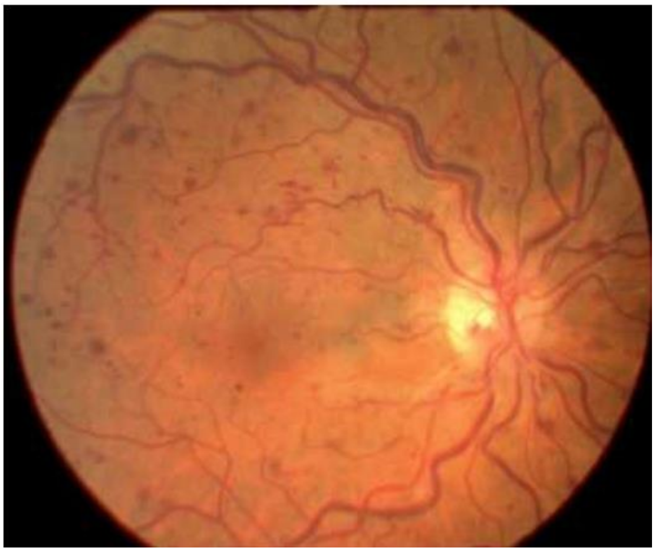
Cataplexy occurs during heightened emotion. Differential to consider with collapse of unknown cause

Cataplexy is a sudden, transient episode of muscular weakness without loss of consciousness. Typically it occurs during heightened emotions, most commonly laughter such as the comedy clue in the question. Often cataplexy co-occurs with narcolepsy which typically presents as patients recurrently falling asleep during the day, as with this patient.

Stokes-Adams syndrome is a transient AV block and results in loss of consciousness, a more progressive history would be expected with neuromuscular dystrophy and although TIAs do present with transient focal motor weakness the patient's age and the bilateral nature of his symptoms make this unlikely.

Question 24 of 409

A 73-year-old man complained of a one day history of blurred vision in the right eye. He has a past history of poorly controlled hypertension and polycythaemia but otherwise enjoys good health. Visual acuity is 6/6 in the left eye and 6/18 in the right eye. Fundoscopy of the right eye is as follows



What is the most likely diagnosis?

A. Ischaemic optic neuropathy
B. Central retinal artery occlusion
C. Papilloedema
D. Central retinal vein occlusion
E. Macular degeneration

D. Central retinal vein occlusion

Central retinal vein occlusion - sudden painless loss of vision, severe retinal haemorrhages on fundoscopy

This slide shows a non-ischaemic central retinal vein occlusion. There are dilated retinal veins and widespread multiple blot haemorrhages.

Question 25 of 409

A 43-year-old gentleman is admitted to the Emergency Department with a 2-week history of worsening drowsiness and confusion. His wife states that he had initially complained of increased tiredness and had started taking to his bed immediately after arriving home from work. One week ago he stopped going to work altogether and his wife reports that he has been sleeping for most of the day since then. This morning she had difficulty waking him, and when she did manage to rouse him he seemed confused with apparent slurring of his speech.

His past medical history is remarkable for epilepsy and bipolar disorder.

On examination, he is responsive only to pain. His vital signs are within normal limits and examination of the chest is unremarkable. His abdomen is soft, with no obvious tenderness and no organomegaly. Bowel sounds are present.

A set of blood tests are taken:

Hb	152 g/l	Na	139 mmol/l	Bilirubin	18 µmol/l
Platelets	278 * 10 /l	K	4.3 mmol/l	ALP	117 u/l
WBC	8.1 * 10 /l	Urea	5.2 mmol/l	ALT	19 u/l
Neuts	5.4 * 10 /l	Creatinine	93 µmol/l	γGT	48 u/l
Lymphs	1.8 * 10 /l	Albumin	41 g/l		
Eosin	0.2 * 10 /l	Ammonia	197 µmol/l		

His wife later remarks that his medications have recently been altered by his GP.

Which of the following is most likely to be responsible?

A. Lithium
B. Sodium valproate
C. Venlafaxine
D. Diazepam
E. Quetiapine

B. Sodium valproate

The patient's presenting symptoms are relatively non-specific and, taken in high enough doses, any of the medications listed could cause impairment of consciousness. The patient's grossly abnormal ammonia level is the critical detail in this case and confirms a diagnosis of valproate associated hyperammonaemic encephalopathy (VHE).

VHE is a well-documented complication of valproate therapy and can occur in patients with therapeutic as well supratherapeutic plasma valproate levels. Valproate inhibits carbamoyl phosphate synthetase I, an enzyme essential for ammonia metabolism in the liver, leading to elevated plasma ammonium levels. Interestingly, asymptomatic hyperammonaemia has been shown to occur in a large proportion of patients taking sodium valproate.

Question 26 of 409

A 23-year-old female has represented 2 days after discharge from the neurology team with a constant diffuse headache, worse on standing than lying down, without neck stiffness or photophobia, but associated with nausea and vomiting. 48 hours ago, she was an inpatient being investigated for intermittent headaches over the past 8 months, typically over the left side of her frontal and temporal regions, of sudden onset during any time of day, associated with double vision, lasting for 'hours' at a time. She was experiencing up to 5 episodes a week, with one episode witnessed during her admission, when the senior house officer noted bilateral restriction in vertical eye movements, adduction and unreactive pupils, spontaneously resolving after 3 hours. Her blood tests were unremarkable.

The patient underwent a CT head, demonstrating no intracranial lesions; and a lumbar puncture:

Opening pressure	12.3 cmH2O
WCC	2 /mm³
RBC	50 /mm³
Protein	0.45 g/l
Glucose	4.5 mmol/l (serum 6.7 mmol/l)
Oligoclonal bands	None present

The patient subsequently self-discharged, reporting no immediate headaches, back pain or lower limb paraesthesia after the lumbar puncture.

During this second admission, she undergoes an MRI head scan, demonstrating significant diffuse meningeal enhancement and bilateral shallow subdural haemorrhages.

What is the appropriate treatment?

A. Oral fluids, caffeine and blood patch
B. Repeat lumbar puncture I
C. ntravenous aciclovir
D. Intravenous ceftriaxone
E. Neurosurgical input

A. Oral fluids, caffeine and blood patch

There are two headaches here: the initial presentation appears to be an unusual migrainous phenomenon, possibly ophthalmoplegic migraine, while the second is clearly a low-pressure headache. The neurologists would have correct in initially ruling out any other possible causes of ocular paresis with a lumbar puncture but the CSF constituents are fairly unremarkable.

Do not be alarmed by the report of the MRI head: meningeal enhancement, thickening and shallow subdural haematoma are features of low-pressure headaches and do not represent meningitis or subdural haematomas regarding neurosurgical drainage. A repeat lumbar puncture would make exacerbate the problem and hence inappropriate. In view of the low-pressure headache occurring soon after a lumbar puncture, encouraging oral fluids, caffeine and a blood patch by the anaesthetists would be most appropriate.

Question 27 of 409

A 17-year-old Caucasian male with no past medical history presents with his first episode of sudden onset left leg weakness and numbness on his anterior left thigh, of sudden onset and persistent after 4 days. On examination, you note 3/5 weakness on flexion of his left hip and loss of sensation to light touch, pain and temperature on his anterior left thigh in the sensory nerve root L1 distribution. A contrasted MRI scan of the patient's spine reveals a hyperintense T2 signal partially within the left side of the cord at the L1, with corresponding enhancement with gadolinium. No masses were observed. Further imaging of the brain is awaited.

What is the most likely diagnosis at present?

- Multiple sclerosis
- Left spinal cord tumour
- Left anterior spinal ischaemic stroke
- Left transverse myelitis
- Guillain Barre syndrome

The history, examination and radiological evidence are strongly suggestive of partial L1 transverse myelitis. The key question is whether this represents a diagnosis of multiple sclerosis (MS) or not. The diagnosis of MS is determined by the McDonald criteria, first proposed in 2001 and most recently revised in 2010 . The lesions or clinical episodes suggestive of acute demyelinating episodes must be disseminated in both time and place. As a result, a patient presenting with only one symptomatic episode can be diagnosed with MS if their MRI scans demonstrate demyelinating plaques that are:

- 1 i) distinguished in age from the current symptomatic lesion
- ii) In at least two of 4 areas typical of MS (periventricular, juxtacortical, infratentorial, spinal cord white matter).

In this case, only one episode in time and space has been demonstrated so far. Although a risk of future MS diagnosis is acknowledged and may go on to be proven following MRI of the head, the diagnosis remains transverse myelitis at present.

It is often quoted that in patients diagnosed with transverse myelitis after their first symptomatic episode, only a small proportion go on to be diagnosed with MS later in their lives. However, more recent evidence suggests the pattern of transverse myelitis is important: only 5-10% of patientswith complete transverse myelitis will be diagnosed with MS, with a viral febrile illness the most likely underlying cause. Patients with incomplete transverse myelitis have up to 72% risk of MS consistent plaques found on MRI head, with 60-90% subsequently being diagnosed MS within 5 years .

Old MS plaques appear better defined on T1 and T2 imaging than acute lesions. Contrast studies with gadolinium are also helpful: acute plaques tend to enhance to a greater degree on T1 imaging, correlated to acute inflammation that persists for up to 8 weeks and diminishes on treatment with glucocorticoids.

Question 28 of 409

A 32-year-old male presents with his 4th episode of worst ever headache in one week. He describes the headache to always be of sudden onset on the left side of his head, of 10 out of 10 severity and that he finds bright lights extremely distressing during these periods. The episodes last for around 30 minutes, typically after dinner. He also describes redness and swelling of his left eye and a blocked left nostril during the headaches, associated with tearing of his left eye.

He has no past medical history and family history of migraines. He denies illicit drug use, is a nonsmoker and drinks two glasses of wine with dinner every night. Over the past 7 days, he has been self-medicating with paracetamol and ibuprofen. On examination, you notice no focal neurology, no meningism and fundoscopy is unremarkable.

What is the most likely diagnosis?

A. Subarachnoid haemorrhage
B. First presentations of migraine
C. SUNCT (short lasting unilateral neuralgiform headache with conjunctival injection or tearing)
D. Medication overuse headache
E. Cluster headaches

E. Cluster headaches

The main differentials are between cluster headaches and SUNCT, both of which are headache syndromes resulting in severely painful headaches associated with autonomic symptoms. It would be unusual for autonomic symptoms such as conjunctival injection, lacrimation and rhinorrhoea with migraines. Subarachnoid haemorrhage headaches rarely re-occur without disastrous consequences, focal neurology and reduced GCS. Medication overuse headache are normally of onset after a longer period of analgesia use and are more chronic in character without autonomic symptoms.

In distinguishing cluster headaches and SUNCT, the former are more prevalent in younger males below the age of 40 while SUNCT is more common in older patients above the age of 40. Cluster headaches typically onset at night, last from 15 minutes to 3 hours, while SUNCT can occur at any time of day and typically lasts for seconds to minutes. Cluster headaches rarely onset more than 3 times per day while SUNCT has been described in up to 75 times per day. A transient Horners syndrome is typical during a cluster headache but may be lacking in SUNCT. Lastly, clusterheadaches are classically, but not always, triggered by alcohol . The combination of severe nocturnal onset unilateral headache following alcohol in a patient under 40 years old, lasting for 30 minutes, suggest cluster headaches over SUNCT

Question 29 of 409

A 21-year-old male presents with difficulties in his work life. He has been fired from four jobs in the past 12 months. He states that his bosses were 'stupid' and that they did not appreciate him or give him the respect that he was due. He states that he wants unlimited success and power and he often gets angry when he cannot get what he wants. He believes that his intelligence is far superior to the rest of the general population.

What is the most likely diagnosis?

A. Antisocial personality disorder
B. Schizotypal personality disorder
C. Narcissistic personality disorder
D. Histrionic personality disorder
E. Schizoid personality disorder

C. Narcissistic personality disorder

Narcissistic personality disorder is characterised by a grandiose sense of self importance

Narcissistic personality disorder is characterised by a grandiose sense of self importance. In addition, they also often have a deep need for excessive attention and admiration, troubled relationships, and a lack of empathy for others.

Schizotypal personality disorder is characterised by social isolation and odd beliefs. Schizoid personality disorder is similar in that a need for social isolation and apathy dominates, however strange beliefs are not a diagnostic criteria of this condition.

Histrionic personality disorder is characterised by excessive attention-seeking and emotional overreaction.

Question 30 of 409

An 82-year-old man attends the clinic with weakness affecting his hands. A systematic enquiry was otherwise unremarkable He has no significant past medical history and takes no regular medications. On examination, you note bilateral weakness of the finger and wrist flexors (MRC grade 3/5) and hip flexion (MRC grade 4/5). The neurological examination was otherwise unremarkable.

Blood results are as follows:

Hb	144 g/L	Male: (135-180) Female: (115 - 160)
Platelets	168 * 10 /L	(150 - 400)
WBC	7.2 * 10 /L	(4.0 - 11.0)
Na	136 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	8.4 mmol/L	(2.0 - 7.0)
Creatinine	96 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
Creatine kinase	1042 IU/L	(40 - 320)

What is the most likely diagnosis?

A. C6/7 radiculopathy
B. Inclusion body myositis
C. Limb-girdle muscular dystrophy
D. Myotonic dystrophy
E. Polymyositis

B. Inclusion body myositis

Older man + quadriceps and finger/wrist flexors weakness + raised CK → inclusion body myositis

Inclusion body myositis is correct. The presence of weakness of the finger/wrist flexors and hip flexors, and a raised CK in an elderly man is highly suggestive of inclusion body myositis.

C6/7 radiculopathy is incorrect. Although bilateral radiculopathy would explain the weakness in hand/wrist flexors, it would not explain the weakness in the hips. Furthermore, the raised CK is suggestive of a myopathy.

Limb-girdle muscular dystrophy is incorrect. Although this remains within the differential diagnosis, the pattern of muscle weakness is more in keeping with inclusion body myositis. Limbgirdle muscular dystrophy would classically affect the shoulder and hips, and weakness in the hands and wrists would be unusual.

Myotonic dystrophy is incorrect. The pattern of involvement, in this case, is not typical of myotonic dystrophy. Myotonic dystrophy classically presents with facial weakness and distal muscle weakness. Furthermore, the absence of any other hallmark feature of this condition (e.g. frontal balding, and grip myotonia) makes it a less likely diagnosis.

Polymyositis is incorrect. The pattern of involvement, in this case, is not typical of polymyositis. The hallmark of polymyositis is a progressive disease with symmetric involvement of the proximal girdle muscles (shoulder and pelvis muscles) and neck flexors. Myalgia is also common.

Question 31 of 409

A 32 year-old accountant presents to the neurology clinic.

For the last year he has been troubled by severe headaches. These occur in the morning, sometimes waking him from sleep. There is a sudden onset of stabbing pain behind the left eye, at the onset of which he feels the need to pace around the room, pounding his head in an effort to ease the pain. During the attacks his left eye is watery and his nose his congested. On more than one occasion he has noticed that his right pupil appears enlarged during the attacks. He tells you very clearly that the pain is so severe that at times during the attacks he has considered jumping out of the top floor of the office building where he works. Each attack lasts one or two hours, and between the attacks he feels fine.

He shows you a detailed headache dairy in which he has documented every attack over the last year. For example, in January he had a period of nine days in which attacks occurred several times daily, but in February and March he was headache free. During April he developed severe headaches which occurred almost every day until June. He then had another period of relief until August, and so on.

He has no other past medical history and no allergies. Examination is unremarkable.

What is the best treatment for prophylaxis of this man's headaches?

A. 100% oxygen
B. Verapamil
C. Sumatriptan
D. Propranolol
E. Lithium

B. Verapamil

Verapamil is used for long-term prophylaxis of cluster headaches

This is a classic description of episodic cluster headache.

Interestingly, the patient mentioned that his right pupil was enlarged, but most likely he is describing ipsilateral Horner's syndrome, which may occur during cluster attacks.

Verapamil is the established first-line agent for the prophylaxis of episodic and chronic cluster headache.

100% oxygen is the first-line treatment for acute attacks of cluster headache.

Sumatriptan is commonly used for acute attacks of cluster headache and migraine, often subcutaneously.

Propranolol is a first-line drug for the prophylaxis of migraine. Lithium is a second-line agent for the prophylaxis of cluster headache.

Question 32 of 409

A 53-year-old lady was admitted to the medical admission unit having presented to the Emergency Department with a severe headache which had developed over the last five days. She described the headache as a continual dull pain across the front of her head and was significantly worsened when she sat up as well as when she coughed or strained. It was alleviated only when she lied down in a dark room; paracetamol 1g QDS and ibuprofen 400mg TDS did not provide any relief. She denied the presence of nausea or vomiting, her vision was not affected and other than feeling tired she did not complain of any other symptoms. Her past medical history was comprised of non-classical migraines and hypothyroidism for which she was prescribed levothyroxine 175mcg OD. Seven days ago she was admitted with a headache, fever and photophobia; review of her medical notes revealed the following results from the previous

admission:

Hb	142 g/l
Platelets	326 * 10 /l
WBC	11.2 * 10 /l

Glucose	5.4 mmol/l
ESR	32 mm/hr
CRP	46 mg/l
PTT	12.2 (NR 12-14s)
APTT	44s (NR 300-46s)
Fibrinogen	5.2 (NR 2-4 g/l)

Urine MCS: NAD Blood MCS: NAD

CT Head: normal intracranial appearances; no space occupying lesion or haemorrhage identified

Lumbar puncture:

Protein	0.3g (NR 0.2-0.4 g/L)
Glucose	3.6 mmol/l
WCC	8 (<5/mm3)
Opening pressure	15 (NR 10-20 cmH2O)
MCS	NAD

Examination revealed the presence of a female in a dark room lying flat. Her temperature was 36.6ºC, heart rate 77bpm, respiratory rate 16/min and blood pressure 136/78 mmHg. Examination her cardiovascular and respiratory systems were unremarkable. Examination of her neurological system revealed the presence of normal functioning cranial nerves 2-12 with unremarkable fundoscopy; there was no neck stiffness or photophobia objectively. There was no neck stiffness and Kernig's sign was negative. Examination of her peripheral neurological system was unremarkable.

What is the single next best management option?

A. Organise urgent cranial MR venogram scan
B. Organise urgent cranial MRI scan
C. Commence therapy with sumatriptan
D. Administer epidural blood patch
E. Send CSF for xanthochromia analysis

D. Administer epidural blood patch

This lady has developed post-lumbar puncture headache (PLPH), a common complication of a lumbar puncture and is thought to be caused by excess leakage of cerebrovascular fluid causing a relatively low intracranial pressure and is aggravated significantly when assuming a non-supine posture. There are of course many other diagnoses that need to be considered, including meningitis, migraine, cortical vein thrombosis, intracerebral haemorrhage and cluster headaches. In most instances however the diagnosis of PLPH can be made clinically. Patients frequently believe the cause of their headaches is due to migraine and therefore report that avoiding bright light alleviates their headache when in fact it is lying down which is alleviating the headache. Management is conservative, including administering analgesia and sufficient fluids. If this fails to resolve the headache the gold standard management is an epidural blood patch.

Question 33 of 409

A 45-year-old woman is admitted to the neurology inpatient unit with a 3-day history of fever and headache. To exclude meningoencephalitis, a lumbar puncture is performed. Following the procedure, she developed a severe headache that was initially attributed to a post-lumbar puncture headache; however, it persists despite lying flat, adequate hydration, and analgesia. Subsequent computed tomography (CT) of the brain reveals a subdural haematoma, although the CT brain scan at admission was normal.

What could have prevented this patient's condition?

A. Fall risk assessment
B. Increased volume of CSF removed
C. Intravenous mannitol
D. Use of cutting needle for LP
E. Use of pencil-point needle for LP

E. Use of pencil-point needle for LP

The use of pencil point (atraumatic) needles reduces the risk of post-lumbar puncture headache

The correct response is use of pencil-point needle for LP because the scenario depicts a patient who has developed a subdural haematoma after a lumbar puncture. Utilisation of an atraumatic pencil-point needle can mitigate this risk. There is an increased likelihood of subdural haematoma formation with larger gauge spinal needles. Additionally, an epidural blood patch can also reduce the incidence of post-lumbar puncture headaches. Notably, the headache associated with a subdural haematoma does not decrease with recumbency, intravenous hydration, or analgesics. Management involves an autologous blood patch, epidural saline or intravenous caffeine administration. Craniotomy and surgical decompression are seldom necessitated.

In this case, the subdural haematoma is attributable to the lumbar puncture rather than trauma. A fall risk assessment is imperative for preventing traumatic subdural haematomas and is crucial in managing patients with diminished consciousness levels; however, it is not pertinent to this situation.The volume of cerebrospinal fluid (CSF) extracted does not contribute to post-lumbar puncture headache or subdural haematoma formation. Consequently, increased volume of CSF removed would not have prevented this patient's condition.

Intravenous mannitol is an incorrect choice as it plays no role in the prophylaxis against postlumbar puncture subdural haematoma.

Since conventional spinal needles elevate the risk of post-lumbar puncture complications, opting for use of cutting needle for LP would not be effective in averting either post-lumbar puncture headaches or haematomas.

Question 34 of 409

A 19-year-old male presents to outpatient clinic with a 3-month history of worsening speech slurring. He finds it extremely embarrassing and is made fun of by his friends in college, who thinks he is turning up to school drunk. He is also finding that he is having difficulty with excessive drooling. Over the past 6 weeks, his has also noted increasing weakness in lifting his right arm. He has no other past medical history, is a non-smoker and drinks alcohol only socially.

On examination, his cranial nerves demonstrate weakness in raising his eyebrows, puffing his cheeks and in pursing his lips. He displays significant scapula winging bilaterally with mild wasting of his right deltoid muscle. The musculature of his left arm is normal. The power of his right shoulder abduction and adduction is 3/5, with 5/5 in all other movements. Reflexes are all present with a normal sensory examination.

His blood tests are as follows:

Hb	144 g/l
Platelets	388 * 10 /l
WBC	5.8 * 10 /l

Na	139 mmol/l
K	4.7 mmol/l
Urea	4.6 mmol/l
Creatinine	55 µmol/l
CRP	2mg/l
Creatine kinase	150 IU/l (50-335)
TSH	2.3 mu/l
HIV	negative

What is the most likely diagnosis?

A. Myoclonic epilepsy with ragged red fibres (MERRF)
B. Myotonic dystrophy type 1
C. Polymyositis
D. Limb girdle muscular dystrophy
E. Facioscapulohumeral dystrophy

E. Facioscapulohumeral dystrophy

Facioscapulohumeral muscular dystrophy: facial weakness (e.g. difficulty closing eyes, smiling, blowing), winged scapula and weakness of the shoulderm upper arm and hip girdle muscles

This is a difficult question regarding the cause of a myopathy, onset at late adolescence and progresses. Firstly, the normal CK, CRP and lack of systemic features point against a systemic inflammatory condition such as polymyositis. Although also involving proximal muscles and presenting typically without cutaneous manifestations, polymyositis is a multisystem disorder with cardiac, pulmonary features and oesophageal involvement.

Similarly, although myotonic dystrophy type 1 patients also present from age of 20 onwards, it is another multisystem disorder with cardiac structural and conduction abnormalities, respiratory muscle involvement, gastrointestinal symptoms, testicular failure and insulin resistance, amongst a large number of clinical features. Classically, patients with myotonic dystrophy display myotonia, a slowing of relaxation following normal muscular contraction.

An absence of myoclonus makes MERRF less likely. It is a mitochondrial disorder typically presenting with myopathy, peripheral neuropathy and frequently, ataxia, Wolff-Parkinson-White syndrome and bilateral deafness. The final assessment of the type of muscular dystrophy relies simply on the muscles involved: in this case, muscles involved are facial and upper limb girdle muscles. Be aware that muscular dystrophies such as facioscapulohumeral dystrophy can initially present asymmetrically before progressing to bilateral involvement.

Question 35 of 409

A 37-year-old Japanese female presents with her second episode of loss of colour vision and significant visual acuity impairment in both eyes. Three days later, she complains of vomiting, acute urinary retention, requiring urinary catheter insertion, and inability to move either leg. On examination, she was unable to correctly name any Ishihara plates. An MRI of her brain and spine demonstrates multiple hyperintense T2 white matter lesions in her spine suggestive of demyelination, one of which extends from C5 to T1.

Which investigation confirms the diagnosis?

A. Lumbar puncture for oligoclonal bands
B. Repeat MRI spine with diffusion weighting
C. Serum aquaporin 4 antibody
D. Serum anti-NMDA antibody
E. Repeat MRI spine with gadolinium contrast

C. Serum aquaporin 4 antibody

Neuromyelitis optica is associated with aquaporin 4 positive serum antibody

The patient has presented with optic neuritis, myelitis and vomiting, strongly suggestive of a diagnosis of neuromyelitis optica (NMO), also known as Devics disease.

In this case, CSF oligoclonal bands neither confirms nor excludes a diagnosis MRI spine with DWI would demonstrate acute ischaemic infarcts if a spinal stroke was suspected. Gadolinium enhanced imaging does not add to the diagnostic criteria for NMO. Anti-NMDA antibody is a serum autoantibody for a subtype of autoimmune encephalitis.

Question 36 of 409

A 72-year-old man is referred to the oncology team after presenting to the emergency department. The patient reports progressive lower thoracic back pain over the past three weeks. The pain had now reached an intensity that had prevented him from sleeping during the past two nights, despite over the counter analgesics. The patient reported that coughing caused a severe exacerbation of the pain, but denied radiation of the pain. The patient had previously suffered mild lower back pain after exercise, but could recall no episodes that compared in intensity to his present symptoms.

The patient's wife reported she felt the patient had been unsteady on his feet over the past few days, and reported that he had nearly fallen on several occasions. The patient denied any history of sphincter disturbance or sensory symptoms. On direct questioning, the patient revealed that he had been troubled by a severe cough over the past two months and had also lost 7 kilograms in weight. He denied any history of fevers or night sweats.

The patient had an unremarkable past medical history and took no regular medications. He was a retired builder, who had stopped smoking when he took retirement seven years previously.

Peripheral nerve examination of upper limbs: normal tone, normal power, normal coordination, normal sensation, reflexes intact and symmetrical.

Peripheral nerve examination of lower limbs: tone generally increased bilaterally with 5 beats of clonus in left lower limb; power generally slightly reduced (4+/5) bilaterally, although patient limited by back pain; normal coordination; light touch sensation reduced to mid-point between symphysis pubis and umbilicus; knee and ankle jerks brisk bilaterally, plantar response up-going in left lower limb.

Respiratory examination: borderline clubbing of fingers; reduced resonance and air entry in left upper zone.

Musculoskeletal examination: point tenderness in midline of back around level of T11 / T12 vertebrae.

What is the appropriate investigation of patient's back pain?

A. MRI whole-spine within 24 hours
B. MRI lumbar-thoracic spine within 24 hours
C. CT lumbar-thoracic spine within 24 hours
D. MRI whole-spine within 7 days
E. CT myelography within 7 days

A. MRI whole-spine within 24 hours

The presentation of this patient raises strong concerns about metastatic spinal cord compression as the cause for his symptoms. In the majority of cases, the condition is secondary to bony metastasis to the vertebral spine with collapse and extra-dural compression of the spinal cord.

In around 20 % of cases of metastatic spinal cord compression there is no pre-existing diagnosis of malignancy. While this is true in the case of this patient, there are several aspects of the above assessment that are highly suspicious of a primary lung cancer.

In 95 % of cases, back pain is the most common first symptom, and can be present for up to two months before other signs occur. The patient's history of progressive pain, exacerbated by coughing, and associated with midline tenderness is typical of pain secondary to a localised lesion; however, pain can also present in a radicular pattern due to nerve root compression.

The normal upper limb examination and presence of upper motor neurone signs in the lower limbs with a sensory level, would localise the lesion to the thoracic spinal cord, and correlates with the vertebral tenderness. Bladder and bowel symptoms are often a late feature of metastatic spinal cord compression, so the absence of autonomic dysfunction does not exclude the diagnosis.

United Kingdom NICE guidance is for MRI whole-spine to be performed within 24 hours in individuals with both pain and neurological symptoms suggestive of metastatic spinal cord compression. In the presence of pain without neurological symptoms, MRI whole-spine should be performed within 7 days. It is necessary to image the entire vertebral column, as multi-level involvement is present in 30-50 % of cases.

CT scanning is often used to aid surgical or radiotherapy treatment planning. CT myelography is occasionally used in individuals with contra-indications to MRI scanning.

Question 37 of 409

A 67-year-old male presents to your neurology clinic with his wife, reporting a 3-month history of worsening vision in his left eye. He is very reluctant to seek any medical help but says that a number of factors have finally convinced him to attend.

Over the past 2 months, he reports a constant and worsening headache, worse at night and with coughing. He has occasionally felt extremely nauseated and vomited on a number of occasions, at least twice waking him from sleep. His wife also notes significant personality change: her husband is a retired farmer who prides him on being a stoic man. She notes that he has become increasingly emotional and occasionally aggressive, which she puts down however to struggling with his symptoms. Prior to these symptoms starting 3 months ago, he has always been fit and well with no past medical or drug history.

On examination, you note a left relative afferent papillary defect with equally sized pupils. Visual acuity in the left eye is 6/60 and 6/9 on the right. Testing of colour vision with Ishihara plates demonstrates 0/17 on the left and 17/17 on the right. A central scotoma is found in the left eye. Fundoscopy of the left eye reveals a pale optic disc with poor vasculature while the right appears swollen. A full range of painless eye movements is demonstrated. The remaining examination of the cranial nerves, upper and lower limbs are unremarkable. Drops of blood are unremarkable, a MRI head is awaited.

What is the most likely diagnosis?

A. Foster-Kennedy syndrome
B. Idiopathic intracranial hypertension (IIH)
C. Multiple sclerosis (MS)
D. Frontotemporal dementia
E. Age related macular degeneration (ARMD)

A. Foster-Kennedy syndrome

This is a difficult question requiring recognition of a high-pressure headache, left optic atrophy and contralateral swollen disc secondary to papilloedema. The combination of an ipsilateral optic atrophy and contralateral papilloedema is an MRCP favourite:

Foster-Kennedy syndrome, typically caused by a frontal lobe mass, normally a meningioma, which compressing on the ipsilateral optic nerve and olfactory nerve, while increasing intracranial pressure for the contralateral optic nerve sheath.

Idiopathic intracranial hypertension may present asymmetrically but typically produces bilateral disc swelling. It is conceivable the patient has multiple sclerosis with optic atrophy as a sequelae of left optic neuritis, followed by a second episode of contralateral optic neuritis presenting as papillitis, inflammation of the optic nerve head. This is unlikely with only one episode of visual dysfunction described with an insidious progressive onset.

Frontotemporal dementia may explain the behavioural changes but does not account for visual symptoms.

Lastly, age-related macular degeneration can mimic papillitis on fundoscopy, with deposition of drusen making the optic disc 'look' swollen. However, the deposition of these retinal cell byproducts is generally more diffuse across the retina, with wet ARMD also displaying abnormal retinal vasculature. While retinal atrophy may be present, it does not typically produce optic atrophy.

Question 38 of 409

A 45 year old previously fit and well man presents to the emergency department with worsening leg weakness. He is in full time employment as a brick layer and is normally very active. Over the last 24 hours he has started dragging his feet and feels unsteady when walking, describing his gait 'like a drunk man'. On questioning he also describes increasing difficulty passing urine and has not had the sensation to empty his bladder for the past eight hours. He denies any preceding trauma, recent viral illness or similar previous symptoms in the past.

On examination he has normal muscle bulk and no fasciculations. There is symmetrical lower limb flaccid paralysis to the hips, with symmetrical hyporeflexia. He has a sensory level to T10 and is in urinary retention. Examination of the upper limbs and cranial nerves is entirely normal.

Which of the following would be the most useful initial investigation?

A. Aquaporin 4 antibodies
B. Lumbar puncture
C. MRI spinal cord
D. MRI brain
E. HIV serology

C. MRI spinal cord

This man presents with signs and symptoms of acute transverse myelitis. The underlying aetiological process can be diverse; it can be associated with underlying autoimmune systemic response, infectious cause or demyelinating process such as neuromyelitis optica.

The presence of a sensory level suggests a spinal cord lesion, as such a CT or MRI Brain would not be the first investigation. The most important initial approach in a patient presenting with acute disturbance of motor, sensory or autonomic function (and a sensory level) is to rule out a compressive cord lesion; an MRI spine is therefore an essential first step. Although HIV serology would be important in this patient, as aforementioned, the most important step is to exclude a compressive lesion.

Question 39 of 409

You are called to see a 67-year-old lady by psychiatry who is asking for your opinion on management. Over the past 3 weeks, her husband has become increasingly concerned by her behaviour. She has become suspicious of him and accused him of stealing 'my true husband'. Initially, the lady would avoid her husband and refuse to eat food that he had prepared. However, today she threatened him with a knife and the police had to be called.

The psychiatry doctor is concerned as he notes that she was admitted to hospital 5 weeks ago and was treated for a suspected urinary tract infection with intravenous antibiotics. Subsequent testing showed the pathogen to be an extended-spectrum beta-lactamase producing bacteria. She currently has a temperature of 38.7 degrees heart rate 105bpm regular RR 18 Sats 99% on room air. Her husband notes that she has been spending more time in the toilet over the past 3 weeks but is unsure if this is due to her paranoia.

Her husband describes an episode 30 years ago where she required antidepressants, antipsychotics and ECT after a close family bereavement. She is otherwise well and has no history of cognitive problems. Her husband states that there is a strong history of mental health problems in her family but he is unable to be more specific.

When you speak to her she appears to be confused and scores 19/30 on the Mini Mental State Examination. She can point to, name and recognise her husband and can also pick him out from pictures. However, she tells you that the man standing next to her is not her husband but a lookalike who has replaced him. Despite all your best efforts to show evidence to the contrary, she cannot be persuaded to change her opinion.

Which of the following below would best describe her presentation?

A. Delirium causing Cotard syndrome
B. Delirium causing Fregoli syndrome
C. Delirium causing Capgras syndrome
D. Late onset schozphrenia causing Capgras syndrome
E. Atypical severe depression

C. Delirium causing Capgras syndrome

Firstly, this woman has features that suggest delirium having a factor to play in her presentation: fever, acute cognitive impairment, infective symptoms, recent treatment for a highly resistant infection. Late-onset schizophrenia is very rare and when it does occur has no association with family history of mental health problems or personal history of depression. In addition, the duration of symptoms is probably too rapid for late onset schizophrenia.

Secondly, the woman is describing a delusion where she believes her husband to be replaced by an imposter. This is known as Capgras syndrome and can be seen in organic states such as delirium as well as in schizophrenia. It is rare but is most commonly seen in older women. The delusion most commonly relates to a life partner and can sometimes lead to serious violence being perpetrated against the supposed imposter.

Cotard syndrome is a nihilistic delusion seen in severely depressed people where they believe that they, or a part of their body is dead.

In Fregoli syndrome, the patient believes that an individual (who is almost always a persecutory figure and someone close to them) has taken on many different guises. This syndrome is named after an artist called Leopoldo Fregoli renowned for his ability to change costumes very quickly. A person with Fregoli syndrome will identify several different strangers as being the persecutor in disguise.

Question 40 of 409

A 28-year-old male presents to the acute medical unit with confusion. His girlfriend states that over the past couple of days he has become progressively more confused. His past medical history includes epilepsy. His drug history includes sodium valproate. On examination, you note myoclonus and his Glasgow coma score is reduced at 13 (M6, V4, E3).

Blood results are as follows:

Hb	142 g/l	Na	138 mmol/l	Bilirubin	14 µmol/l
Platelets	388	K	4.4 mmol/l	ALP	82 u/l
WBC	10.8	Urea	5.8	ALT	24 u/l
Neuts	8.4	Creatinine	72	γGT	36 u/l
Lymphs	1.2	Albumin	42 g/l	Plasma ammonia	65 µmol/L (normal range 11-32 µmol/L)

What treatment is indicated?

A. L-carnitine
B. Lactulose
C. Rifaximin
D. Sodium phenylbutyrate
E. Sodium benzoate

A. L-carnitine

L-carnitine can be used in the treatment of hepatotoxicity or hyperammonemic encephalopathy in the context of an acute or chronic overdose of sodium valproate

Valproate-induced hyperammonaemic encephalopathy (VHE) is an unusual complication characterised by a decreasing level of consciousness, focal neurological deficits, cognitive slowing, vomiting, drowsiness, and lethargy. Asymptomatic hyperammonaemia occurs in 15-50% of patients on valproate.

Treatment with L-carnitine may be beneficial in reducing ammonia levels. Lactulose and rifaximin are used in the prevention of hepatic encephalopathy.

Intravenous sodium phenylbutyrate and sodium benzoate are used to treat hyperammonaemia in patients with urea cycle enzyme deficiencies.

Question 41 of 409

A 52-year-old male presents to the emergency department with a 5-week history of constipation not relieved by over the counter laxatives. His past medical history was significant for hypertension, COPD and schizophrenia. His current medications include ramipril, clozapine and tiotropium. He denied weight loss, poor appetite or other alarming symptoms. His family history was significant for bowel cancer with his father and uncle having died of colon cancer aged 78 and 82 respectively. His sister had a hysterectomy at the age of 72 but he was not sure why. On examination, his blood pressure was 124/78mmHg lying and 115/80mmHg standing. Pulse was 63/min. Clinical examination did not reveal any significant findings.

Hb	137 g/l
MCV	82 fl
Platelets	420 * 10 /l
WBC	7 * 10 /l
Creatinine	89 umol/L
Urea	4.7 umol/L
Na+	143 mmol/L
K+	3.9 mmol/L
Corrected Calcium	2.3mmol/L
FOB	negative
Abdominal X-ray	faecal loading

What is the most likely cause of constipation in this case?

A. Clozapine
B. Colon cancer
C. Illicit drugs
D. Dehydration
E. Malingering

A. Clozapine

One of the most common side effects of clozapine is constipation/intestinal obstruction

This is an interesting case and the differential is between colon cancer and clozapine-induced constipation. Clozapine is reserved for drug-resistant schizophrenia and rightfully so as it comes with serious side effects one of which is constipation.

Constipation occurs in 14% of people on clozapine and it is believed to be an anticholinergic effect. There are papers in literature which report more serious implications like bowel infarction and death from longstanding clozapine-induced constipation.

Cancer is unlikely here as this patient has no other alarming symptoms or signs (no weight loss, normal haemoglobin, negative FOB) to suggest this and also the cancer cases in his family history are unlikely due to a hereditary condition as it has appeared in elderly relatives with no evidence of anticipation. In practice though cancer should be excluded.

There is no indication of illicit drug use and dehydration is unlikely to cause such long history of constipation without physical findings. Here we are not told of any finding suggesting dehydration on clinical examination. Malingering usually indicates personal gains of which there are not mentioned.

Clozapine is a common cause of constipation and should not be ignored. The above case is a good example.

Question 42 of 409

A 74-year-old man is brought to the emergency by ambulance with limb weakness and speech disturbance. He awoke at 8 am with the symptoms and was last seen by his wife at 10 pm the previous night, at which point he was well. His past medical history includes hypertension and hypercholesterolemia. He takes ramipril and atorvastatin. He does not smoke or drink alcohol. He is functionally independent at baseline and is a non-executive director of a major multinational organization.

His observations are heart rate 88 beats per minute, blood pressure 128/67 mmHg, respiratory rate 17/minute, oxygen saturation 96% on room air and temperature 37ºC.

Neurological examination reveals an expressive dysphasia and 3+/5 power in the right upper and lower limbs with correspondingly reduced sensation.

Blood glucose testing is normal. An ECG demonstrates atrial fibrillation.

Urgent CT head and CT angiography are organized which demonstrate a proximal occlusion of the anterior circulation and no haemorrhage.

The patient proceeds to a diffusion-weighted MRI, which demonstrates a limited core infarct volume.

What is the best choice of management?

A. Apixaban
B. Clopidogrel
C. Intravenous thrombolysis
D. Intravenous thrombolysis + thrombectomy
E. Thrombectomy

E. Thrombectomy

For thrombectomy in acute ischaemic stroke, an extended target time of 6-24 hours may be considered if there is the potential to salvage brain tissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume.

Thrombectomy is the correct answer. This treatment can be offered to those patients who were last known to be well 6-24 hours previously (including wake-up strokes) and who have confirmed occlusion of the proximal anterior circulation but limited core infarct volume on diffusionweighted MRI. This patient fulfils all of those criteria.

Apixaban is incorrect. While this patient has new atrial fibrillation, anticoagulation is typically delayed for two weeks after an ischaemic stroke to prevent haemorrhagic complications.

Clopidogrel is incorrect. This is used for secondary prevention of ischaemic stroke (not caused by atrial fibrillation) and typically follows treatment in the initial period with high dose aspirin.

Intravenous thrombolysis is incorrect. This patient presents outside the thrombolysis window (4.5 hours) and so this treatment is unsuitable.

Intravenous thrombolysis + thrombectomy is incorrect. This patient presents outside the thrombolysis window and so this treatment would not be offered in combination with thrombectomy.

Question 43 of 409

An 85-year-old woman was referred by her General Practitioner to the stroke team on an urgent outpatient basis after her rest home staff reported an unusual episode the previous week. The patient normally suffered from mild dementia but was independent with activities of daily life with minimal assistance from care staff. One week previously, she had been found unusually drowsy in an armchair at her home. Staff recalled that she had been inconsistent with following commands and in particular was unable to raise her left arm in the air and was unable to stand. The drowsiness and arm weakness had resolved within 30 minutes. However, the patient had subsequently been more confused than normal with reduced mobility. On direct questioning, rest home staff report that a few days before the above episode, the patient had lost her balance and had sat down heavily on the ground. The care worker with her at the time was certain that the patient had not hit her head during this incident.

Past medical history included mild dementia, myocardial infarction and atrial fibrillation. Regular medications included aspirin 75 mg daily, ramipril 2.5 mg daily, bisoprolol 2.5 mg daily, simvastatin 20 mg daily and warfarin (target INR 2-3). Review of recent blood test monitoring showed that the patients INR had been well controlled over recent months with no results outside of the therapeutic range. The patient did not drink and was a long-term ex-smoker. As mentioned above, the patient normally needed minimal assistance with self-care and was fully continent.

Examination in clinic demonstrated a significant cognitive impairment (abbreviated mental test score 4/10) but without evidence of dysphasia. Pupils were equal and reactive to light with no papilloedema on fundoscopy. There was a full range of conjugate eye movements. No facial weakness or sensory loss was demonstrated. Tongue and palate function was unremarkable with no weakness of trapezius muscle. Examination of the peripheral nerves was unremarkable except for possible slight pronator drift in the left arm and an up going left plantar response. Cardiovascular examination was unremarkable except for an irregular pulse. The respiratory and abdominal examination was unremarkable.

Results of investigations performed at the time of clinic assessment are given below. Electrocardiogram: atrial fibrillation at rate 80 bpm, normal axis, inferior T wave inversion Chest x-ray: clear lung fields

Carotid doppler: no significant stenosis in right internal carotid artery; 50 % stenosis in the left internal carotid

Transthoracic echocardiogram: mild left ventricular systolic impairment, normal valvular function, no mural thrombus

What is most likely finding on CT brain scan performed after clinic review?

A. Sub-arachnoid haemorrhage
B. Cerebral infarction
C. Intracerebral haemorrhage
D. Normal pressure hydrocephalus
E. Sub-dural haematoma

E. Sub-dural haematoma

The diagnosis of sub-dural haematoma can be challenging, especially in those individuals with underlying dementia. In particular, a high index of suspicion is required in elderly patients treated with anticoagulant drugs. Sub-dural haemorrhage commonly occurs after minor injury, with up to 50 % of cases preceded by a fall without head injury. Transient focal neurological deficit can occur in up to 20 % of cases, leading to the potential for diagnostic confusion with transient ischaemic attack.

In this case the patient's history of a fall, anticoagulation and worsening confusion all point towards sub-dural haematoma as the most likely underlying pathology. The lack of risk factors for cerebral infarction other than appropriately treated atrial fibrillation make this less likely. The history is less likely to be consistent with the other possible answers.

Question 44 of 409

An urgent medical consult was requested regarding a 52-year-old female who had been admitted to the neurology ward a few hours previously and who had developed hypotension. She had presented to the Emergency Department with new weakness in her legs that had occurred over a course of three days. She also complained of continual lower back pain and pain in the top of her thighs, and as her illness progressed she was no longer able to weight bear. She had a past medical history of hypothyroidism, for which she was prescribed levothyroxine 125mcg OD, and other than an episode of viral gastroenteritis diagnosed by her GP two weeks prior to her current admission she was fit and well. Upon transfer to the neurology ward blood investigations, a chest x-ray, CT head scan and lumbar puncture were performed, the results of which are as follows:

Hb	132 g/l
Platelets	248 * 10 /l
WBC	8.2 * 10 /l

Na	138 mmol/l
K	5.2 mmol/l
Urea	6.4 mmol/l
Creatinine	77 µmol/l

CRP	15 mg/l
Glucose	7.2 mmol/l
TSH 0.26	(NR 04-3.6 mu/l)
Free T4 10.6	(NR 10 - 20 pmol/L)

Autoantibody screen: awaiting results

Urinalysis: negative Urine MCS: awaiting results Blood MCS: awaiting results

Chest x-ray: normal appearances of heart and lung fields

CT head: normal intracranial appearances

Lumbar puncture:

Protein	0.8g (NR 0.2-0.4 g/L)
Glucose	6.3 (blood glucose 7.2)
WCC 8	(<5/mm³)
Opening pressure	15 (NR 10-20 cmH2O)
Microscopy	nil seen, awaiting culture and sensitivity result

Whilst awaiting definitive measurement her blood pressure was noted to fluctuate between 55/30 mmHg and 162/84 mmHg within a matter of minutes; at present her blood pressure was 62/42 mmHg. Upon examination of her cardiovascular system, she was clinically well perfused with a normal and palpable radial pulse, a JVP of 3cm and a peripheral and central capillary refill time of less than two seconds. He heart rate was 82 bpm. Examination of her respiratory system was unremarkable with no respiratory distress, a respiratory rate of 16/min and oxygen saturations of 99% on air. Examination of her gastrointestinal system was unremarkable. Examination of her peripheral nervous system revealed a power deficit of grade 2/5 in all muscle groups of the lower limbs, power 5/5 in the upper limbs and normal sensation and coordination throughout. Knee and ankle reflexes were absent bilaterally. Cranial nerve examination was unremarkable.

What is single next best step with regards to management of her blood pressure?

A. Commence dobutamine infusion
B. Commence noradrenaline infusion
C. Commence intravenous fluid resuscitation with 500ml of colloid stat
D. Commence intravenous immunoglobulin
E. Arrange urgent plasmapheresis

D. Commence intravenous immunoglobulin

IVIG is generally used first-line for Guillain-Barre syndrome

This lady has developed Guillain Barre Syndrome (GBS) with evidence of a temporary autonomic neuropathy, as manifested by her highly labile blood pressure. The treatment of this is therefore to treat the underlying disorder, which in this instance is with intravenous immunoglobulin. In the presence of GBS complicated by autonomic neuropathy blood pressure is not a reliable indicator and any thus any decisions regarding fluid status must be in concordance with clinical examination findings. In this question, she is clearly euvolaemic clinically and so there is no indication for fluid or inotropic support.

Question 45 of 409

A 60-year-old man presents to the neurology clinic with progressive weakness in the upper and lower limbs bilaterally. Symptoms initially came on gradually over 3 years and he is now bedbound. His past medical history is significant for hypertension, which is well controlled on amlodipine 10 mg once daily. On examination, there is no sensory abnormality and deep tendon reflexes are intact.

Calcium	2.5 mmol/L	(2.1-2.6)
Phosphate	1.2 mmol/L	(0.8-1.4)
Magnesium	0.9 mmol/L	(0.7-1.0)
Thyroid stimulating hormone (TSH)	4.0 mU/L	(0.5-5.5)
Free thyroxine (T4)	13 pmol/L	(9.0 - 18)
Amylase	80 U/L	(70 - 300)
Uric acid	0.53 mmol/L	(0.18 - 0.48)
Creatine kinase	1020 U/L	(35 - 250)
Electromyography (EMG)	Suggestive of inflammatory myopathy	

Power is significantly reduced to 1/5 in the quadriceps and wrist flexors. Relevant investigations are shown below:

What is the most likely specific finding on muscle biopsy?

A. Absent dystrophin protein
B. CD8+ T-cell infiltrates
C. Cytoplasmic inclusions
D. Muscle necrosis
E. Ragged red fibers

C. Cytoplasmic inclusions

Older man + quadriceps and finger/wrist flexors weakness + raised CK → inclusion body myositis

The scenario describes a patient with inclusion body myositis. Weak flexors and extensors and involvement of both proximal and distal muscles, as described in this scenario, are characteristic of inclusion body myositis. It typically occurs in older males and CK is raised, as with all inflammatory myopathies. Normal sensations and intact deep tendon reflexes also point towards inflammatory myopathy. Muscle biopsy findings of cytoplasmic inclusions are the distinguishing feature of inclusion body myositis. The cytoplasmic inclusions are ovoid, electron-dense bodies that are surrounded by clear haloes.

The age and onset of this patient's disease do not favour a diagnosis of Duchenne muscle dystrophy, which would arise in childhood. A biopsy would instead show absent dystrophin proteins.

Polymyositis is the most common AIDS-related myopathy, characterised by the presence of CD8+ T-cell infiltrates in the muscles. The patient in this scenario denies any significant medical problems and has no history of repeated infections, weight loss, fever or any HIV-related features.

Muscle necrosis, muscle fibre regeneration, and inflammatory infiltrates are the biopsy findings of all inflammatory myopathies. These are not specific to inclusion body myositis.

Ragged red fibres on muscle biopsy are a feature of mitochondrial myopathies. These rare diseases are unlikely in this patient, as they would present at a much younger age.

Question 46 of 409

A 55-year-old male is found confused on street by a policeman. Hospital records document that he is a known to be a type 2 diabetic with previously DNAs to clinic and known poor compliance with medications. He also had two previous admissions to hospital, 2 and 10 years ago, for alcohol withdrawal. On examination, the patient is not orientated in time or place, scoring 0 out of 10 on abbreviated mental. He is able to follow your commands in lifting his upper and lower limbs during his neurological exams. All reflexes were present. He fails to follow your finger with his eyes on cranial nerve examination. His gait is grossly ataxic, as you noted when he tried to walk to the toilet against medical and nursing advice. His blood sugar is awaited.

What is the diagnosis?

A. Wernicke's encephalopathy
B. Delirium
C. Miller-Fisher syndrome
D. Hypoglycaemia secondary to anti-glycaemic overdose
E. Acute ischaemic stroke

A. Wernicke's encephalopathy

The patient presents with a triad of ophthalmoplegia, ataxia and encephalopathy, suggestive of Wernicke's encephalopathy. The pathophysiology relies on an underlying thiamine deficiency, which is a key co-factor in energy metabolism and is often deficient in alcoholics. Miller-Fisher syndrome is a key differential in this case: this is a variant of Guillain-Barre syndrome presenting with ophthalmoplegia, ataxia and areflexia. Delirium and hypoglycaemia should not present with ophthalmoplegia.

Question 47 of 409

You have been referred a 45-year-old man by the Accident and Emergency doctors with a severe headache. The headache woke him up at 3am, and he describes it as the worst headache he's ever had, (although he admits he's not a regular headache sufferer). He has had seven episodes like this over the past two weeks that have followed a very similar pattern, with the other two headaches lasting around 60 minutes before going. The pain is mainly around the left eye and temple and is sharp in nature. You have to ask him to sit down to examine him because he is up and pacing around his room, clearly very agitated. On examining him you note that his left eye is watering and swollen, and there's some redness and mild bruising just above the eye. When you ask him about this bruising he says that the pain was so bad he bashed his head against the fridge door to try and help take it away.

On examination he has normal power, sensation and reflexes in all four limbs.

On examining his cranial nerves you notice that he has a mild left sided ptosis and miosis, and there is conjunctival injection and lacrimation on that side too. His neck movements are slow but complete, and he has no obvious stiffness or photophobia

What is the most likely cause of his headache?

A. Cluster headache
B. Subarachnoid haemorrhage
C. Paroxysmal hemicrania
D. Migraine
E. Tension headache

A. Cluster headache

What is described above is the classical cluster headache. NICE guidelines characterise cluster headaches as one-sided headache in or around the eye or temporal region associated with signs of autonomic dysfunction on the same side.

Attacks of pain:

- Usually last for 15-180 minutes
- Almost always described as the most severe pain known
- Tend to recur at the same time each day
- Often wake the person shortly after falling asleep

Signs of symptoms of autonomic dysfunction include:

- Rhinorrhoea or nasal congestion
- Red eye and/or lacrimation
- Facial or forehead sweating or flushing
- Constriction of the pupil and/or ptosis
- Eyelid oedema
- A sense of aural fullness

Tension headaches tend to be bilateral, pressing, with a pain intensity of mild to moderate and without other associated signs or symptoms.

Migraines can be both unilateral or bilateral and tend to be throbbing or banging in nature. While they can be severe in nature, they tend not to be described as the worst pain the patient has ever had. Unlike the agitation that comes with cluster headaches, patients with migraines tend to avoid activities of daily living shutting themselves in quiet dark rooms to provide relief. In addition the headaches tend to be longer, most commonly being between 4 hours and 3 days in adults.

Paroxysmal hemicrania attacks then to be much shorter (2-30 minutes), happen with much higher frequency (>5 times/day), and are more common in women. In an exam situation they will also tend to mention that the patient has found complete relief with indometacin (or this will be the subject of the question).

Subarachnoid haemorrhage headaches do not have a preceding history of previous attacks.

Question 48 of 409

A 54-year-old gentleman is referred to Neurology clinic with a 2 month history of nocturnal headache and difficulty walking.

On examination he has an ataxic gait and impaired co-ordination affecting the left arm and leg. Blood results show the following

Hb	190 x10 /L	130-168 x10 /L
WCC	5.4 x10 /L	4.2-10.6 x10 /L
Platelets	180 x10 /L	130-370 x10 /L
CRP	4 mg/L	0-5 mg/L
Creatinine	90 µmol/L	60-125 µmol/L
eGFR	>90 mL/min/1.73 m	>90 mL/min/1.73 m
Na	140 mmol/L	133-146 mmol/L
K	4.1 mmol/L	3.5-5.3 mmol/L
ALT	31 IU/L	0-45 U/L
ALP	54 IU/L	30-130 IU/L
Bilirubin	10 µmol/L	0-21 µmol/L

A CT (computed tomography) brain scan is done which shows shows as a well-defined, low attenuation region in the posterior fossa with an enhancing nodule on the wall

What is the most likely underlying lesion?

A. Meningioma
B. Cerebellar metastasis
C. Astrocytoma
D. Haemangioblastoma
E. Medulloblastoma

D. Haemangioblastoma

Cerebellar haemangioblastomas release erythropoietin so can cause a rise in haemoglobin

Cerebellar haemangioblastomas release erythropoietin as a paraneoplastic syndrome causing an elevated haemoglobin. None of the other tumours mentioned are associated with this phenomenon.

Haemangioblastoma is an uncommon tumour, but it is the most common primary intra-axial tumours in the posterior fossa in adults.

Astrocytomas and medulloblastomas are encountered in the posterior fossa of younger adults but are rare in older adults, accounting for <1% all tumours

The outcome for haemangioblastomas is very good, if surgical extraction of the tumor can be achieved

Haemangioblastomas are commonly seen in von- hippel Lindau (VHL) syndrome. These individuals have a worse prognosis than those who have sporadic tumors since those with VHL syndrome usually have more than one lesion

Question 49 of 409

A 35-year-old gentleman presents with weakness raising up his arms and some drooping of the eyelids and his shoulder blades are pronounced. He says his symptoms are mild and he probably would not have noticed it except his father had similar symptoms that have steadily got worse. This gentleman has no other past medical history of note and is taking no regular medications. On examination there is mild evidence of scapula winging, proximal weakness of both upper limbs, ptosis and he has difficulty whistling. There is normal power of his lower limbs and reflexes and sensation is intact throughout.

Creatine kinase 220 units/L

A muscle biopsy is sent but is pending, what is the most likely diagnosis?

A. Facioscapulohumeral dystrophy
B. Myotonic dystrophy
C. Emery-Dreifuss muscular dystrophy
D. Becker muscular dystrophy
E. Oculopharyngeal muscular dystrophy

A. Facioscapulohumeral dystrophy

Facioscapulohumeral muscular dystrophy: facial weakness (e.g. difficulty closing eyes, smiling, blowing), winged scapula and weakness of the shoulderm upper arm and hip girdle muscles

Facioscapulohumeral dystrophy is usually an autosomal dominant condition and although it affects men and women equally, men may be more symptomatic. Shoulder, upper arm and facial muscles are the most often implicated and lower limb involvement is less common. Winging of the scapulae are one characteristic finding which may necessitate surgical fixation. It is a progressive condition however prognosis is usually good with minor disability and lifespan unaffected.

Myotonic dystrophy is the most common muscular dystrophy of which symptoms include delayed relaxation of muscles wasting and weakness as well as cardiac conduction deficits, cataracts and characteristic facies. Becker muscular dystrophy usually presents in childhood with predominantly lower limb and girdle weakness. Patients with Emery-Dreifuss muscular dystrophy also usually present in childhood, characteristically with contractures and oculopharyngeal muscular dystrophypresents usually over the age of 40 with eyelid, facial and throat muscle weakness initially followed by pelvic and shoulder weakness.

Question 50 of 409

A 45-year-old man complains of lower limb numbness associated with weakness. He also noted some recent problems with urinary incontinence and has recently attended the opticians due to some blurring of vision

On examination he has bilateral lower limb weakness (grade 3+/5). His tone was spastic on both sides with exaggerated reflexes. The planter reflexes were up-going bilaterally. The sensory level was at the tenth thoracic vertebra (T10). Eye examination revealed a normal visual acuity with a normal fundal examination.

He has a history of asthma and is currently well controlled with just a salbutamol inhaler.

Magnetic resonance imaging (MRI) of the brain is normal. MRI of the spine shows a hyper intense lesion spanning from (T7-T12). The following investigations had been ordered:

Na+	135 mmol/l
K+	4 mmol/l
Creatinine	80 µmol/l
Urea	4.5 mmol/l
CRP	5 mg/l
ESR	10 mm/hr
Urine analysis	Normal
ANA	Negative

Which one of the following investigations would be most useful to reach a diagnosis?

A. Auditory evoked response potentials
B. CSF analysis for oligoclonal bands
C. Anti-aquaporin 4 antibodies
D. Serum B12
E. Visual evoked response potentials

C. Anti-aquaporin 4 antibodies

Neuromyelitis optica is associated with aquaporin 4 positive serum antibody

Neuromyelitis optica (Devic disease) should be suspected when the following is noted:

- quadriparesis or paraparesis within days to weeks
- vision changes
- normal brain MRI
- presence of anti-NMO antibodies (anti-aquaporin 4 antibodies)
- responsive to immunosuppressant

Question 51 of 409

A 62-year-old man is being reviewed in the neurology clinic for 6 months of progressive difficulty walking and memory issues. He has difficulty initiating movements and has become increasingly forgetful. He also suffers from increased urinary frequency, with a few instances of urinary incontinence. The patient has a history of subarachnoid haemorrhage 8 months prior, for which a craniotomy and clipping were performed.

A CT scan is requested and performed.

What abnormality is most likely to be relevant to his presentation?

A. Frontal & temporal lobe atrophy
B. Midbrain atrophy & enlargement of third ventricle
C. Normal
D. Ventriculomegaly with enlarged sulci and shrunken gyri
E. Ventriculomegaly with normal-sized sulci and gyri

E. Ventriculomegaly with normal-sized sulci and gyri

Urinary incontinence + gait abnormality + dementia = normal pressure hydrocephalus

Dementia, urinary incontinence, and gait abnormality, as described in this scenario, are the classic triad of normal pressure hydrocephalus (NPH). The patient's symptoms started 2 months after a subarachnoid haemorrhage, most likely due to reduced cerebrospinal fluid (CSF) absorption by the arachnoid villi. Neuroimaging in NPH shows ventriculomegaly with normal-sized sulci and gyri. There is an enlargement of the frontal, temporal, and occipital horns of the lateral ventricles. This enlargement is disproportionate to the sulci, which are mostly normal in size. The definitive treatment for NPH is ventriculoperitoneal (VP) shunting. The dementia, gait disturbance, and incontinence associated with NPH are reversible and patient improves significantly after a successful VP shunt.

Frontal and temporal lobe atrophy may be seen in a patient with frontotemporal dementia (FTD). Behavioural changes are the most common presenting feature of FTD, which is absent in this scenario and therefore FTD is a less likely diagnosis here. A history of urinary incontinence along with dementia and gait abnormality is more in favour of normal pressure hydrocephalus(NPH) than FTD.

Midbrain atrophy and enlargement of the third ventricle is a characteristic imaging feature of progressive supranuclear palsy (PSP). Gait disorder in PSP is also associated with a typical supranuclear gaze which is absent in this scenario.

NPH is diagnosed by ventricular enlargement on neuroimaging and so a normal study is unlikely to be seen in such a scenario.

Alzheimer's disease may show ventriculomegaly with enlarged sulci and shrunken gyri on imaging. The acute onset of symptoms and urinary incontinence in this scenario makes Alzheimer's disease much less likely.

Question 52 of 409

A 62-year-old man is admitted to the emergency department at 09:15 with right-sided arm and leg weakness and dysphasia. The symptoms were present when he woke up that morning around 08:30. He was asymptomatic when he went to bed last night around midnight.

He lives alone and is fully independent. He drives to the shops each weekend. He is an ex-smoker. His past medical history consists of hypertension and carpal tunnel syndrome.

On arrival, he has a National Institutes of Health Stroke Scale (NIHSS) of 9. His Glasgow coma scale (GCS) is 15. His cardiac monitor shows he is in atrial fibrillation.

He is transferred to radiology where he has a CT angiogram with CT perfusion. The report reads evidence of ischaemic stroke to the left proximal anterior circulation. On perfusion imaging, there is a small central area with markedly decreased cerebral blood flow suggestive of a limited ischaemic core. In proportion, there is a large surrounding area with only moderately reduced cerebral blood flow and near-normal cerebral blood volume suggestive of penumbra. There is mild cerebral oedema.

What is the appropriate management?

A. Delayed thrombolysis
B. Start the patient on a direct-acting oral anticoagulants
C. Start the patient on aspirin and apply anti-embolism stockings
D. Start the patient on aspirin and high-dose statin
E. Thrombectomy

E. Thrombectomy

For thrombectomy in acute ischaemic stroke, an extended target time of 6-24 hours may be considered if there is the potential to salvage brain ptissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume.

As the patient was well going he went to sleep, the longest time from onset to presentation is 9 and a half hours. He has a good baseline function (functional status would be less than 3 on the modified Rankin scale) and his NIHSS is greater than 5 making him a potential candidate for thrombectomy. This is usually used within 6 hours of onset but if there is potential to salvage brain tissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume, then it can be considered up to 24 hours from onset (including wakeup strokes).

Thrombolysis with alteplase should only be given if it is administered within 4.5 hours of the onset of stroke symptoms. In this case, the stroke onset is likely outside this window and therefore thrombolysis should not be considered.

NICE has written guidance for 'Interventions for people with acute coronary syndromes or acute stroke or for acutely ill patients' where it is advised 'do not offer anti-embolism stockings for VTE prophylaxis to people who are admitted for acute stroke.'

Atrial fibrillation and stroke is a common combination. NICE recommends 'that people with disabling ischaemic stroke who are in atrial fibrillation are treated with aspirin 300 mg for the first 2 weeks before anticoagulation treatment is considered'.

Immediate initiation of statin therapy isn't recommended in acute stroke. There is an association with an increased risk of haemorrhagic transformation. Treatment should be delayed by 48 hours after stroke symptom onset (as per BNF and NICE).

Question 53 of 409

A 66-year-old male is brought to the emergency department by ambulance complaining of an abrupt onset of bilateral weakness progressing over the last 4 hours. He has a past medical hypertension and hypercholesterolaemia. His medications include amlodipine, ramipril and atorvastatin. He does not smoke cigarettes.

On examination, there is bilateral flaccid weakness of the lower limbs, with power 0/5 in all muscle groups. The patient is areflexic. There is loss of pain and temperature sensation from the level of the umbilicus to the feet. Proprioception and vibration sense is preserved.

Over the course of the next few weeks, the weakness becomes spastic in nature. The lower limbs develop hyperreflexia and the plantar reflexes are now noted to be upgoing.

What is the likely diagnosis?

A. Anterior spinal artery occlusion
B. Basilar artery occlusion
C. Cauda equina syndrome
D. Posterior spinal artery occlusion
E. Vitamin B 12 deficiency

A. Anterior spinal artery occlusion

Bilateral spastic paresis and loss of pain and temperature sensation - anterior spinal artery occlusion

Anterior spinal artery occlusion is the correct answer. The patient has risk factors for atherosclerosis (hypertension, hypercholesterolaemia) and this is a common cause of anterior spinal artery occlusion. An infarct of this artery causes bilateral weakness below the level of the lesion (in this case, the umbilicus suggests T10 as the level) associated with loss of pain and temperature sensation.

This anterior cord syndrome is caused by injury to the spinothalamic and corticospinal tracts. Initially there were will be a flaccid paralysis but this will become more reflective of an upper motor neuron lesion with development of spastic paraparesis over the following days to weeks. Basilar artery occlusion is incorrect. This causes 'locked-in syndrome' which causes complete paralysis of voluntary muscles, except for the muscles that control the eyes.

Posterior spinal artery occlusion is incorrect. This causes a dorsal cord syndrome characterized by loss of proprioception and vibration.

Vitamin B 12 deficiency is incorrect. This causes subacute combined degeneration of the spinal cord if severe. However, the onset would be more insidious and there would be mixed upper motor and lower motor neuron signs in the lower limbs that would occur concurrently e.g. absent ankle reflexes but upgoing plantar reflexes.

Cauda equina syndrome is incorrect. This causes lower motor neuron weakness. It would not progress to a spastic paraparesis.

Question 54 of 409

A 78-year-old male with a background of atrial fibrillation, ischaemic heart disease, hypertension is brought to hospital by his wife who is concerned about a recent deterioration in his health. For the last few weeks his wife has noticed that the patient has been more unsteady on his feet which has resulted in falls around the house. His wife also informs you that the patient has been more forgetful and less interested in his hobbies than usual. When you ask the patient about his symptoms, his main concern is that he has recently developed problems with urinary incontinence which he finds embarrassing.

As part of the investigation into this patient's condition, a CT scan of the patient's head is requested.

What is the most likely finding?

A. Diffuse cerebral atrophy with enlargement of cortical sulci and ventricles
B. A hyper-dense bi-convex extra-axial collection beneath the squamous part of the temporal bone
C. Small areas of low density in the distribution of the middle cerebral artery, suggestive of old lacunar infarcts
D. A concave-shaped extra-axial collection with increased attenuation
E. Enlarged third and lateral ventricles, disproportionate to the enlargement of the cortical sulci

E. Enlarged third and lateral ventricles, disproportionate to the enlargement of the cortical sulci

Normal pressure hydrocephalus neuroimaging findings: ventriculomegaly in the absence of, or out of proportion to, sulcal enlargement

The patient's history of atrial fibrillation places him at increased risk of stroke and so it may be tempting to attribute his deterioration to cerebrovascular disease. Another pitfall with this question is the report of falls at home, which may lead to a suspicion that the patient has developed a subdural haematoma (SDH). However, it is important to appreciate that his symptom of ataxia pre-dates his tendency to fall. The critical part of this question is that this patient's presenting complaints of ataxia, dementia and urinary incontinence are the classical triad of clinical findings associated with normal pressure hydrocephalus. As such, a CT scan of his head would be expected to show ventricles which are dilated out of proportion to the enlargement of his sulci.

Question 55 of 409

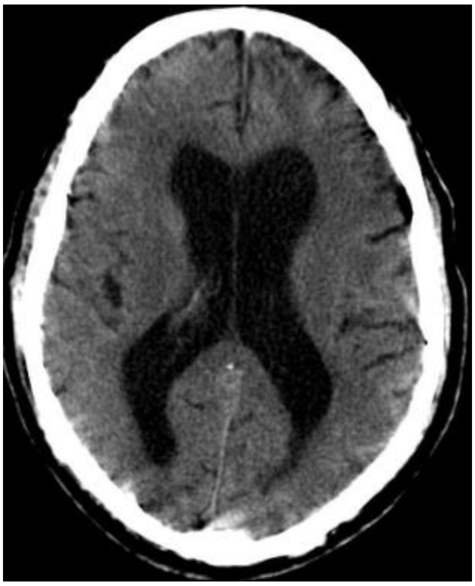
A 62-year-old man is reviewed in the neurology clinic due to a gait disorder for the last 2 months. His wife tells that he has become forgetful and has difficulty continuing his job. The patient has a history of hospital admission 4 months back due to bacterial meningitis requiring intravenous antibiotics. Past medical history is significant for hypertension well-controlled on amlodipine 10 mg once daily.

A lumbar puncture is performed and an interpretation of the CSF analysis is shown below:

Appearance	Clear, colourless	(Clear, colourless)
Opening pressure	6 mmHg	(8-16)
Cells	4 cells /mm	(0-4)
Glucose	3.9 mmol/L	(2.5-4.4)
Protein	50 mg/100 mL	(20-60)

Blood glucose	5.6 mmol/L

A CT head is performed, as shown below:



What is the most appropriate treatment option for this patient?

A. Intravenous corticosteroids
B. Intravenous mannitol
C. Oral memantine
D. Therapeutic lumbar puncture
E. Ventriculoperitoneal (VP) shunting

E. Ventriculoperitoneal (VP) shunting

The scenario describes a patient with normal pressure hydrocephalus, for which the definitive treatment is ventriculoperitoneal shunting . The patient has gait apraxia and dementia that started 2 months after meningitis. The CT scan shows enlarged frontal, temporal, and occipital horns of the lateral ventricles disproportionate to the sulci, which appear normal in size. These CT findings when combined with the patient's history suggest the diagnosis of normal pressure hydrocephalus (NPH) in this scenario. NPH can occur following meningitis or subarachnoid haemorrhage due to reduced CSF absorption by arachnoid villi. The classical triad of NPH includes gait apraxia, dementia, and urinary incontinence. LP reveals a normal or low opening pressure which is also hinted at in this question. The definitive treatment for NPH is VP shunting. Symptoms of NPH including dementia are reversed with successful VP shunting in 60-90 % of the patients. 10% develop complications like postural headache, subdural effusion, shunt infection, and bacterial meningitis.

The history of gait problems and dementia in this scenario may suggest Alzheimer's disease for which memantine is the most appropriate treatment option. However, the acute onset of symptoms and normal sulci on CT scan in this scenario rule out Alzheimer's disease. Neuroimaging in Alzheimer's reveals dilated ventricles with enlarged sulci and decreased volume gyri.

Intravenous mannitol is unlikely to benefit this patient with NPH. It is an osmotic diuretic and helps in decreasing intracranial pressure.

There is no role of intravenous corticosteroids in treating NPH. Corticosteroids are used to reduce hearing loss and neurological sequelae in meningitis.

Therapeutic lumbar puncture (LP) treats conditions with increased intracranial pressure without a space-occupying lesion. It is an important treatment option for idiopathic intracranial hypertension. This patient with NPH requires continuous drainage of CSF which is not possible via LP. A lumbar peritoneal (LP) shunt may be used as an alternative to VP shunt to treat NPH.

Question 56 of 409

A 76-year-old gentleman with diabetes mellitus was referred to a specialist memory clinic by his family doctor. His wife was concerned as he had been more forgetful recently and had developed urinary incontinence. His family doctor had treated him with a course of trimethoprim for a urinary tract infection but his symptoms had persisted.

On examination this gentleman smelt strongly of urine. He had a broad-based, unsteady gait. Examination of his cardiovascular and respiratory systems was unremarkable but on abdominal examination there was suprapubic tenderness. He was orientated to place but scored only 22/30 on a Mini Mental State Examination (MMSE).

Urinalysis:

- Blood negative
- Protein Trace
- Nitrites -
- White cells +
- Microscopy 50 white cells seen, bacteria +
- Cultures Mixed growth, please send repeat sample

Magnetic Resonance Imaging (MRI) of the brain: 'Disproportionately enlarged ventricular system compared with the degree of sulcal atrophy.'

Lumbar Puncture (LP):

Opening pressure	18 cmH20 (12 20)
Appearance	Clear and colourless
Red cells	4
White cells	1 (0 5)
Gram stain	No organisms seen
Culture	No organisms seen
Protein	30 mg/100ml (15 60)
Glucose	98mg/100ml (50 80)
Virology	No viruses detected on PCR
Cytology	No abnormal cells seen
Timed 10 metre walk pre-LP	15 seconds
Timed 10 metre walk post-40 mL CSF drainage	12 seconds

Given the underlying diagnosis what is the definitive treatment of choice?

A. Repeated therapeutic lumbar punctures
B. Acetazolamide
C. Referral for a ventriculo-peritoneal shunt
D. Vitamin B12 and folate replacement
E. Referral for lumbar drain insertion

C. Referral for a ventriculo-peritoneal shunt

This gentleman presents with all three components of the classic triad of Normal Pressure Hydrocephalus (NPH): urinary incontinence, ataxia and memory impairment. He may also have a co-existent urinary tract infection but this alone cannot explain his presentation. Further evidence to support a diagnosis of NPH includes the MRI scan, which shows ventricular enlargement, and the improvement in his 10 metre walk time following therapeutic CSF drainage.

This gentleman needs a referral to the neurosurgical team for consideration of a definitive surgical procedure. There are alternative surgical options and the specifics of each particular case will dictate which approach is used. The most commonly performed procedure is ventriculo-peritoneal shunting as this has a lower failure rate than alternative procedures.

Repeated therapeutic lumbar punctures (LP) can be performed but this approach has fallen out of favour as it is unpopular with patients and exposes them repeatedly to an invasive procedure with associated risks.

Acetazolamide is a diuretic used to treat Idiopathic Intracranial Hypertension and does not have a role in NPH.

Vitamin B12 and folate replacement is not indicated in this case although vitamin B12 deficiency can cause memory impairment and walking problems (subacute combined degeneration of the cord).

A lumbar drains diverts CSF from the lumbar subarchnoid space to the outside world. It can be useful in determining whether or not a patient may respond well to a shunting procedure but due to the high risk of infection it is not in itself a definitive treatment for NPH.

Question 57 of 409

Vincent, 28, has treatment resistant schizophrenia, with his usual symptoms being auditory hallucinations and persecutory delusions. He was recently prescribed clozapine, fluoxetine and lactulose. He has been complaining of constipation recently, but now presents to the emergency department with acute abdominal pain and vomiting. On examination abdomen is distended.

What is the most likely cause?

A. Intestinal obstruction
B. Appendicitis
C. Constipation
D. A bezoar
E. Ingestion of foreign object

A. Intestinal obstruction

One of the most common side effects of clozapine is constipation/intestinal obstruction

The most likely cause of this patients presentation is intestinal obstruction. Intestinal obstruction is one of the more under-recognised complications of clozapine therapy, yet one of the more serious. Gastric hypomotility is common in patients who are treated with clozapine, and its presentation can range from a simple constipation to more severe conditions such as intestinal obstruction, bowel ischaemia and necrosis.

The important pieces of information to consider when answering this question are the recent prescription of clozapine, the presence of constipation previous to current presentation, and his physical presentation of acute abdominal pain and vomiting with distension. When answering a question such as this, recent prescriptions of medications prior to the deterioration of their physical condition should raise the thought that maybe one of the medications is causing the symptoms. In this scenario, the patient has recently been prescribed clozapine, fluoxetine and lactulose. Therefore, considering each of these medications and their side effects is a must.

The patients presentation, and recent past medical history, provides a good indication of what could be the underlying issue. The patient has presented with acute abdominal pain and vomiting. When you consider this with the recently experienced constipation, it becomes clear that this patient is likely suffering from an obstruction, as opposed to the other options on offer.Constipation would be an inappropriate answer to this question. Although he has had constipation recently, and abdominal pain could be a presentation of constipation, vomiting is not generally observed in constipation. This would means that this diagnosis is less likely.

Bezoars are indigestible masses that become trapped in the gastrointestinal tract. They can occur when individuals consume a variety of items, including hair, soil, chewing gum etc. These items form a mass, which ultimately becomes lodged in the gastrointestinal tract, often requiring surgical intervention to relieve the obstruction. The symptoms that the patient in this scenario has experienced could be explained by a bezoar, however, we do not have any evidence that he consumes any items that may lead to a bezoar. Furthermore, the recent commencement of clozapine means that we cannot select a bezoar as the most likely cause of this patients symptoms above intestinal obstruction. Similarly, we do not have any evidence that the patient ingests foreign objects, meaning that this cannot be classed as a likely cause in this question.

Appendicitis could explain the acute presentation of this patient. However, the fact that the patient experienced constipation prior to him developing acute abdominal pain and vomiting means that appendicitis is less likely.

Question 58 of 409

An 84-year-old male is reviewed in clinic after a 7-month history of progressive confusion, unsteadiness on his feet and new urinary incontinence. He had previously minimal past medical history and continued to volunteer at his local charity shop, taking ramipril alone for hypertension. On examination, his abbreviated mental test score was 2/10, his gait was wide based and ataxic. A mini-mental state examination scores 17/30. His urine dip demonstrated no positive findings and serum results were unremarkable. Although there has been no history of head trauma, a CT head was performed, demonstrated no acute haemorrhages or infarcts. A subsequent MRI demonstrated large ventricles with periventricular white matter changes. Lumbar puncture demonstrated acellular cerebrospinal fluid with no organism growth. Opening pressure was 16 cm H20. You arrange a CSF infusion test, demonstrating raised CSF outflow resistance.

Which treatment is most appropriate?

A. Therapeutic repeat lumbar punctures
B. Ventriculoperitoneal shunt
C. Donepezil
D. Acetazolamide
E. Aspirin 300mg

B. Ventriculoperitoneal shunt

The history and examination are consistent with normal pressure hydrocephalus, with the triad of new onset dementia, urinary incontinence and gait disturbance. The key points in the investigations indicate the suitability of the patient for a ventriculoperitoneal shunt: the raised CSF resistance on CSF infusion test indicates impaired CSF absorption and correlates towards surgical improvement. In addition, prominent gait disturbance also points towards an increased likelihood of surgical success.

Question 59 of 409

A 78-year-old male presents with a one-year history of progressive unsteadiness on walking. He had previously been extremely fit and healthy, walking around 2 miles to the shops every day and only retired as a publicist 3 years ago. He underwent radiotherapy for localised squamous cell carcinoma of his vocal cords 18 months ago but otherwise had no other past medical history. He admits to having drunk 'more than he should have' while working in the city but says he has since cut down to moderate levels. He stopped smoking 5 years ago, with a 30 pack year history. Over the past 3 months, he has become incontinent of urine and has to rely on pads, which he is greatly embarrassed by.

On examination, he has a shuffling gait in his lower limbs with good arm swing. He is markedly slowed and takes 120 seconds to walk 20 metres. He turns around 180 degrees in 6 steps with no resting tremor, rigidity or bradykinesia. Examination of his tone, power, sensation, coordination and reflexes are all unremarkable. His voice is quiet and whispering. His cranial nerves are normal with a full range of eye movements. An abbreviated mental test scores 9/10, a Montreal cognitive assessment (MOCA) scored 29/30. His initial blood tests are as follows:

Hb	94 g/l
MCV	103.3 fl
Platelets	232 * 10 /l
WBC	6.3 * 10 /l
Na	139 mmol/l
K	4.9 mmol/l
Urea	7.5 mmol/l
Creatinine	98 µmol/l
CRP	2 mg/l
Vitamin B12	327ng/l
Folate	5.2 nmol/l

An MRI head is performed, demonstrating diffuse mild microangiopathic changes with prominently dilated lateral and third ventricles. No intracranial masses are noted. You perform a lumbar puncture, with the patient lying in the left lateral position using a 22G spinal needle and obtain cerebrospinal fluid with the first pass. His opening pressure is 16.6 cmH2O.

What is the most appropriate course of action?

A. Remove 30mls cerebrospinal fluid and refer to neurosurgeons
B. Prescribe urgent intravenous pabrinex
C. Urgent urological referral for urodynamic studies +/- flexible cystoscopy
D. Prescribe Sinemet 250 with anti-emetic and re-measure walking time
E. Urgent CT angiography and prescribe aspirin 300mg

A. Remove 30mls cerebrospinal fluid and refer to neurosurgeons

There are two of three features of the classic triad of gait disturbance, urinary incontinence and cognitive impairment, suggestive of normal pressure hydrocephalus (NPH). The normal opening pressure and dilated prominent ventricles lend further support to this diagnosis. Mild microangiopathic disease is not uncommon in this age group and potentially could cause gait disturbances; there is no indication of an acute ischaemic stroke secondary to embolic events however, urgent vascular imaging and aspirin loading would thus be inappropriate. Despite the previous alcohol history, the patient's vitamin B12 and folate are within normal range with no neuroimaging features of degeneration, intravenous Pabrinex is unlikely to resolve these symptoms. Although there may be a primary urological cause for the patient's urological symptoms, his gait features are not easily explained. The patient does not display any 'hard signs' of Parkinsonism to warrant a Sinemet trial.

The definitive treatment for normal pressure hydrocephalus is neurosurgical implantation of a ventricular shunt, most commonly into the peritoneum. Of the three main features of NPH, gait apraxia is the most commonly improved feature with shunting, while dementia and cognitive impairment rarely improve after surgery. Despite the normal pressure, removal of a relatively significant amount of CSF and repeat of the patients walking time is a useful clinical predictor of whether the patient will improve after surgery.

Question 60 of 409

A 35-year-old woman is referred to a headache clinic with frequent migraines over the last 9 months. They occur unpredictably, around 3 times a month. Her past medical history includes eczema, brittle asthma and depression. She is not sexually active.

She is keen on something to reduce the frequency of her migraines. In the past, she has tried topiramate but stopped as she felt it caused her to get eye discomfort.

What is the most appropriate management option?

A. Candesartan
B. Pizotifen
C. Propranolol
D. Re-trial topiramate
E. Zolmitriptan

A. Candesartan

Candesartan may be considered for migraine prophylaxis if other first-line options either don't work or are contradicted

Either topiramate or propranolol is usually used first-line for prophylaxis of migraine. When standard treatments are not appropriate then other treatment options may be considered by specialists, but these are outside the remit of NICE guidelines. Candesartan is recommended by the British Association for the Study of Headache guidelines.

Pizotifen is no longer recommended as adverse effects such as weight gain and drowsiness are common.

In this case, topiramate has caused side effects on previous use. Eye discomfort is a recognised uncommon side effect and can rarely cause eye inflammation. Hence, this should be avoided.

Propranolol is best avoided given the risk of bronchospasm, listed as an uncommon side effect in the BNF. This is because this patient is asthmatic and particularly given that it is brittle asthma.Zolmitriptan can be used as a type of 'mini-prophylaxis' for women with predictable menstrual migraine. However, this patient suffers from unpredictable migraines so this is not likely to be effective.

Question 61 of 409

A 38-year-old man with severe ulcerative colitis presents to his GP with a red right eye that has developed over the last 24 hours. He is finding it uncomfortable to move his eye in any direction but feels his vision is unchanged. On examination his left eye is normal, but his right eye is erythematous, watery, and there is asymmetric miosis. During the examination, he asks you to turn down the lights as he finds them uncomfortable.

Which of the following is the most appropriate treatment for this man's red-eye?

A. Supportive management
B. Topical atropine
C. Topical corticosteroids
D. Topical cyclopentolate and topical corticosteroids
E. Topical pilocarpine

D. Topical cyclopentolate and topical corticosteroids

Anterior uveitis is most likely to be treated with a steroid + cycloplegic (mydriatic) drops

The painful eye movements, lacrimation and irregular small pupil are strongly indicative of anterior uveitis. Uveitis may be idiopathic but is often associated with HLA-B27-related diseases, such as inflammatory bowel disease (IBD). Uveitis occurs in 0.5%-3% of patients with IBD and is often bilateral, but not in this case. In terms of extraintestinal manifestations of IBD, uveitis is less common than episcleritis. However, episcleritis is not typically painful and does not present with photophobia. If episcleritis were the diagnosis, then supportive management would be appropriate.

Anterior uveitis describes inflammation of the anterior portion of the uvea - the iris and ciliary body. Uveitis does not affect visual acuity unless it involves the posterior segment - the posterior vitreous, retina, choroid, retinal vasculature and optic nerve. Uveitis can lead to blindness and should be referred to an experienced ophthalmologist. Treatment is with topical corticosteroids and cycloplegic (mydriatic) drops. Topical corticosteroids are appropriate in anterior uveitis but note that intermediate and posterior uveitis usually require locally injected or systemic corticosteroids.Cyclopentolate is a muscarinic antagonist, and cycloplegic. It relieves the pain associated with uveitis as it dilates the pupil and prevents iridospasm. Atropine is another cycloplegic medication that can be used in anterior uveitis. Used alone it is less appropriate than the combination of cyclopentolate drops and steroids, which is the single best answer here.

Topical pilocarpine is a muscarinic receptor agonist and would cause miosis, worsening the situation here. It may be used in acute-angle glaucoma, another cause of acute red eye which would instead present with increased pain in the dark.

Question 62 of 409

A 70-year-old male presents with a 3-month history of left foot drop. He complains of having to lift his thighs higher than normal to accommodate this pathology. On examination, he has a high stepping gait. Power is normal in all movements except left ankle dorsiflexion (2/5) and eversion (2/5). Ankle inversion is intact (5/5), ankle jerks are present and plantars are downgoing. He reports reduced sensation on the dorsum of his foot.

What is the most likely diagnosis?

A. L5 radiculopathy
B. Common peroneal palsy
C. Functional neurology
D. Sciatic nerve compression
E. Lumbar plexopathy

B. Common peroneal palsy

'Foot drop' - ?common peroneal nerve lesion

The differential diagnosis of foot drop is a MRCP favourite. In this case, a number of features favour a common peroneal nerve palsy instead of a L5 radiculopathy: common peroneal nerve palsy patients normally have an intact ankle inversion and flexion of the big toe. Sensory loss is usually around the lateral aspect of the lower leg and the dorsum of the foot while L5 appears as a thin strip down the middle of the anterior lower limb, usually not affect the lateral lower leg. Ankle jerks are present in both, as the tibial nerve is branched from S1 and the sciatic nerve. There is little to suggest the involvement of multiple lumbar levels in this scenario. The most common causes of common peroneal nerve palsy are trauma or compression at the fibula head, classically by tight plaster casts.

Question 63 of 409

A 46-year-old woman presents to her GP with a neck lump. After examination and initial investigations, she is urgently referred to the local endocrine multidisciplinary team, which perform further scans and diagnose cancer of the thyroid.

Ultimately, she undergoes a thyroidectomy. The procedure itself is uneventful.

Post-thyroidectomy, she notices that her voice has become very hoarse, which was not a symptom prior to the surgery.

What is most appropriate next?

A. Acoustic analysis
B. Chest X-ray
C. Laryngeal electromyography
D. Laryngoscopy
E. Reassure and monitor

D. Laryngoscopy

Hoarseness following total thyroidectomy should be investigated with laryngoscope.

Hoarseness following thyroidectomy indicates damage to the recurrent laryngeal nerve. This is a relatively common complication of thyroidectomy surgery. The correct answer is laryngoscopy this should be performed if hoarseness develops, to assess for vocal cord paralysis and evaluate motility.

Acoustic analysis - that is, assessment of the change in voice itself - is insufficient. This may help to give an idea of the extent to which the hoarseness has affected speech, but more objective assessment is required via laryngoscopy.

Chest X-ray is inappropriate. This would not allow for assessment of the vocal cords. Laryngoscopy is required.

Laryngeal electromyography can be used to assess vocal cord paralysis and estimate prognosis.However, first-line, laryngoscopy is generally performed before any further investigation.

Reassurance and monitoring would be inappropriate. Further assessment is required here, given the new onset of hoarseness following thyroidectomy.

Question 64 of 409

A 40-year-old lady with myasthenia gravis is admitted under the medical team with pneumonia. She is also experiencing a flare of her myasthenia symptoms. She is treated with antibiotics, pyridostigmine and methylprednisolone begins to improve clinically. She is also given IV magnesium replacement to correct hypomagnesemia.

The next day her symptoms suddenly worsen and she develops profound weakness on exertion and new dysphagia requiring insertion of a nasogastric (NG) tube.

Which of the following drugs administered by the medical team is the most likely cause?

A. IV magnesium
B. Co-amoxiclav
C. Low molecular weight heparin
D. Cyclizine
E. Naproxen

A. IV magnesium

Don't given IV magnesium in myasthenia as can precipitate a crisis Important for me Less important The following drugs may exacerbate myasthenia:

- Magnesium
- Penicillamine
- Quinidine
- Procainamide
- Beta-blockers
- Lithium
- Phenytoin
- Antibiotics: gentamicin, macrolides, quinolones, tetracyclines

Question 65 of 409

A 56-year-old man presents to the emergency department complaining of weakness and shortness of breath. His symptoms started initially with a tingling sensation and weakness in his feet and hands about 1 week ago. This has got progressively worse and now he is struggling to lift his arms and cannot walk. Over the last 24 hours, he has become short of breath.

He has a past medical history of asthma and anxiety. He felt that he had a mild asthma flare alongside a cold around 3 weeks ago but recovered well without antibiotics or steroids. Usually, his asthma is well-controlled.

An arterial blood gas reveals type 2 respiratory failure with a pH of 7.33. He is commenced on non-invasive ventilation.

What is the most appropriate management?

A. Intravenous botulinum antitoxin
B. Intravenous immunoglobulin
C. Intravenous methylprednisolone
D. Intubation and ventilation
E. Plasma exchange

B. Intravenous immunoglobulin

IVIG is generally used first-line for Guillain-Barre syndrome

The ascending neurological impairment coupled with a recent upper respiratory tract infection is highly suggestive of Guillain-Barre syndrome. In this case, this has progressed to the extent of affecting the respiratory muscles. Intravenous immunoglobulin or plasma exchange can be used in treatment. Immunoglobulin is as effective as plasma exchange, is better tolerated, and is easier to administer. Therefore, immunoglobulin is generally used first-line for Guillain-Barre syndrome where patients require immunomodulatory therapy.

Steroids and immunosuppressants have not been shown to be beneficial in Guillain-Barre syndrome. Therefore, intravenous methylprednisolone is incorrect. Immunoglobulin is better tolerated and easier to administer than plasma exchange. Therefore plasma exchange would not be the first-line management choice.

Intravenous botulinum antitoxin is the treatment for botulism. This typically presents with a descending weakness, starting in the cranial nerves. Given this patient has ascending weakness this diagnosis is less likely and so the treatment is not correct.

For patients with severe respiratory failure, intubation and ventilation may be required. Given that this patient is only mildly acidotic it can be inferred that type 2 respiratory failure is not too severe, especially given it is acute so there will not be significant metabolic compensation. Intubation and ventilation carry risks and are not warranted at present. If there was poor response to non-invasive ventilation then this would need to be re-considered.

Question 66 of 409

A 54-year-old man presents to the emergency department with reduced mobility. He describes an absence of feeling in his lower limbs bilaterally that makes him feel very unsteady on his feet. His past medical history includes type 2 diabetes, hypercholesterolaemia and hypertension, for which he takes metformin, sitagliptin, atorvastatin and ramipril.

On examination, he has 5/5 power in his upper limbs. There is increased tone and rigidity in his lower limbs, although he is able to weight bear. His proprioception is intact but there is an absence of pain and temperature sensation.

What is the most likely diagnosis?

A. Anterior spinal artery occlusion
B. Brown-Sequard syndrome
C. Central cord syndrome
D. Primary lateral sclerosis
E. Subacute combined degeneration of the spinal cord

A. Anterior spinal artery occlusion

Bilateral spastic paresis and loss of pain and temperature sensation - anterior spinal artery occlusion

This patient has anterior spinal artery occlusion, affecting the lateral corticospinal and spinothalamic tracts. Symptoms of anterior spinal artery occlusion include bilateral spastic paresis and loss of pain and temperature sensation, as described in this scenario. This patient has significant risk factors for arterial occlusion including diabetes, hypertension and hypercholesterolaemia.

Brown-Sequard syndrome refers to hemisection of the spinal cord, usually secondary to traumatic injury. Symptoms include ipsilateral spastic paresis below the level of the lesion along with ipsilateral loss of proprioception and vibration sensation and contralateral loss of pain and temperature sensation. The absence of these symptoms and history of trauma make BrownSequard syndrome less likely.Central cord syndrome is a very common type of incomplete spinal cord injury, usually secondary to trauma (e.g. following a hyperextension injury in a patient with cervical spondylosis). Rather than a complete loss of movement or sensation, there tends to be a partial pattern of motor and sensory loss with greater motor impairment seen in the upper limbs and variable sensory loss below the level of the injury.

Primary lateral sclerosis, or motor neuron disease, is a neurodegenerative condition affecting the upper and lower motor neurons, causing a combination of upper motor neuron signs (increased tone) and lower motor neuron signs (muscle fasciculations and weakness). The combination of symptoms in primary lateral sclerosis is purely motor, unlike this patient's presentation that also has a sensory deficit, making primary lateral sclerosis unlikely.

Subacute combined degeneration of the spinal cord is commonly related to vitamin B12 deficiency, causing degeneration of the lateral corticospinal tracts and the dorsal columns. Symptoms include bilateral spastic paresis similarly to this patient. However, sensory symptoms in subacute combined degeneration of the spinal cord are secondary to dorsal column loss and include the absence of proprioception and vibration sensation rather than pain and temperature sensation.

Question 67 of 409

A 42 year old caucasian man presents to his GP because of concerns about weight gain. He has put on 10kg in weight in the past 6 months but has been eating and exercising the same amounts for the past few years. The GP decides to do some further investigations and finds the following abnormalities. He tells you that he was on a medication for schizophrenia but this was changed one year ago due to abnormal movements. In the past year he has also been given medications to help with symptoms of nausea and has recently started medication for gynaecomastia.

ECG: sinus rhythm 84/min QTC 462ms

Hb	13.8 g/dl
Platelets	154 * 10 /l
WBC	3.8 * 10 /l
Neuts	1.5 * 10 /l
Lymphs	1.0 * 10 /l
Eosinos	1.2 * 10 /l
Fasting glucose	11.9 mmol/l
Prolactin	264 mu/l

Which drug is most likely to have caused these abnormalities?

A. Haloperidol
B. Clozapine
C. Bromocriptine
D. Domperidone
E. Ondansetron

B. Clozapine

One of the most common side effects of clozapine is constipation/intestinal obstruction

Clozapine is an atypical antipsychotic that is used in treatment resistant schizophrenia and also if there has been tardive dyskinesia on a previous antipsychotic which is described in this question. Clozapine can cause neutropaenia, eosinophilia and prolongation of the QTc as well as increased weight gain and reduced insulin tolerance which are all seen in this individual

Haloperidol can also cause QTc prolongation. It is less likely to cause weight gain and reduced glucose tolerance than clozapine and it is not associated with neutropaenia or eosinophilia. Haloperidol more commonly causes tardive dyskinesia than Clozapine and it is possible that he was on this before switching due to hyperprolactinaemia and tardive dyskinesia

Bromocriptine is a treatment designed to reduce prolactin levels and does not cause reduced glucose tolerance or neutropaenia.

Domperidone can cause prolonged QTc but would not explain any of the other abnormalities.

Ondansetron can cause prolongation of the QTc but does not cause any of the other abnormalities described here

Question 68 of 409

A 68-year-old man presents with back pain. He was recently diagnosed with peripheral neuropathy however no cause was identified. He has no other past medical history and takes no regular medicines. On examination he has tenderness of his lumbar spine. You also note hepatosplenomegaly and hyperpigmentation of his skin.

Blood results are as follows:

Hb	105 g/l	Na	136 mmol/l
Platelets	110 * 10 /l	K	5.1 mmol/l
WBC	10.2 * 10 /l	Urea	14.6 mmol/l
Neuts	8.1 * 10 /l	Creatinine	162 µmol/l
Lymphs	1.1 * 10 /l	CRP	24 mg/l
Eosin	0.2 * 10 /l	Calcium (corrected)	2.85 mmol/l

Serum electrophoresis and immunofixation was also performed:

Monoclonal band	45 g/l
Immunofixation	IgG light chain spike

A whole body MRI scan is performed:

Whole body MRI	Osteoblastic lesion present in L4 vertebrae

What is the most likely diagnosis?

A. Osteosarcoma
B. Plasmacytoma
C. POEMS syndrome
D. Waldenstrom macroglobulinemia
E. Monoclonal gammopathy of unexplained significance

C. POEMS syndrome

POEMS syndrome is a rare paraneoplastic syndrome caused by a clone of abnormal plasma cells. It is associated with polyneuropathy, organomegaly, endocrinopathy, M-protein band from a plasmocytoma, and skin pigmentation

The patient has anaemia, renal impairment, and hypercalcaemia. This triad of features should raise suspicion of multiple myeloma, especially in elderly patients who present with back pain. The monoclonal band of plasma cells confirms a plasma cell dyscrasia. The differential for plasma cell dyscrasias include myeloma, monoclonal gammopathy of unexplained significance, plasmacytoma, POEMS syndrome and Waldenstrom macroglobulinemia.

The features of organomegaly, hyperpigmentation of the skin, and a single osteoblastic lesion in the spine should raise concern of POEMS syndrome. POEMS syndrome is a rare paraneoplastic syndrome caused by a clone of abnormal plasma cells. It is associated with polyneuropathy, organomegaly, endocrinopathy, M-protein band from a plasmacytoma, and skin pigmentation. It is therefore the most likely diagnosis in this patient.

Waldenstrom macroglobulinemia is a type of non-Hodgkin lymphoma (NHL) associated with very high levels immunoglobulin M (IgM). IgM is a very large molecule and when present in excess can result in hyperviscosity syndrome. This can also result in organomegaly, peripheral neuropathy and a variety of other features. In this case, the presence of an IgG monoclonal band suggest an alternative diagnosis.

The presence of end-organ damage rules out the diagnosis of monoclonal gammopathy of unexplained significance.

Question 69 of 409

A 62-year-old man presents with an episode of collapse. He states that the episode of the collapse was preceded by the worst headache of his life. He denies any recent head injuries. On examination, you note nuchal rigidity and photophobia. Observations are within normal limits.

A CT brain is arranged: CT brain (non-contrast) Hyperdense material filling the subarachnoid space

What is urgently required?

A. CT angiogram
B. Digital subtraction angiogram
C. Endovascular coiling and neurosurgical clipping
D. Lumbar puncture
E. MRI angiogram

A. CT angiogram

In non-traumatic subarachnoid haemorrhages, a CT angiogram should be performed to identify intracranial aneurysms

CT angiogram is correct. A non-contrast CT has confirmed a SAH. The patient does not have a history of trauma and as such an aneurysmal bleed is at the top of the differential diagnosis. Therefore an urgent CT angiogram is required to identify the causal pathology, define the anatomy of the aneurysm, and plan specific treatment.

Digital subtraction angiogram is incorrect. Digital subtraction catheter angiography remains the gold standard for diagnosis and characterisation of vascular abnormalities, and in many centres, even if the causative lesion is identified on MRA or CTA and it is thought to require surgical management, a catheter study is carried out. However, in the first instance, a CT angiogram is required.

Endovascular coiling and neurosurgical clipping is incorrect. Although this may well be required for definitive management of an aneurysmal bleed, in the first instance the lesion needs to beidentified and characterised by a CT angiogram.

Lumbar puncture is incorrect. A lumbar puncture is only required if the initial CT brain is negative. In this case, the CT demonstrates clear evidence of a SAH.

MRI angiogram is incorrect. Although MRI is helpful to assess underlying brain parenchyma, MRI angiograms (MRA) are not as good as CT angiograms. Unlike CT angiography, MRA is not able to see and capture images of calcium deposits within the blood vessels. MRA evaluation of small vessels, in particular, may be difficult.

Question 70 of 409

An 82-year-old woman is brought to see you by her daughter. They are concerned as she has had a tremor for several years that has been worsening and is feeling slightly more forgetful and slowed down in the past 2 months.

On examination, there is a relatively large amplitude tremor on finger-nose testing which is worse on the left side and improves when moved passively. Gait is normal and there is no lower limb involvement. A 10-point abbreviated mental test score is 10/10.

Given the likely diagnosis, what would be the treatment of choice?

A. Dopamine agonists
B. Primidone
C. Propranolol
D. Quinine sulphate
E. Rivastigmine

C. Propranolol

Propranolol is the treatment of choice for essential tremor

The most likely diagnosis here is essential tremor given the worsening of the tremor on intentional movement and improvement when the muscles are relaxed and moved passively by the examiner. In essential tremors, the upper limbs and head/neck are most commonly affected. If there is lower limb involvement alternative pathology should be suspected.

Propranolol is the correct answer. This is the first-line treatment for essential tremors.

Primidone is incorrect. This would usually form second-line management, or treatment if propranolol was contraindicated.

Dopamine agonists is incorrect. These would form part of the management of Parkinson's disease. In this case, we have a tremor that is worsened by movement rather than a resting tremor, gait is normal, and the lower limbs are not affected. Parkinson's disease is therefore less likely.

Rivastigmine is incorrect. This is a cholinesterase inhibitor used in the treatment of Alzheimer's dementia, dementia associated with Parkinson's disease, and Lewy body dementia. In this case, the patient did notice some deterioration in her cognitive function, but the initial mental screening was normal. It may be reasonable to investigate this further with more in-depth mental testing, blood testing, and consideration of a CT head. An MMSE, for example, helps us grade dementia as being mild, or more severe. According to the ICD-10 classification, a decline in memory should have occurred over at least 6 months before a diagnosis of dementia is determined. Given that the symptoms of cognitive decline have been recent - over the past 2 months - it would be acceptable to take a 'watch and wait' approach after risk assessing the symptom severity.

Quinine sulphate is incorrect. This medication is used to treat malaria but also can be used in the management of leg cramps. Lower limb symptoms are not present here, and in fact, the most recent drug and safety guidance is that it should not be prescribed routinely for leg cramps unless very severe or frequent, where organic causes have been ruled out, and where nonpharmacological measures have been ruled out (e.g. exercises, passive stretching) as there is a risk of severe thrombocytopenia and impact on QT interval.

Question 71 of 409

A 50-year-old woman attends an annual diabetic retinopathy screening appointment. She has a past history of type 1 diabetes mellitus. She reports a gradual decrease in vision in her left eye over the past year.

Examination reveals retinal neovascularisation and formation of fibrous tissue anterior to the retinal disc. The macula appears normal. Her recent HbA1c level is 48 mmol/mol. She is advised that she will need pan-retinal laser photocoagulation (PRP).

In addition to PRP, what is the most appropriate treatment option for this patient?

A. Intravenous aflibercept
B. Intravitreal ranibizumab
C. Optimise glycaemic control
D. Screening for cataract
E. Vitreoretinal surgery

B. Intravitreal ranibizumab

Intravitreal VEGF inhibitors may be used in addition to panretinal laser photocoagulation to treat proliferative diabetic retinopathy

Intravitreal VEGF inhibitors should be used in combination with PRP for the treatment of patients with proliferative diabetic retinopathy. The scenario describes a patient with proliferative diabetic retinopathy (neovascularisation and fibrous tissue on the retina) for which she is already advised PRP. In addition to PRP, intravitreal ranibizumab slows the progression of diabetic retinopathy and improves visual acuity. The best effective treatment of proliferative diabetic retinopathy is PRP plus intravitreal VEGF inhibitors.

Intravitreal, not intravenous, aflibercept is used in treating proliferative diabetic retinopathy. Aflibercept is an anti-vascular endothelial growth factor (anti-VEGF) and its intravenous preparation has a role in chemotherapies.

The most important step in managing diabetic retinopathy is to optimise glycaemic control. However, the patient in this scenario has current HbA1c within the limits which implies goodcontrol already.

Screening for cataracts is an incorrect response because, although important, in a diabetic patient, cataract screening is irrelevant in this scenario.

The fundoscopy in this scenario does not show any vitreous haemorrhage - therefore, vitreoretinal surgery like vitrectomy is not a suitable treatment option here. Vitrectomy is for severe proliferative diabetic retinopathy with vitreous haemorrhage.

Question 72 of 409

A 40-year-old man presents to the clinic with a three-day history of left-sided headache. He reports tearing in his left eye and pain on eye movement. Examination reveals periorbital swelling and reduced sensation in the distribution of the ophthalmic nerve on the left side. His past medical history is unremarkable, except for a recent visit to an ENT clinic for sinusitis. An MRI of the brain is pending.

What is the most appropriate treatment option for this patient?

A. Heparin, Indomethacin, and prednisolone
B. Heparin, indomethacin, and metronidazole
C. Heparin, prednisolone, and metronidazole
D. Heparin, vancomycin, ceftriaxone, and metronidazole
E. Prednisolone, ceftriaxone, and vancomycin

D. Heparin, vancomycin, ceftriaxone, and metronidazole

Unilateral headache, periorbital inflammation, ophthalmoplegia → ? cavernous sinus thrombosis

The correct response is heparin, vancomycin, ceftriaxone, and metronidazole because the clinical presentation suggests a diagnosis of cavernous sinus thrombosis (CST) in this patient. Features such as unilateral headache, painful ophthalmoplegia, and periorbital swelling are indicative of CST. Additionally, the involvement of the ophthalmic division of the trigeminal nerve corroborates this diagnosis. The patient's history of sinusitis is relevant due to its association with septic CST, which necessitates treatment with intravenous antibiotics and anticoagulation. The appropriate antibiotic regimen includes vancomycin to target methicillin-resistant Staphylococcus aureus (MRSA), supplemented by ceftriaxone or cefepime. Metronidazole should be added when a sinus or dental infection is suspected, as indicated in this scenario. Antibiotic therapy should be continued for at least 3 weeks due to limited penetration into the thrombus. Early initiation of anticoagulation with a continuous infusion of heparin has been shown to improve outcomes in patients with septic CST.

Heparin, indometacin, and metronidazole constitutes an incorrect answer because it omits ceftriaxone, which is the first-line antibiotic for managing septic CST. Additionally, vancomycin isessential for MRSA coverage. Indomethacin is not indicated in treating CST; it is utilised for paroxysmal hemicranias characterised by unilateral headache, ptosis, and ophthalmoplegia but lacks efficacy in CST management.

The choice of heparin, indomethacin, and prednisolone is also incorrect. Prednisolone does not have a therapeutic role in CST; instead, steroids are primarily used in managing Tolosa-Hunt syndrome—an important differential diagnosis for CST—which involves idiopathic granulomatous inflammation of the cavernous sinus. In contrast to Tolosa-Hunt syndrome which has no preceding infection history typically seen with CST such as sinusitis described here antibiotics combined with heparin remain the cornerstone treatments for septic CST.

Selecting heparin, prednisolone, and metronidazole fails to provide an adequate treatment strategy because it lacks an appropriate first-line antibiotic therapy combination necessary for managing CST effectively; moreover vancomycin must be included for MRSA coverage Steroids do not play a part in treating CST

Lastly prednisolone ceftriaxone and vancomycin represents an inaccurate response due to the absence of heparin which is integral to the recommended treatment protocol

Question 73 of 409

A 47-year-old man is brought in by ambulance to the emergency department. He was found agitated and wandering the street by a member of the public. Collateral history from his relative reveals that he has a past medical history of hepatic steatosis, hypertension and asthma. His regular medications include amlodipine and Symbicort. He drinks up to 1 litre of vodka daily and has smoked 20 cigarettes per day for 30 years. There is no history of recreational drug use. He has not been seen by his family for 2-3 days before these events.

His observations are heart rate 111 beats per minute, blood pressure 170/94 mmHg, respiratory rate 23 /min, oxygen saturations 97% on air and temperature 37.2ºC. He is tremulous, diaphoretic and agitated. Cardiovascular, respiratory and abdominal examinations are otherwise unremarkable.

Shortly after he is examined, he has a seizure lasting 30 seconds that is self-terminating.

Blood tests

Hb	164 g/L	Male: (135-180) Female: (115 - 160)
Platelets	189 * 10 /L	(150 - 400)
WBC	6.0 * 10 /L	(4.0 - 11.0)
Na	129 mmol/L	(135 - 145)
K	4 mmol/L	(3.5 - 5.0)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	77 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
Glucose	4.1 mmol/L	(4 - 11)

A CT head is organized, which is reported as being normal.

What is the most appropriate medication choice to prevent further seizures?

A. Oral chlordiazepoxide
B. Intravenous glucose
C. Intravenous hypertonic saline
D. Intravenous levetiracetam
E. Intravenous pabrinex

A. Oral chlordiazepoxide

Chlordiazepoxide, lorazepam or diazepam are used in the treatment of delirium tremens/alcohol withdrawal

Chlordiazepoxide is the correct answer. Minor alcohol withdrawal symptoms such as tremor, anxiety and headache start approximately 6-12 hours after alcohol is stopped. This can progress to alcoholic hallucinosis after 12-24 hours and subsequently withdrawal seizures and delirium tremens from 48 hours onwards. The combination of tachypnoea, tachycardia, agitation and seizures suggest delirium tremens and alcohol withdrawal seizures as the diagnosis. The first-line treatment for delirium tremens and to prevent further seizures is chlordiazepoxide. The Clinical Institute Withdrawal Assessment for Alcohol (CIWA) score is used for the management of alcohol withdrawal in hospital. It is a ten item scoring system where higher total scores correspond to a greater severity of alcohol withdrawal. Depending on the score, specific management decisions are suggested, such as the administration of benzodiazepines.

Intravenous glucose is incorrect. The patient's glucose is within the normal range, albeit at the lower end, making this an unlikely cause of seizures.

Intravenous hypertonic saline is incorrect. While his sodium is mildly low at 129, this value is not typically low enough to cause seizures.

Intravenous levetiracetam is incorrect. While this is an effective anti-seizure medication, it is not the most appropriate choice given the underlying diagnosis.

Intravenous pabrinex is incorrect. This will not prevent or terminate seizures but is used to prevent the development of Wernicke's encephalopathy.

Question 74 of 409

A 31-year-old patient is referred to the neurology outpatient department with recurrent migraines. These occur 4-5 times a month. She has a past medical history of asthma. She has previously trilled amitriptyline, riboflavin, and acupuncture but unfortunately, these have been ineffective.

At the time of review, the examination is unremarkable.

What is the best option for preventing the recurrence of her headaches?

A. Candesartan
B. Ibuprofen
C. Medical cannabis
D. Propranolol
E. Sumatriptan

A. Candesartan

Candesartan may be considered for migraine prophylaxis if other first-line options either don't work or are contradicted

Candesartan is correct. This patient presents with recurrent migraines and requires prophylactic treatment in an effort to decrease their frequency. Candesartan is an option for this indication if other options are unsuitable, ineffective, or not tolerated.

Ibuprofen is incorrect. This is a treatment for acute migraine rather than prevention. Furthermore, her history of asthma makes this option unsuitable.

Medical cannabis is incorrect. There is emerging evidence that cannabidiol (CBD) oil may relieve the symptoms of migraine. However, it is not currently approved for migraine prophylaxis in the UK and so this is incorrect.

Propranolol is incorrect. This is a good option for the prevention of migraine but it is contraindicated in patients with asthma.

Sumatriptan is incorrect. This is a treatment for the acute relief of migraine. It is not indicated in the prophylaxis of migraine.

Question 75 of 409

A 20-year-old man presents to the neurology clinic following his second seizure. His partner describes episodes during which the patient is unresponsive and appears to be 'staring into space'. The patient has no recollection of these events but does recall that after his reported absences, he often feels nauseous and disorientated for several hours.

Blood tests to identify electrolyte abnormalities are all within normal limits. An MRI head is reportedly within normal limits. An EEG (electroencephalogram) shows interictal epileptiform discharges.

Given the likely diagnosis, which of the following drug therapies would be the most appropriate first-line agent?

A. Sodium valproate
B. Levetiracetam
C. Carbamazepine
D. Phenytoin
E. Lamotrigine

A. Sodium valproate

Absence seizures: sodium valproate and ethosuximide are first-line

This patient has a history and EEG consistent with a diagnosis of absence seizures. Sodium valproate or ethosuximide are considered first-line in the treatment of absence seizures.

Question 76 of 409

A 55-year-old woman attends neurology clinic for follow-up. At her first appointment 6 months previously, a clinical diagnosis of trigeminal neuralgia had been made and treatment with carbamazepine initiated. During clinic review the patient complained of ongoing symptoms with only limited benefit from drug treatment.

On her previous assessment, the patient had reported pain episodes associated with the cheek and jaw of the right side of her face. Subsequently, in addition to similar ongoing episodes, the patient had suffered from two episodes of pain affecting the forehead and peri-orbital region on the left side of her face. On one occasion, she had suffered from both right and left sided pain at the same time. She reported that the carbamazepine treatment had initially reduced the intensity of the pain episodes by perhaps 50 %, but that the severity of recent attacks had again worsened to their original level. When her drug history was checked, it was apparent that the carbamazepine dose had been titrated up appropriately by the patients GP.

The patient also stated that following her previous clinic appointment she had been discussing the situation with her sister, who had reminded the patient that their mother had suffered several episodes of visual loss during her life but had not undergone any medical investigation.

Cranial nerve examination demonstrated normal eye movements and pupillary responses. There was no evidence of facial nerve weakness, however a subjective numbness of sensation was noted in the left cheek region (this had not been noted on previous examination in clinic). There were no lesions around the head and neck or inside the mouth. Peripheral neurological examination was remarkable for borderline dysdiadochokinesia in the right upper limb and a positive Babinski response in the right lower limb.

What is the most appropriate investigation for this patient?

A. Visual evoked potentials
B. Three-plane fine-slice MRI brain with contrast
C. CSF oligoclonal bands
D. CT brain with contrast
E. Standard protocol MRI brain with contrast

E. Standard protocol MRI brain with contrast

The patients previous clinical diagnosis of trigeminal neuralgia clearly needs to be reviewed in light of several red-flag features. In particular, the limited response to carbamazepine, the occurrence of simultaneous bilateral pain and the history of pain associated with the ophthalmic division are inconsistent with a typical presentation of trigeminal neuralgia. Moreover, the patient has developed some soft neurological signs that are suggestive of CNS lesions in various areas of the brain.

Multiple sclerosis is the most likely alternative diagnosis, although other causes of trigeminal pain such as space occupying lesions, malignant invasion of the trigeminal nerve or thalamic infarction are also possibilities. The best investigation to assess for all these differentials is standard protocol MRI brain with contrast. Demyelination or trigeminal nerve infiltration would not be reliably noted on CT brain with contrast making this less likely to progress the diagnosis.

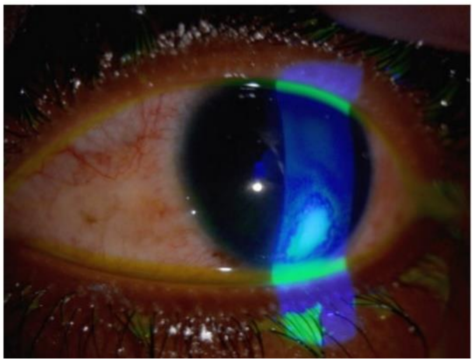
Visual evoked potentials and CSF oligoclonal bands are other investigations that may support a diagnosis of multiple sclerosis but would not confirm or refute this diagnosis in isolation.

Typical cases of trigeminal neuralgia are considered to result from contact between blood vessels and the trigeminal nerve. Such vascular contacts can be observed on specialised MRI protocols requiring fine-slicing in three-planes. However, given the additional expense and the fact that such contacts can be a normal variant, this investigation is not normally performed. A standard protocol MRI brain is sufficient to assess for the important differentials of trigeminal neuralgia discussed above.

Question 77 of 409

A 23-year-old man presents to the eye casualty department with 3 days of pain in the right eye, accompanied by photophobia and watering. He has also noticed frequent bouts of yellow discharge. The patient has no significant past medical history but is a contact lens wearer. He admits to having fallen asleep and leaving his contact lenses in, several nights ago.

The eye is urgently examined using a slit lamp and appears as shown below:



Given the likely diagnosis, what is the most appropriate management?

A. Intramuscular ceftriaxone
B. Oral moxifloxacin
C. Topical dexamethasone
D. Topical ganciclovir
E. Topical gentamicin

E. Topical gentamicin

This patient's presentation, coupled with his history of contact lens overuse, is suggestive of keratitis. This is confirmed by the examination - fluorescein staining has been used and, under slit lamp investigation, a corneal ulcer is clearly demonstrated on the right eye. Treatment depends on the underlying cause. With the history of discharge, a bacterial cause can be presumed and so treatment involves the use of antibiotics - topical gentamicin is an appropriate choice and is often combined with another antibiotic such as topical vancomycin.

Intramuscular ceftriaxone is generally not recommended except for suspected gonococcal eye infection. In the absence of any systemic symptoms being mentioned here, this is unlikely.

Oral moxifloxacin is a suitable choice when oral antibiotics are indicated for keratitis. This is not usually necessary except for in cases of corneal perforation, which is not seen here.

Topical dexamethasone is used in a variety of eye diseases to reduce inflammation. However, it is not usually used in bacterial keratitis or corneal ulcers, as the evidence demonstrates no significant benefit.

Topical ganciclovir is used in the management of dendritic or herpetic keratitis, which is viral in nature. This is differentiated upon careful slit lamp examination - fluorescein staining instead would show a distinct branching pattern.

Question 78 of 409

A 27 year-old woman attends the neurology clinic complaining of headache and visual disturbance. She has recently immigrated from Ghana. Her symptoms began approximately one month ago, shortly after the birth of her first child. She experiences dull frontal headache which is worst in the mornings and on coughing or straining, as well as transient episodes of 'darkening' of her vision. She saw a doctor in Ghana and was diagnosed with idiopathic intracranial hypertension. She is taking acetazolamide 250mg BD and no other medication.

On examination the visual fields are markedly constricted and the right blind spot is enlarged. Fundoscopy shows bilateral papilloedema worse on the right. The remainder of the neurological examination is unremarkable. BMI is 18 kg/m².

Plain computed tomography of the brain is normal.

Incidentally as she is leaving the clinic she mentions that she has also been experiencing pins and needles in the hands and feet.

What is the best course of action?

A. Increase dose of acetazolamide
B. Request nerve conduction studies
C. Organise for therapeutic lumbar puncture
D. Refer to neurosurgeons for consideration of ventriculo-peritoneal shunting
E. Request CT venography

E. Request CT venography

The history of headache suggestive of raised intracranial pressure associated with transient visual obscurations, as well as the examination findings, are all compatible with idiopathic intracranial hypertension (IIH). However, the onset of symptoms in the puerperium, in a slim patient with no other risk factors for IIH, raises the suspicion that this may actually be a cerebral venous sinus thrombosis. All patients with IIH should have imaging of the venous system with CT or MR to exclude a thrombus which can be more appropriately treated with anticoagulation.

Therapeutic lumbar puncture can ease the headache of IIH but is a short-term measure.

Ventriculo-peritoneal shunting can be used where medical management has failed.

There is no role for nerve conduction studies in this patient. Paraesthesia are a common side effect of acetazolamide, and this patient is unlikely to tolerate an increase in the dose.

Question 79 of 409

A 56-year-old consultant surgeon has recently been diagnosed with idiopathic Parkinson's disease, and attends clinic for review.

You read the previous clinic letter and see that he presented with tremor affecting mainly the right hand, which forced him to stop operating. On examination he also had some bradykinesia and rigidity of the right hand. He was started on co-beneldopa 100/25, initially one tablet three times daily, with instructions to up-titrate as tolerated.

When you see him today, he is concerned that there has been no improvement in the tremor. This is causing him considerable distress as he hopes to return to clinical work. His motor control is otherwise good, and throughout the day and night he has no difficulty with 'off' periods or freezing. He currently takes co-beneldopa 100/25, two tablets three times daily, and reports no complications.

On examination there is a resting tremor of the right hand. There is no discernable rigidity or bradykinesia.

What is the best treatment option?

A. Increase dose of co-beneldopa
B. Increase frequency of co-beneldopa
C. Add procyclidine
D. Add entacapone
E. Add selegiline

C. Add procyclidine

Tremor-predominant Parkinson's disease can be highly disabling and tremor may persist despite standard treatment with dopaminergic agents, which primarily improve bradykinesia. First-line treatment is such cases is the addition of an anticholinergic drug such as procyclidine, orphenadrine, or trihexyphenidyl.

The main side-effect which limits the use of anticholinergics in older patients is cognitive dysfunction, and dementia is a relative contra-indication. Other side effects include blurred vision, urinary retention, nausea, constipation, and dry mouth.

Second-line treatments for persistent tremor include amantidine, clozapine, and propranolol. Deep brain stimulation may be used in refractory cases.Increasing the dose of L-dopa is required when 'off' symptoms (bradykinesia, rigidity, freezing) do not respond to the starting dose, however this patient is taking a reasonable dose of L-dopa (600mg) and is not troubled by 'off' symptoms.

Increasing the frequency of L-dopa, which has a short half-life, is required when patients become 'off' in between doses. As the disease progresses the on period after each dose becomes shorter.

Entacapone and selegiline are used as adjuncts to prolong the 'on' period after a dose of L-dopa

Question 80 of 409

You see a 46 year-old man who has been referred by his GP to the neurology clinic.

He gives a one year history of facial pain. The pain particularly comes on when he is shaving or brushing his teeth, and he describes it as 'stabbing' through the teeth of his upper jaw and over the left side of his face. He has seen a succession of dentists and had several teeth removed, with no relief. The pain has been getting progressively worse, and whereas before it occurred in discrete attacks, it now occurs almost all the time. He has read several online sources and has become convinced that he has a brain tumour, which has led to him becoming depressed and withdrawn.

His past medical history includes essential hypertension, for which he takes perindopril. He also suffers from sinusitis, and has had a sinus washout on more than one occasion. Two years ago whilst on a business trip abroad he had a problem with the vision in his right eye, which spontaneously resolved over a few weeks, and for which he sought no treatment.

General examination is unremarkable. Cranial nerve examination is largely normal but you notice that there is a patch of numbness over the left cheek. Power is 5/5 across all muscle groups in the limbs, reflexes are normal, and plantars are downgoing. Sensation is the limbs is normal.

What is the most appropriate course of action?

A. Reassure him he has trigeminal neuralgia, for which unfortunately there is no treatment
B. Reassure him he has trigeminal neuralgia, and start carbamazepine 300mg daily
C. Refer to the neurosurgeons for microvascular decompression
D. Perform MR head with gadolinium contrast
E. Perform CT head with contrast

D. Perform MR head with gadolinium contrast

This man needs investigation before any further management is considered. He has pain which is typical for trigeminal neuralgia. However, objective sensory loss does not occur in idiopathic trigeminal neuralgia and is highly suggestive of an underlying cause. This may occur due to compression of the trigeminal nerve by a space-occupying lesion such a tumour, or by a demyelinating plaque of multiple sclerosis affecting the trigeminal root at the pons. The episode of transient unilateral visual disturbance that this man suffered two years ago raises the possibility of optic neuritis, and thus the history is suspicious for MS. Malignancy is also a distinct possibility. Gadolinium-enhanced MR of the head is the best investigation to detect both.

Carbamazepine is an effective treatment for trigeminal neuralgia and produces at least some response in 70% of patients. Neurosurgical options such as microvascular decompression are considered only once medical options have been exhausted.

Question 81 of 409

A 68-year-old man who has a history of Type 2 diabetes for the past 12 years comes to the clinic for review. His diabetes is currently managed with BD mixed insulin and over the past year he has suffered increasing pins and needles and pain in both feet. Apart from Type 2 diabetes, a previous myocardial infarction and intermittent urinary retention over the past year are noted. His GP has diagnosed him with benign prostatic hypertrophy. Examination reveals a blood pressure of 148/82 mmHg, his pulse is 80 beats per minute and regular. There is peripheral neuropathy affecting both feet, which are numb to just below the ankle. Routine bloods including renal function are unremarkable.

Which of the following is the most appropriate intervention?

A. Amitriptyline
B. Carbamazepine
C. Duloxetine
D. Pregabalin
E. Tramadol

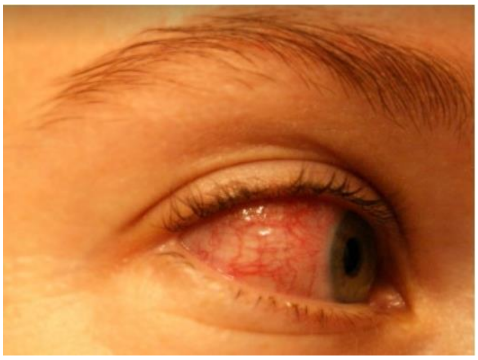
D. Pregabalin

The correct answer is pregabalin. Pregabalin is a GABA analogue and is recommended as an option by NICE for the treatment of neuropathic pain. it has the advantage versus gabapentin of less frequent daily dosing which drives improved compliance. It is also not associated with urinary retention which drives its selection versus other options listed.

Both amitriptyline and duloxetine are alternative first-line options for the treatment of diabetic neuropathic pain, although they are avoided here because both can be associated with urinary retention. Carbamazepine is not recommended for first-line treatment of diabetic neuropathy, and nor is tramadol because it is only partially effective and has addictive potential.

Question 82 of 409

A 42-year-old woman with rheumatoid arthritis presents to the clinic with complaints of pain and redness in the right eye. Her symptoms of rheumatoid arthritis are well-controlled and she is currently taking methotrexate and hydroxychloroquine. On examination, her right eye is watery and red. An image of her right eye is attached.



What is the most appropriate next step?

- A. Reassurance only
- B. Same-day assessment by an ophthalmologist
- C. Stop hydroxychloroquine
- D. Topical chloramphenicol
- E. Topical glucocorticoids

B. Same-day assessment by an ophthalmologist

The patient in this scenario has developed scleritis and therefore requires same-day assessment by an ophthalmologist . Painful red eye in a patient with rheumatoid arthritis and the image shown in this scenario is typical of scleritis. The image shows a thickening of the sclera (pinkishcoloured) with dilated episcleral vessels. Scleritis is a full-thickening inflammation of the sclera and is characterised by pain and redness of the eye with a gradual decrease in vision. Rheumatoid arthritis is the most common disease associated with scleritis. Patients with scleritis should be offered a same-day assessment by an ophthalmologist because vision-threatening complications can occur if scleritis is left untreated.

Episcleritis is the most important differential here that can be managed by reassurance only , in contrast to scleritis. Episcleritis is characterised by a gritty sensation in the eye and redness of the sclera with normal vision. Episcleritis is a painless condition and a history of painful red eye in this scenario rules out episcleritis.

There is no indication to stop Hydroxychloroquine as this drug has no role in causing scleritis. Hydroxychloroquine is known for its ophthalmic toxicities but it rarely causes scleritis. Ocular sideeffects of hydroxychloroquine include retinopathy, colour blindness, lens opacity, and keratopathy.

Topical chloramphenicol has no role in treating scleritis. Chloramphenicol ointment is the firstline agent to treat conjunctivitis which can be considered here given the acute onset of red eye. There is no history of itching or discharge in this scenario which makes conjunctivitis a less-likely diagnosis.

Oral glucocorticoids, and not topical glucocorticoids are used in treating scleritis. Oral glucocorticoids are reserved for only severe presentations of scleritis. Other immunosuppressive drugs are used to treat resistant cases of scleritis.

Question 83 of 409

A 52-year-old man is admitted to the stroke unit with a right total anterior circulation syndrome (TACS) infarct. He arrived at hospital 2.5 hours after the onset of his symptoms and was treated with intravenous alteplase at 3 hours post-onset.

He is known have an atrial septal defect which was discovered after a murmur was heard at a routine insurance medical several years ago. He works in the oil business and has recently returned from a business trip to Saudi Arabia.

On examination the following day there subtle signs of improvement with increased movement in his left hand. However, the rest of his arm remains flaccid and he has persisting dense hemiplegia affecting his right leg. He has a notable homonymous hemianopia on examination. A routine CT Brain 24-hours post-thrombolysis revealed established ischaemic changes in the MCA territory with new petechial haemorrhage along the border of the infarct.

Later that evening, his conscious level falls. His Glasgow Coma Scale changes from E4 M6 V2, to E2, M4 V2. His blood pressure is 187/112 mmHg.

Urgent bloods reveal: Haemoglobin is 120 g/l, Prothrombin time is 27 seconds, Activated partial thromboplastin time (APTT) 49 seconds

What intervention is likely to have the most benefit?

- A. Correction of coagulopathy
- B. Decompressive craniotomy
- C. Control of blood pressure
- D. Protamine sulphate
- E. Tranexamic acid

B. Decompressive craniotomy

This patient is at high risk of malignant middle cerebral artery (MCA) syndrome. Malignant MCA syndrome typically occurs in younger patients who have suffered an extensive ischaemic stroke (usually in the MCA territory). After infarction the brain swells. As younger brains are likely to have less atrophy, there is less room for expansion. Subsequently, intracranial hypertension develops.This typically presents 48 hours after onset of stroke with reduced conscious level.

Thrombolysis should reduce the risk of infarction and subsequent brain oedema, however, recanalisation is not achieved in every patient and thus thrombolysed patients can still develop malignant MCA syndrome. Furthermore, this patient was thrombolysed 3 hours after onset and so is likely to have established tissue infarction regardless. Treatment with urgent decompressive craniotomy can be life-saving. The procedure is particularly indicated in situations like this, where the patient has a non-dominant stroke and is, therefore, likely to recover language functions and have a more favourable outcome if they survive the acute event.

Acute haemorrhagic transformation is the main differential in this case. While the change in his conscious level should prompt repeat imaging (which would discriminate bleeding from oedema) the risk of large haemorrhagic transformation >24 hours post-thrombolysis is lower than the risk of malignant MCA syndrome. This is especially true when the previous scan has shown only grade I

Haemorrhagic infarction (HI-1) as classified using the ECAS II grading system. Urgent discussion with neurosurgery is recommended.

Question 84 of 409

An 86-year-old man is brought in by ambulance following suspicion of a stroke. His wife noticed sudden right-sided weakness. He describes sudden onset of weakness with no preceding symptoms. He has a past medical history of hypertension, diabetes and glaucoma. On examination, he has right sided pyramidal weakness of the arm and leg with associated sensory loss as well as reduced tone. His left side is normal. Cranial nerve examination shows homonymous hemianopia but is otherwise normal.

What is the most likely diagnosis?

A. Total anterior circulation stroke
B. Partial anterior circulation stroke
C. Lacunar stroke
D. Posterior circulation stroke
E. Brainstem stroke

B. Partial anterior circulation stroke

The correct answer is partial anterior circulation stroke. He has had sudden onset of unilateral weakness and sensory loss with homonymous hemianopia but no other evidence of higher cognitive dysfunction. The most likely diagnosis, as per the Oxford classification, is partial anterior circulation stroke. If he would have had evidence of higher further higher cognitive dysfunction, such as dysphasia, then a total anterior circulation stroke would be a better description. A lacunar stroke would cause isolated sensory or motor symptoms, not both. A posterior circulation stroke is more likely to affect cerebellar function whilst a brainstem stroke would affect cranial nerves profoundly.

Question 85 of 409

A 24-year-old female is reporting difficulty in walking in an inpatient rehabilitation unit during recovery from spinal surgery. Six weeks previously, she underwent emergency spinal haematoma evacuation surgery under the neurosurgeons from T2 to T4 after sustaining a fall playing netball. She was previously fit and well, with no past medical history, giving birth to a healthy baby boy 18 months ago.

On examination, the patient has normal tone in her upper and lower limbs. Examination of her power while lying on her bed demonstrates 5/5 on the MRC power scale with normal sensation to cotton wool, pin prick and proprioception. Reflexes were present (2+) in her biceps, triceps, supinator, patella and ankles, both plantars were downgoing. On walking, the patient's gait is markedly abnormal, with both feet sliding along the floor for 80 metres of walking without lifting of her feet between steps. Cognition is intact.

What is the optimal management?

A. Repeat MRI head
B. Repeat MRI whole spine
C. Nerve conduction studies and electromyography
D. Lumbar puncture
E. Education and reassurance

E. Education and reassurance

This patient's gait is inconsistent with any pattern of organic pathology: it is inconsistent to be unable to lift your feet but have normal ankle dorsiflexion and plantarflexion. The patient has a combination of recent significant organic pathology and inorganic pathology, which is frequently the case in functional neurological disorders. Repeat MRI imaging, electrophysiology or lumbar puncture are unlikely to help and only medicalise the disorder. It is crucial to reinforce this message by avoiding unnecessary investigations or treatments. Management of functional neurology is based on education and reassurance, telling the patient that it is a 'conceptualisation' problem and not an issue with the brain or nerves. Psychiatric input may also have a role in this situation if the patient continues to be refractory to first line management: cognitive behavioural therapy may be helpful.

Question 86 of 409

A 36-year-old male presents to your outpatient clinic with a progressive history over the past 5 years of increasing, progressive 'clumsiness'. His work colleagues had a long running joke with him that he is poorly coordinated for about the past five years but in recent weeks, he has noticed that he is unable to write legibly or even hold a key still using either hand to open a door. He denies any recent weight loss of night sweats, is otherwise healthy with no other past medical history. He is a lifelong non-smoker with a minimal alcohol history and lives with his wife and 2 children.

On examination, his cranial nerves were unremarkable except for mild multidirectional nystagmus at primary gaze. Fundoscopy was normal. Limb examination revealed a significant impairment of finger-nose and heel-shin testing. His gait, tone, power, sensation and reflexes were normal with downgoing plantars. A brief mini-mental state examination scored 30/30. An MRI head is awaited. His blood tests are as below:

Hb	158 g/l
Platelets	323 * 10 /l
WBC	6.5 * 10 /l
Na	141 mmol/l
K	4.9 mmol/l
Urea	6.6 mmol/l
Creatinine	85 µmol/l
CRP	2 mg/l
Creatine kinase	223 IU/l (50-335)
TSH	3.3 mu/l
Free T4	17 nmol/l
HIV	negative
Anti-neuronal antibodies	negative

Which investigation is most likely to yield the diagnosis?

A. Neurogenetics testing
B. CT chest, abdomen, pelvis
C. Vitamin B12 and folate levels
D. Lumbar puncture for cerebrospinal fluid including 14-3-3 and S100
E. Anti-GQ1b antibodies

A. Neurogenetics testing

There appears to be a chronic onset syndrome of pure ataxia, without systemic features or cognitive impairment, nor history of alcohol excess. The likely diagnosis is one of spinocerebellar ataxias (SCA), in particular one of the classified 'type III' syndrome such as SCA6, an adult onset cerebellar ataxia diagnosed by neurogenetic testing.

It is important to rule out key differential diagnoses however: patients with acute onset cerebellar syndrome should be considered for Miller-Fisher syndrome, a post-viral variant of Guillain Barre syndrome resulting in a triad of ophthalmoplegia, ataxia and areflexia, commonly after gastrointestinal infections, diagnosed with positive anti GQ1b antibodies. The time course for this illness over 5 years makes Miller-Fisher unlikely.

A subacute course of weeks and small number of months should alert you to possible prion disease such as Creutzfeldt-Jakob disease (CJD) and a paraneoplastic syndrome. The former typically presents with rapid cognitive decline and myoclonus, classically with MRI features (pulvinar sign, cortical ribboning), CSF features (14-3-3, S100, real-time QUIC) and EEG features (periodic spiking). The latter can present years before a solid tumour is identified on structural imaging with positive anti-neuronal antibodies, resulting in progressive symptoms as the cerebellum degenerate over months. Due to the low sensitivity of anti-neuronal antibodies, a negative result does not necessarily rule out paraneoplastic syndrome but such a long time course of 5 years would be unusual. The likelihood of identifying a significant mass on cross sectional CT imaging is low.

Lastly, the lack of a alcohol or gastrointestinal history makes cerebellar degeneration due to vitamin deficiency very unlikely. As a result, neurogenetics testing for SCA is most likely to yield the underlying diagnosis.

Question 87 of 409

A 32-year-old female presents with a 6-month history of progressive lower limb weakness and suprapubic tenderness. On examination, cranial nerves and upper limbs were unremarkable. You note 1/5 power in both lower limbs, hyperreflexic patella and ankle reflexes, bilateral clonus and upgoing plantar reflexes. The abdominal examination also revealed a suprapubic mass. After a urethral catheter was inserted, you note a residual volume of 1.8l. She is known to be HIV positive, diagnosed 8 years ago. Blood tests from an outpatient appointment revealed:

CMV IgG	positive
EBV IgG	positive
HTLV antibody	positive
Hepatitis B	negative
Hepatitis C	negative

An MRI spine is awaited.

What is the most likely diagnosis?

A. Tropical spastic paraparesis
B. Spinal toxoplasmosis
C. CMV transverse myelitis
D. EBV transverse myelitis
E. Tabes dorsalis

A. Tropical spastic paraparesis

This is a HIV and HTLV-1 positive patient presenting with paraparesis and urinary retention, a classic presentation of tropical spastic paraparesis. Toxoplasmosis in HIV patients typically presents in the brain, lungs or as a chorioretinitis. Transient viral inflammatory transverse myelitis by CMV and EBV typically resolves within 3 months, the presence of IgG in both suggest previous exposure and is of limited significance. Tabes dorsalis is a possibility but peripheral reflexes are typically lost with an extensor plantar reflex. Diagnosis of HTLV-1 tropical spastic paraparesis relies on a combination of clinical features and HTLV-1 load in serum and CSF. Treatments are limited, with steroids, presumably as an anti-inflammatory, producing only mild effects in a small population of patients.

Question 88 of 409

A patient with refractory focal epilepsy on two agents is commenced on levetiracetam in addition.

Which adverse effect should patients that have been commenced on this drug most importantly be warned about?

A. Oral hairy leukoplakia
B. Weight gain
C. Irritability and aggression
D. QT-interval prolongation
E. Nystagmus

C. Irritability and aggression

It is important to recognise and know something about levetiracetam as it is increasingly becoming a favourite for neurologists to use these days, not least because of its favourable adverse effects profile (wherein it hardly has any compared to many others), but also its ease of use given that you do not need to monitor levels, and its oral and IV bioavailability are the same (useful in nil by mouth patients). It is also recently more affordable having now lost its patent. The one thing to watch out (and ensure you warn patients about) with levetiracetam is behavioural abnormalities and psychotic symptoms. These range from irritability to frank aggression. If there is a background of psychotic symptoms you may wish to avoid levetiracetam. It is something not to miss in the drug history of an epileptic patient who presents to the acute take with a change in behaviour.

Question 89 of 409

A 48-year-old lady develops a sudden-onset left-sided headache in the face and neck areas 36 hours ago whilst at rest. It is of 10/10 severity and reached this maximum intensity within seconds. It has not subsided since and is throbbing in nature. She also developed a transient period of loss of vision in the left eye lasting 2 hours before resolving. She also says that 'food tastes funny' since these problems developed. On examination, she has small, sluggishly light-responsive left pupil compared to the right and partial left ptosis. The face is otherwise unremarkable to examine as is the remaining neurological examination. Routine blood investigations are unremarkable. Plain computerised tomography (CT) of the head is unremarkable. Lumbar puncture is negative for xanthochromia. CT

angiogram of the head and neck vessels demonstrates a pseudo-lumen of the carotid artery.

Which of the following treatments would you initiate?

A. High flow 100% oxygen
B. Prednisolone
C. Indomethacin
D. Aspirin
E. Acetazolamide

D. Aspirin

She has an internal carotid artery dissection on the left side culminating in a partial left-sided Horner's syndrome. The term 'partial' Horner's is used because anhidrosis is absent. The sympathetic fibres innervating the facial sweat glands are anatomically located on the external rather than the internal carotid artery; thus, anhidrosis is not a finding in the setting of internal carotid dissection.

In terms of management, there is little role for surgery in spontaneous carotid artery dissections. All dissections put people at risk of thromboembolic complications because of turbulent flow at the sight, therefore we normally initiate antiplatelet or anticoagulation therapy. There is little evidence for which is better over the other in this area although pragmatically speaking antiplatelets are safer. Candidates for angioplasty and stent placement include patients with persistent ischaemic symptoms despite adequate anticoagulation, patients with a contraindication to anticoagulant/antiplatelet therapy, and patients with significantly compromised cerebral blood flow.

In this particular case, the loss of vision points towards possible amaurosis fugax, backing up the need for anti-thromboembolic agents.

Question 90 of 409

A 28-year-old gentleman student from Germany presents to you with right foot drop ongoing for two weeks with some numbness and tingling of the foot. These symptoms developed after he knelt down to pick something up from the floor. Three years ago he woke up from sleep with clawing of his fourth and fifth digit after having been asleep in a prone position and this lasted a week. Eight years ago he also had a left wrist and finger drop lasting three weeks after he sat on the couch with his left arm draped over the back of the couch for ten minutes. He denies falling asleep or remaining on the couch for a prolonged period. He has no other past medical history of note and has never sought medical advice for his problems. On examination, there is right foot drop (2/5 power) and similar weakness of dorsiflexion and eversion of the right foot. There is also sensory loss over the lower lateral part of the right leg and dorsum of the right foot in all modalities. Reflexes are intact. Neurological examination and general examination are otherwise unremarkable.

Which of the following tests would confirm the suspected diagnosis?

A. Nerve conduction studies
B. Electromyography
C. Nerve biopsy
D. PMP22 gene testing
E. HBA1C

D. PMP22 gene testing

The diagnosis is Hereditary Neuropathy with Liability to Pressure Palsy (HNPP). This is a neurological syndrome in which trivial trauma to a peripheral nerve e.g. sleeping on a limb, results in a mononeuropathy which may take weeks to resolve. It usually presents in second or third decade of life. The condition is most common in families with Dutch or German ancestry. It is caused by a deletion in the peripheral myelin protein 22 gene on chromosome 17. It is an autosomal dominant condition.

The patient's presenting mononeuropathy is a common peroneal nerve palsy. Three years ago he had an ulnar nerve palsy and eight years ago he had a radial nerve palsy (also called Saturday night palsy).

Nerve conduction studies in HNPP are characteristic of a demyelinating neuropathy: conduction is slow and action potentials are small. Nerve biopsy may show a predominance of smaller fibres and localised thickening of the myelin sheath. These investigations are helpful in supporting the diagnosis although gene testing, if positive, is confirmatory.

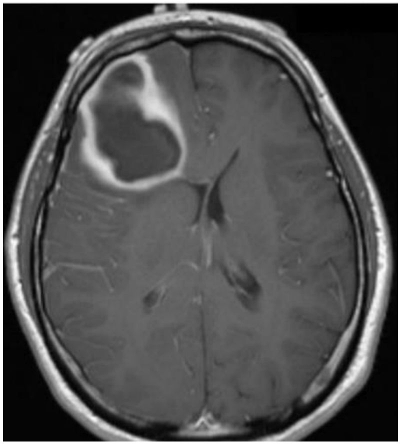
Management is conservative with e.g. wrist splints, ankle-foot orthoses, and protective padding.

Question 91 of 409

A 51-year-old man presents to the emergency department following a witnessed tonic-clonic seizure of 2 minutes duration. There is no history of epilepsy and he has never had a seizure before. Over the last week, he has been complaining of intermittent headaches and fevers. His past medical history includes hypertension for which he takes amlodipine, ramipril, and indapamide once daily.

On examination, he is drowsy with a GCS of 13 (E3V4M6). His chest sounds are clear and his heart sounds are normal. He has a soft and non-tender abdomen. Temperature is recorded as 38.1ºC.

A contrast-enhanced MRI scan is performed, as shown below:



Given the likely diagnosis, which of the following is the most probable causative pathogen?

A. Cytomegalovirus

B. Cryptococcus neoformans
C. Mycobacterium tuberculosis
D. Staphylococcus aureus
E. Toxoplasma gondii

D. Staphylococcus aureus

This patient's MRI brain shows a radiolucent space-occupying lesion with outermost ring enhancement in the frontal lobe. Causes of intracerebral lesions with ring enhancement include toxoplasmosis and intracerebral abscesses. Bacterial intracranial abscesses commonly arise from infections in adjacent structures including otitis media, sinusitis or mastoiditis. Symptoms of intracerebral abscesses depend on the structures involved but commonly include headache, fever, signs of increased intracranial pressure (e.g. papilloedema and seizures) and focal neurological signs. The clinical history of fever, headache and seizures combined with the imaging point toward the diagnosis of an intracerebral brain abscess. The most common pathogens responsible for intracerebral abscesses include Staphylococcus aureus and Streptococcus pneumoniae.

Cytomegalovirus (CMV) is a viral infection that commonly causes illness in patients with HIV, particularly in those with a CD4 count < 50 cells/mL. The most common form of CMV is CMV retinitis. However, CMV encephalitis is also common. On imaging, cerebral oedema may be seen. Meningoencephalitis and ventriculitis are also features of infection with CMV. These are not seen here, making CMV encephalitis unlikely.

Cryptococcus neoformans causes an opportunistic fungal infection (most frequently seen in patients with a history of human immunodeficiency virus) that causes headache, fevers, confusion and signs of raised intracranial pressure. Imaging studies show leptomeningeal enhancement, cryptococcomas, hydrocephalus or dilated perivascular spaces. These features are not seen in the imaging above, and the absence of a history of immunosuppression makes cryptococcal meningitis unlikely.

Mycobacterium tuberculosis can cause tuberculous meningitis with similar symptoms to those of bacterial meningitis (e.g. fever, headache, meningism). Tuberculous meningitis is more common in patients with HIV and can be seen on imaging as leptomeningitis from the presence of thick exudative material in the subarachnoid space.

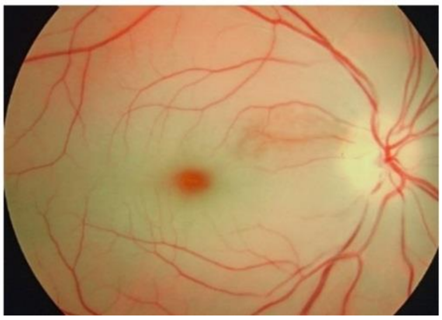
Toxoplasmosis is an opportunistic infection caused by the parasite Toxoplasma gondii. It is the most common cause of neurological brain abscesses in patients with HIV with symptoms including headache, fever and neurological changes including seizures, hemiplegia, cerebellar signs, or an acute confusional state. Toxoplasmosis also presents with ring enhancement on contrast imaging. However, toxoplasmosis often presents with multiple ring-enhancing lesions. Furthermore, the absence of a history of immunosuppression makes an intracerebral abscess more likely.

Question 92 of 409

A 65-year-old man presents to the emergency department with sudden onset blindness in his left eye. He reports only being able to see out of his right eye since waking this morning. There is no history of eye pain or photophobia. His past medical history includes hypertension and hypothyroidism. He takes amlodipine, levothyroxine and regular co-codamol for recurrent headaches over the past 4-6 weeks.

On examination, he is alert and oriented with a GCS of 15/15. There is normal power and sensation in his upper and lower limbs bilaterally with normal tone and coordination. The visual acuity in his right eye is 6/9 and his left eye is only able to make out gross hand movements. The remainder of his cranial nerves are intact.

Fundoscopy of his eye is completed, as shown below:



Laboratory investigations are requested: ESR 55 mm/hr < (age / 2)

What is the recommended management for this patient?

A. Hyperbaric oxygen therapy
B. Intravenous methylprednisolone
C. Intravitreal anti-vascular endothelial growth factor (anti-VEGF)
D. Oral aspirin and referral for intra-arterial thrombolytic therapy
E. Topical corticosteroids

B. Intravenous methylprednisolone

This patient has a fundoscopic image representing central retinal artery occlusion with the classic appearance of a 'cherry red spot' on a pale retina. Central retinal artery occlusion presents as an acute onset painless loss of vision that can either be secondary to thromboembolic or arteriopathy (e.g. temporal arteritis). The history of recurrent headaches and raised ESR makes temporal arteritis the more likely underlying diagnosis.

It is important to note that temporal arteritis can cause visual loss via two mechanisms. Most commonly, patients lose their vision secondary to arteritic anterior ischaemic optic neuropathy, which causes occlusion of blood supply to the optic nerve. However, in 10% of patients with visual loss secondary to temporal arteritis, the visual disturbance is caused by central retinal artery occlusion, as in this case.

Intravenous methylprednisolone is correct. Visual loss secondary to temporal arteritis is an ophthalmological and rheumatological emergency and treatment should be initiated promptly including intravenous methylprednisolone to avoid permanent vision loss. This can later be deescalated to oral prednisolone.

Hyperbaric oxygen therapy is incorrect. This has been used as a treatment method to maintain adequate oxygenation of the retina whilst waiting for reperfusion. However, this treatment is not routinely used and would not reverse the underlying inflammatory process in temporal arteritis.

Intravitreal anti-vascular endothelial growth factor (anti-VEGF) is incorrect. This is used in the management of proliferative retinopathy (e.g. proliferative diabetic retinopathy). Proliferative retinopathy presents with multiple tortuous vessels and pre-retinal haemorrhages which are not seen here.

Oral aspirin and referral for intra-arterial thrombolytic therapy is incorrect. This would be an appropriate treatment for a thromboembolic cause of central retinal artery occlusion. However, this patient has a history of chronic headaches in association with a raised ESR which is suggestive of temporal arteritis. The pathology of artery occlusion in temporal arteritis is arteriopathy and inflammatory change rather than emboli and, therefore, methylprednisolone would be more appropriate.

Topical corticosteroids is incorrect. This is used to treat inflammatory ocular diseases such as anterior uveitis. This usually presents with eye pain and reduced visual acuity. Topical corticosteroids are not potent enough to treat arteriopathy. Rather, intravenous methylprednisolone is needed in the initial stages.

Question 93 of 409

A 34 year old man attended the Emergency Department after experiencing a severe sudden onset headache at home. The pain was felt across the whole of the head and reached a 10/10 severity within a few seconds of onset. Since the headache began the patient had experienced a loud pulsatile pounding noise in his right ear. There was no reported loss of consciousness or other neurological symptoms. In the preceding days the patient had been fit and well. On close questioning he recalled that that morning he had been struck hard in the face by a soccer ball while watching his son's team.

The patient had no significant past medical history and took no medications. There was no family history of neurological disease.

On examination, the patient's right pupil was constricted compared to his left, with both pupils reactive to light. There was a partial ptosis of the right eye. Cranial nerve examination was otherwise unremarkable except for possible right hypoglossal palsy. Examination of the remainder of the peripheral nervous system was remarkable.

Details of initial investigations are given below.

CT brain (non-contrast): no acute intracranial pathology identified; normal ventricular system; no boney injury.

Lumbar puncture:

CSF red cells	2 / mm³
CSF white cells	4 / mm³
CSF gram stain	unremarkable
CSF glucose	60 % serum level
CSF protein	0.65 g / L
CSF	negative for haemoglobin break down products

What is the correct diagnosis?

A. Vertebral artery dissection
B. Internal carotid artery dissection
C. Posterior reversible encephalopathy syndrome
D. Reversible cerebrovascular vasoconstriction syndrome
E. Posterior communicating artery aneurysm

B. Internal carotid artery dissection

Internal carotid artery dissection can present with thunderclap headache, commonly following minor trauma, as in this case. Possible associated symptoms and signs include homolateral Horner's syndrome, tinnitus or tongue palsy. CT brain and lumbar puncture are usually normal (or near normal in the case of LP) with diagnosis confirmed by angiography.

The remaining options are all possible causes of thunderclap headache. Vertebral artery dissection would typically cause a posterior circulation stroke pattern of signs and symptoms. Reversible cerebrovascular vasoconstriction syndrome is associated with hypertension and seizures and diagnosed by arterial beeding on angiography. Posterior reversible encephalopathy syndrome is also associated with hypertension and specific changes on MRI brain secondary to vasogenic brain oedema. Posterior communicating artery aneurysm causes compression of the third nerve with unilateral mydriasis without other signs of third nerve palsy.

Question 94 of 409

An 18-year-old female attends the clinic complaining of speech difficulties and slowing of movements. On examination you note bilateral rigidity, akinesia with loss of arm swing, and bradykinesia.

What drug may have caused this disorder?

A. Sodium valproate
B. Lithium
C. Metoclopramide
D. Fluoxetine
E. Domperidone

C. Metoclopramide

Metoclopramide can cause extrapyramidal effects, especially in children and young adults (15-19 years old)

The clinical features are suggestive of Parkinsonism. Drug induced Parkinsonism often presents with bilateral feature (in contrast to idiopathic Parkinson's disease which often presents asymmetrically). It can be caused by several drugs including anti-psychotics, anti depressants, antiemetics and calcium channel blockers.

Metoclopramide has a high risk of extrapyramidal effects, especially in children and young adults (15-19 years old), making this the best answer.

Several weak studies have shown an association of sodium valproate, lithium, domperidone and SSRIs to drug induced Parkinsonism, however the evidence is much weaker and they are less common causes compared to metoclopramide.

In many cases, the first approach to treatment will be to try stopping the offending drug for a sufficient length of time, reducing it, or changing it to another drug that may be less likely to cause drug-induced parkinsonism. If it is not possible to stop taking the offending drug, then anticholinergic drugs may be used, for example procyclidine.

Question 95 of 409

A 74-year-old man is admitted to the acute medical unit with loss of consciousness. His wife states that she found him slumped in the arm chair in an unresponsive state approximately one hour ago. He had been feeling well before hand.

On examination you note bilateral 1mm pupils. His Glasgow coma score (GCS) is 4 (M2, E1, V1).

His past medical history includes hypertension, hypercholesterolaemia and osteoarthritis. His drug history includes codeine, paracetamol, ramipril and atorvastatin. You administer 400 micrograms of naloxone. There is no change in GCS or pupil size.

What is the most likely diagnosis?

A. Pontine haemorrhage
B. Medulla haemorrhage
C. Midbrain haemorrhage
D. Subarachnoid haemorrhage
E. Opioid overdose

A. Pontine haemorrhage

Pontine haemorrhage commonly presents with reduced GCS, paralysis and bilateral pin point pupils

The patient has severely reduced GCS and is in a coma. The differential of coma is wide and includes vascular (e.g. intracerebral haemorrhage), inflammatory (e.g. cerebral vasculitis), neoplastic (e.g. paraneoplastic encephalitis, or cerebral space occupying lesion), drugs (e.g. sedatives), infective (e.g. meningitis, encephalitis), and metabolic (e.g. hyponatraemia, hypoglycaemia, hypercapnia) causes.

Pontine haemorrhage commonly presents with reduced GCS, paralysis and bilateral pin point pupils. Lesions of the pons can compress the first order sympathetic tracts resulting in bilateral Horner's syndrome.The differential clearly includes opioid overdose, however there is nothing to suggest that an overdose has occurred, and the fact that his GCS and pupil size do not respond to naloxone further suggests that this is not the correct diagnosis.

Midbrain lesions typically cause fixed, midpoint pupils.

Lesions of the lateral medulla can result in an ipsilateral Horner's syndrome and a pin point pupil. A bilateral medulla lesion is a possible differential, however the sudden onset of coma and pin point pupils is more characteristic of pontine haemorrhage.

Question 96 of 409

A 28-year-old female is admitted after a paracetamol overdose. She took twenty 500mg tablets. She states that she wants to die and that life is not worth living any more. She had left a note for her parents. On mental state examination she has poverty of thought, a low affect and evidence of delusions of nihilism. She has a past medical history of severe depression. She is deemed to be medically fit for discharge however due to ongoing suicidal ideation she is transferred to a psychiatric unit for further assessment. During the admission she develops catatonia and stops eating and drinking.

Your team decides that electroconvulsive therapy is indicated.

Which one of the following options is an absolute contraindication for electroconvulsive therapy?

A. Retinal detachment
B. Cardiac conduction disease
C. Malignant hypertension
D. Raised intracranial pressure
E. Myocardial infarction within the last 3 months

D. Raised intracranial pressure

The only absolute contraindication for electroconvulsive therapy is raised intracranial pressure

With the exception of raised intracranial pressure, there are no absolute contraindications to ECT, although there are a number of clinical situations in which extra caution is required.

All the other options listed are relative contraindications.

ECT leads to increases in cerebral blood flow and increased intracranial pressure (ICP). This is the reason that raised ICP is an absolute contraindication.

Initially, the seizure activity causes a large parasympathetic discharge with bradycardia, atrial or ventricular premature beats, and occasional asystole. Therefore, cardiac conductive disease is a relative contraindication.

The initial parasympathetic stimulus is followed by sympathetic discharge causing tachycardia, hypertension, ST-segment depression and T-wave inversion not associated with myocardialenzyme changes. It can rarely cause ventricular tachycardia. Therefore, uncontrolled hypertension, and recent MI are relative contraindications.

Question 97 of 409

A 28-year-old female presents with a frontal headache with associated fever and photophobia. She states that she has been suffering from an ear infection over the past week.

Lumbar puncture results are as follows:

Cell count 228 (95% neutrophils) Protein 1.2 g/l (normal 0.2-0.4) Glucose 2.2 mmol/l

A plasma glucose is as follows: Plasma glucose 6.8 mmol/l

What is the most likely organism?

A. ECHO virus
B. Streptococcus pneumoniae
C. Neisseria meningitidis
D. Listeria monocytogenes
E. Mycobacterium tuberculosis

B. Streptococcus pneumoniae

Meningitis which occurs as a complication of an ear infection is nearly always caused by Streptococcus pneumoniae

The patient has clinical features of meningitis. The CSF results confirm a neutrophilic pleocytosis with a high protein and low glucose. This is indicative of bacterial meningitis. Streptococcus pneumoniae and Neisseria meningitidis are high up the differential. Meningitis occurring as a complication of an ear infection is almost always caused by Streptococcus pneumoniae, making this the best answer.

ECHO virus is a cause of viral meningitis which presents with a lymphocytic pleocytosis and normalglucose, and normal / mildly raised protein. Listeria monocytogenes meningitis tends to only affect elderly and immunosuppressed individuals.

Mycobacterium tuberculosis meningitis causes a lymphocytic pleocytosis and tends to present subacutely with a several week prodrome phase.

Question 98 of 409

A 24-year-old woman presents with right eye vision loss and painful eye movements. She had a previous episode affecting her left eye last year. Following an MRI head and spine with contrast and a lumbar puncture examination, she is diagnosed with multiple sclerosis. She is started on high-dose steroids which induces remission.

You start the patient on maintenance ocrelizumab.

What is the mechanism of action of this drug?

A. Anti-TNF
B. Dihydrofolate reductase inhibitor
C. Humanized anti-CD20 monoclonal antibody
D. Recombinant monoclonal antibody that antagonises alpha-4 beta-1-integrin
E. Sphingosine 1-phosphate (S1P) receptor modulator

C Humanized anti-CD20 monoclonal antibody

Ocrelizumab is considered a high-efficacy drug that is often used first-line to reduce the risk of relapse in MS

Humanized anti-CD20 monoclonal antibody is correct. Ocrelizumab selectively targets the CD20-positive B-cells by binding to the surface proteins of the cells and protecting the nerve cells from mediated damage caused by CD20-positive B lymphoma cell lines.

Anti-TNF is incorrect. Drugs in this class include adalimumab, infliximab, and etanercept. Dihydrofolate reductase inhibitor is incorrect. This is the mechanism of action of methotrexate.

Recombinant monoclonal antibody that antagonises alpha-4 beta-1-integrin is incorrect. This is the mechanism of action of natalizumab.

Sphingosine 1-phosphate (S1P) receptor modulator is incorrect. This is the mechanism of action of fingolimod.

Question 99 of 409

A 56-year-old man comes to the office due to blurred vision and drooping of his left eyelid for over two weeks. He was diagnosed with hypertension and hyperlipidaemia 2 years ago, for which he takes lisinopril and atorvastatin. The patient has smoked a pack of cigarettes daily for the past 30 years.

Vital signs are within normal limits. Physical examination shows normal pupils and eye movements. After closing the eyes for 5 minutes, the drooping resolves. However, after a few minutes, the drooping recurs, worsening progressively. His cardiovascular, respiratory and neurological examinations are normal.

Which of the following is the best next step in the management of this patient?

A. Botulinum antitoxin
B. Intravenous immunoglobulin
C. Prednisone
D. Pyridostigmine
E. Smoking cessation

D. Pyridostigmine

Pyridostigmine is the 1st line drug in the management of ocular myasthenia gravis

This patient with ptosis and eyelid fatigue has ocular myasthenia gravis. Ocular myasthenia gravis presents with ptosis and oculomotor paresis. The ptosis is often unilateral and may alternate from one side to another. Eyelid fatigability is another classic sign of ocular myasthenia gravis. In myasthenia gravis, autoantibodies against acetylcholine receptors prevent acetylcholine from properly binding to these receptors. Furthermore, acetylcholine is quickly broken down into choline and acetic acid by the cholinesterase enzyme at the neuromuscular junction. Pyridostigmine is a cholinesterase inhibitor. It slows down the breakdown of acetylcholine and is the first-line drug in the management of symptomatic myasthenia, like ocular myasthenia gravis.

Patients with botulism present with acute symmetric descending flaccid paralysis which progresses over time. This patient's presentation is not progressing, and is therefore, unlikely to be botulism.IV immunoglobulins and plasmapheresis are used in the management of Guillain-Barre syndrome. They don't have a role in treating ocular myasthenia gravis.

The use of prednisone and other corticosteroids is controversial in ocular myasthenia gravis. Corticosteroids are associated with severe adverse effects and difficulty weaning off. Moreover, several weeks to months of corticosteroid therapy are required to maintain beneficial effects in patients with ocular myasthenia gravis. Anticholinesterase agents, like pyridostigmine, should be used before resorting to corticosteroids.

While this patient should consider smoking cessation, quitting smoking is unlikely to improve symptoms of ocular myasthenia gravis.

Question 100 of 409

A 23-year-old woman presents to the emergency department having been found by her father in a reduced state of consciousness one hour ago. She has a past medical history of epilepsy for which she is taking levetiracetam and anxiety and depression for which she has been prescribed short courses of diazepam in the past. Several empty packets of diazepam were found by her bedside.

On initial assessment, her oxygen saturations are 91% on 15L via a non-rebreather. Her heart rate is 61/min and her blood pressure is 91/64mmHg. She is responsive to pain only.

What is the most appropriate next step in management?

A. Activated charcoal
B. Anaesthetic support
C. Haemofiltration
D. Intravenous flumazenil
E. Naloxone

B. Anaesthetic support

Benzodiazepine overdose is best managed supportively and with airway protection and ventilation if needed. Flumazenil should be avoided unless for reversal of anaesthesia Important for me Less important

The primary concern here is related to this woman's airway. Despite 15L of oxygen via a nonrebreather, her oxygen saturations are only holding at 91%. Airway obstruction is likely a result of her reduced conscious level. As per the ALS algorithm, airway manoeuvres and anaesthetic support for potential intubation and ventilation should be sought.

Activated charcoal may be helpful in acute ingested poisonings to limit subsequent serum levels however this does not address the most urgent concern here which is airway obstruction and is therefore not the most appropriate first step.

Haemofiltration can be used to clear various drugs however again this will take some time to have an effect and does not address the most pressing concern, airway obstruction. Therefore this is not the correct answer.

Intravenous flumazenil is the primary reversal agent for benzodiazepine overdose however has to be used with extreme caution as its use can cause intractable seizures and arrhythmias. As thiswoman is young and particularly as she has a history of epilepsy, airway support and ventilation if required would be a more favoured approach in this case.

Naloxone is an agent used to reverse opioid overdose however as there is no indication of opioid use here, this is unlikely to reverse this woman's condition.

Question 101 of 409

A 27-year-old woman comes for review. She is having problems with increasingly frequent migraine attacks. These occur throughout her menstrual cycle and have no relation to her periods. She has tried a combination of paracetamol and ibuprofen to try and control the attacks but this seems to have had a limited effect. Her current medication includes paracetamol and ibuprofen as required and Cerazette (a progestogen-only pill).

What is the most appropriate medication to try and reduce the frequency of her migraine attacks?

A. Propranolol
B. Zolmitriptan
C. Topiramate
D. Amitriptyline
E. Switch Cerazette to a combined oral contraceptive pill

A. Propranolol

Propranolol is preferable to topiramate in women of childbearing age (i.e. the majority of women with migraine)

Zolmitriptan is useful to abort attacks but is not generally used for prophylaxis, except in the case of menstrual-related migraine (see below for more details). From the history it is clear that the headaches are not confined to the days around menstruation.

NICE recommend either propranolol or topiramate for migraine prophylaxis. Propranolol should be used in preference to topiramate in women of child bearing age as it may be teratogenic and it can reduce the effectiveness of hormonal contraceptives

The combined oral contraceptive pill is contraindicated given her history of migraine.

Question 102 of 409

A 34-year-old woman attends with weakness in her left leg. The symptoms started over a few hours and have persisted for 2 days.

On examination of the left leg, she has a brisk ankle jerk and an upgoing plantar, dorsiflexion is reduced in power, and tone is normal. Examination of the right leg is unremarkable.

Further questioning reveals an episode of numbness and tingling in her right hand 3 months ago.

Given the likely diagnosis, what treatment is most likely to reduce relapses for this patient?

A. Dexamethasone
B. Fingolimod
C. Glatiramer
D. Interferon beta
E. Natalizumab

E. Natalizumab

Monoclonal antibodies such as natalizumab have the strongest evidence base for reducing relapse in multiple sclerosis

The most likely diagnosis here is multiple sclerosis given the upper motor neuron signs separated by time. MR imaging of the brain and spinal cord would be appropriate to confirm the diagnosis. Be aware that, during the acute phase, tone may be normal.

Natalizumab is the correct answer. Natalizumab is a high-efficacy disease-modifying therapy and has the strongest evidence base for reduced relapse rates.

Dexamethasone can be used in acute relapsing disease, but it does not confer any long-term benefit in reducing further relapses.

Fingolimod is a SIP1 modulator. It can be used as a disease-modifying treatment in multiple sclerosis but has less supporting evidence for reducing relapses compared to natalizumab.

Interferon beta is another disease-modifying drug used in the treatment of multiple sclerosis. It is what is termed a 'low-risk' therapy as it has been around for quite a long while and has a goodsafety profile. Some clinicians favour starting with a 'low-risk' therapy and escalating to 'high efficacy' treatments if relapses aren't controlled. The evidence, however, does state that natalizumab has better evidence for controlling relapse rates overall.

Glatiramer is also termed a 'low-risk' therapy due to its good safety profile. Again, the evidence for a reduction in relapse rate is not as strong as that for natalizumab.

Question 103 of 409

A 28-year-old man presents to his general practitioner with peripheral vision loss. He explains that his vision has gradually 'narrowed' over the last 2 months. He also describes difficulty seeing in the dark, which has preceded the current symptoms by several years, although he has not sought medical attention for this.

On examination, fundoscopy reveals black bone spicule-shaped pigmentation in the peripheral retina. Blood tests are also performed:

Na	138 mmol/L	(135 - 145)
K	3.3 mmol/L	(3.5 - 5.0)
Bicarbonate	29 mmol/L	(22 - 29)
Urea	9.1 mmol/L	(2.0 - 7.0)
Creatinine	320 µmol/L	(55 - 120)

What is the most likely cause of this patient's abnormal blood tests?

A. Alport syndrome
B. Autosomal dominant polycystic kidney disease (ADPKD)
C. Autosomal recessive polycystic kidney disease (ARPKD)
D. Bartter syndrome
E. Renal artery stenosis

A. Alport syndrome

Retinitis pigmentosa classically presents with black bone-spicule pigmentation on fundoscopy

Tunnel vision, night blindness, and fundoscopy findings in this patient are characteristic of retinitis pigmentosa. The presence of renal disease with retinitis pigmentosa hints at Alport syndrome , which is due to an abnormality in the gene that codes for type 4 collagen. Sensorineural hearing loss, although not featured in this scenario, is another prominent feature of Alport syndrome.

The common disease associations of autosomal dominant polycystic kidney disease (ADPKD) are cerebral aneurysms, hepatic cysts, colonic diverticula, mitral regurgitation and mitral prolapse.Retinitis pigmentosa is not associated with ADPKD.

Patients with autosomal recessive polycystic kidney disease (ARPKD) rarely survive beyond 5 years of age. ARPKD is not associated with retinitis pigmentosa.

Although mild hypokalemia and alkalosis are present in this scenario, this is less likely to be due to Bartter syndrome , which is extremely rare. Furthermore, there is no association between Bartter syndrome and retinitis pigmentosa.

Hypokalemic metabolic alkalosis may be seen with renal artery stenosis (RAS) due to the stimulation of the renin-angiotensin-aldosterone system. The normal blood pressure and presence of retinitis pigmentosa make Alport syndrome more likely.

Question 104 of 409

A 42-year-old woman is referred into the TIA clinic due to recurrent left arm weakness. She has been having recurrent episodes of left sided weakness with associated unilateral throbbing headache, nausea and photophobia. During each episode she find that her left arm becomes weak. She has a past medical history of headaches, DVT during pregnancy and hypothyroidism. Currently there are no neurological features.

What is the most likely diagnosis?

A. TIA
B. Subdural haematoma
C. Sinus venous thrombosis
D. Brain tumour
E. Migraines

E. Migraines

Recurrence of the same neurological signs or symptoms is unlikely to be due to TIA

This patient has recurrent weakness as a feature of neurology with headache and photophobia. The most likely diagnosis is migraines which can cause weakness. The recurrence of symptoms makes TIA less likely. This is because it is unlikely for clots to occur in the same vessel and cause the same symptoms. Subdural haematoma is unlikely to cause photophobia, and also unlikely to cause intermittent weakness. Brain tumours are associated with progressive and unrelenting headaches as well as mass effect symptoms.

Question 105 of 409

A 76-year-old residential home resident was seen in the neurology clinic. She had a history of Alzheimer's disease, and her behaviour had become progressively more challenging over the past 4 months, for which she had been started on regular haloperidol.

The residential home staff had reported that over the previous four weeks she had developed involuntary movements of her mouth, with frequent tongue protrusion and lip-smacking. There were no neurological deficits and no history of blackouts. Two weeks ago she was reviewed by the general practitioner who stopped her haloperidol. However, her involuntary facial movements became more prominent following this.

On examination, she appeared well, other than continuous involuntary lip-smacking, tongue protrusion, and frequent eye-blinking. She was alert, and there were no focal neurological deficits.

What is the most likely cause for her symptoms?

A. Temporal lobe epilepsy
B. Progression of Alzheimer's disease
C. Chronic tardive dyskinesia
D. Frontotemporal dementia
E. Huntington's disease

C. Chronic tardive dyskinesia

Antipsychotics may cause tardive dyskinesia

First-generation antipsychotic agents (e.g. haloperidol, chlorpromazine) may result in extrapyramidal side effects due to relatively non-selective dopamine blockade. This may manifest as chronic tardive dyskinesia, as in this case. Clinical features of chronic tardive dyskinesia include involuntary repetitive movements, such as lip-smacking, tongue protrusion, and distal chorea. It is treated by withdrawal of the offending agent, though it may paradoxically worsen in the first few weeks of stopping the drug. The typical features and temporal relationship make chronic tardive dyskinesia secondary to haloperidol the most likely diagnosis in this case. Other extrapyramidal side effects include acute dystonic reactions, akathisia, and Parkinsonism.Lip-smacking may occur in temporal lobe epilepsy, but this would be associated with impaired consciousness and would only last a few minutes. Advanced Alzheimer's disease may be associated with involuntary movements (e.g. myoclonus), but is not typically associated with dyskinesias. Parkinsonism may occur in frontotemporal dementia, but dyskinesia is not associated. A new diagnosis of Huntington's disease would be very unlikely in this age group.

Question 106 of 409

A 42 year old computer programmer is brought to the Emergency Department by his wife with chest pains. He is haemodynamically stable with a blood pressure of 105/69mmHg and a heart rate of 92bpm but he is peripherally shut down with cool, dusky extremities and weak peripheral pulses. He complains of crushing central and left sided chest pain with some evidence of sweating and pallor. He also complains of severe global headache. His chest is clear and his heart sounds are normal. Chest x-ray is unremarkable.

An ECG shows pronounced inferior and lateral ST segment depression. A baseline troponin at 4 hours since onset of chest pain is raised. His wife tells you he has been taking clarithromycin from the GP for the past 6 days for a chest infection and she has been concerned he has been acting strangely since starting this with confusion, excitability, delusions and visual hallucinations. He has also had stomach cramps and diarrhoea for the past 2 days. His medical history is significant for migraines for which he takes PRN zolmitriptan and prophylactic ergotamine.

Which one of the following explains this patients symptoms most completely?

A. Acute non-ST segment myocardial infarction
B. Acute meningoencephalitis
C. Clarithromycin induced haemolytic uraemic syndrome (HUS)
D. Ergotism
E. Serotonin syndrome

D. Ergotism

Concomitant use of ergotamine and macrolides may cause ergot poisoning (ergotism) with confusion, headache, seizures, psychosis and global vasoconstriction leading to critical limb ischaemia, cardiac ischaemia and bowel hypoperfusion

In this case, this patient is quite clearly having an acute coronary event but non ST elevation myocardial infarction does not explain all his symptoms. Meningoencephalitis is a possibility but without further evidence of infection is difficult to prove and does not explain the cardiac ischaemia or bowel and limb symptoms. Serotonin syndrome may well be seen with drugs which modulate serotonergic neurotransmission such as zolmitriptan and cause confusion and agitation but the hallmark of this syndrome is hyperpyrexia which is absent here; cool peripheries would notbe expected. Clarithromycin induced HUS could explain the majority of symptoms described here, however it is exceedingly rare and given that this patient has taken both clarithromycin and ergotamine concomitantly, ergotism is a far more likely diagnosis.

Management of ergotism is largely supportive and discontinuation of offending drugs is important. Seizures and psychosis may be controlled with benzodiazepines. Hypotension and haemodynamic instability should be managed with filling; avoid vasopressors such as adrenaline, noradrenaline or vasopressin; dobutamine or milrinone may be used cautiously if needed. Vasodilators such as GTN, iloprost or nitroprusside may be needed for critical ischaemia. Coronary ischaemia should be assessed as in any patient. Rebound migraine may be expected on cessation of ergot derivatives.

Question 107 of 409

A 22 year old woman is brought to the Emergency Department by ambulance. She is accompanied by her boyfriend who tells you he thinks she has taken a deliberate overdose of up to 80 fluoxetine tablets (20mg) within the past eight hours. On assessment her airway is patent but threatened with a respiratory rate of 26 and peripheral oxygen saturations of 97% on air. Her chest is clear. The heart rate is 118bpm and the blood pressure is 98/39mmHg. Capillary blood glucose is 5.0mmol/L. The ECG shows a sinus tachycardia with QRS duration 114msec and corrected QT interval 575msec. She is globally hypertonic, shivering, nauseated, vomiting and sweaty with a tympanic temperature of 37.7°C and dilated pupils and prominent clonus. She suddenly has a prolonged tonic-clonic seizure and receives 20mg intravenous diazepam with no response after 15 minutes.

Which of the following is the safest subsequent intervention in this patients management?

A. Further 10mg intravenous diazepam
B. 10mg rectal diazepam
C. Phenytoin infusion 20mg/kg
D. Levetiracetam 1000mg intravenous infusion
E. Intubate and ventilate

E. Intubate and ventilate

Care should be taken in status epilepticus due to drug toxicities refractory to benzodiazepines; phenytoin is cardiotoxic and phenobarbital is a potent respiratory depressant. Intubation is often safest

Seizures in drug overdoses are relatively common occurrences and may be related to the drug itself, its metabolites or as a consequence of electrolyte derangements. Generally, brief and isolated convulsions do not require specific treatment and may be managed conservatively. Recurrent or prolonged seizures predispose to injury, hypoxia and renal failure; first line treatment is with benzodiazepines such as diazepam, lorazepam or midazolam. In pre-hospital environments, or in those patients in whom intravascular access is yet to be established, rectal diazepam is a reasonable route of administration since it is rapidly absorbed across the bowel wall and enters the pudendal vasculature and is rapidly distributed to the central nervous system without passing through the liver first. If intravenous access is present however, as in the above patient, this routeshould be used. If a choice of intravenous benzodiazepines is available, lorazepam should be used preferentially since diazepam emulsion has a high risk of thrombophlebitis. In the above vignette, 20mg intravenous diazepam has been administered with no clinical effect; this is the maximal dose permitted in 4 hours and further doses are unlikely to be helpful. Second line agents which are recommended in persistent seizure activity are phenytoin or phenobarbital. Care must be taken when using phenytoin as an anti-seizure drug in overdoses since it exerts its anti-epileptic effects by inhibiting sodium channels; this is an effect shared by many cardiotoxic drugs taken in overdose. Co-administration of phenytoin and many drugs may lead to significant widening of the QRS duration, prolongation of the QT interval and ultimately to torsades de pointes, ventricular tachycardias and cardiac arrest. Phenytoin should not be used when there is any ECG evidence of prolongation of QRS or QT phases.

Levetiracetam is a relatively new antiepileptic drug which works by modulating NMDA glutamate neurotransmission. It can be given intravenously when oral routes are unavailable but it is licensed only for use in established epilepsy and not as a treatment for status epilepticus or drug induced seizures and should not be used here.

Phenobarbital is a drug which is rarely used in status epilepticus due to the risk of significant respiratory depression. It is however considered a second line agent to treat seizures as an alternative to phenytoin and could potentially be used here, although given the rest of the clinical information and probable evolving serotonin syndrome, intubation, ventilation and paralysis is probably safest.

In poisonings with cardiotoxic drugs, use of antiarrhythmic drugs to control ECG anomalies is not recommended; intravenous sodium bicarbonate may be given in patients with prolongation of QRS duration and magnesium sulphate can be given in QT prolongation or torsades de pointes, although the QT duration may not reduce but the incidence of escape rhythms is lessened.

Question 108 of 409

A 58-year-old man presents to the emergency department with eight hours of a painful red eye. He has a past medical history of inflammatory bowel disease, type 2 diabetes and hypertension. His regular medications include metformin, amlodipine and mesalazine. He does not smoke or drink alcohol. He wears contact lenses.

On examination, his right eye is red. Visual acuity is decreased in the right eye (6/18) in comparison to the left eye (6/6). The pupil in the right eye is fixed and mid-dilated.

Fluorescein staining of the right eye is normal.

Which of the following options is used in the management of the likely diagnosis?

A. IV acetazolamide
B. Oral steroids
C. Saline irrigation
D. Topical antibiotics
E. Topical steroids

A. IV acetazolamide

Alongside eye drops, IV acetazolamide is used in the initial emergency medical management of acute angle-closure glaucoma

IV acetazolamide is the correct answer. The patient presents with a painful red eye with reduced visual acuity. The characteristic finding of acute glaucoma is a fixed mid-dilated pupil. Diabetes and hypertension are risk factors for the development of this condition. Alongside eye drops, IV acetazolamide is used in the emergency management of this condition.

Saline irrigation is incorrect. This has a place in the management of a chemical injury to the eyes but there is no history of such an event.

Topical and oral steroids are both incorrect. Both these options have a place in the management of anterior uveitis. However, the pupil is typically miotic in this condition. Additionally, the onset is more insidious and frequently bilateral when affecting those patients with inflammatory bowel disease.Topical antibiotics is not correct. This may be indicated in the management of bacterial conjunctivitis or a corneal abrasion. The lack of discharge and the existence of visual obscuration make conjunctivitis an unlikely cause. Normal fluorescein staining makes a corneal abrasion unlikely despite the history of contact lens use.

Question 109 of 409

A 72-year-old man is brought to the emergency department by ambulance after complaining of sudden onset weakness. He has a past medical history of hypertension and atrial fibrillation. His medications include amlodipine, bisoprolol and apixaban.

On examination, power is 4/5 in the right upper limb and right lower limb. Cranial nerve examination reveals his left eye to have deviated inferiorly and laterally. There is left-sided ptosis. The pupillary responses are normal.

A CT head is unremarkable.

Based on the likely diagnosis, which cerebral artery is most likely affected?

A. Left anterior cerebral artery
B. Basilar artery

C. Left middle cerebral artery
D. Left posterior cerebral artery
E. Left retinal artery

D. Left posterior cerebral artery

Weber's syndrome is a form of midbrain stroke characterised by the an ipsilateral CN III palsy and contralateral hemiparesis

Posterior cerebral artery is correct. The patient presents with an ipsilateral third nerve palsy and contralateral hemiplegia. The sudden onset and history of hypertension and AF suggest a vascular event. This is suggestive of Weber's syndrome, which is caused by infarction of a branch of the posterior cerebral artery in the midbrain.

Basilar artery is incorrect. Infarction as a consequence of basilar artery thrombosis would cause 'locked-in syndrome. This is when the body and most of the facial muscles are paralyzed but consciousness and eye movements are preserved.

Left middle cerebral artery is incorrect. A stroke affecting this region may result in contralateral (i.e. right-sided) weakness, sensory disturbance and speech disturbance.

Left anterior cerebral artery is incorrect. This is characterized by weakness and sensory lossaffecting the lower limbs more than the upper limbs.

Left retinal artery is incorrect. This would cause monocular visual loss.

Question 110 of 409

A 24-year-old woman presents to her general practitioner complaining of frequent headaches, occurring 3-4 times a month. They last for approximately 4 hours at a time. They are throbbing in nature and associated with photophobia, phonophobia, nausea and a visual aura. There is no specific pattern of timing to when the headaches occur. She has no past medical history and does not take any regular medications.

On examination, she has a raised body mass index (32 kg/m²). The neurological examination is unremarkable and she is headache-free at the time of review.

Given the likely diagnosis, what is the most appropriate medication to prevent further headaches?

A. Acetazolamide
B. Propranolol
C. Sumatriptan
D. Topiramate
E. Zolmitriptan

B. Propranolol

Propranolol is preferable to topiramate in women of childbearing age (i.e. the majority of women with migraine)

Propranolol is the correct answer. This woman presents with typical features of migraine (episodic throbbing headache associated with aura, photophobia, phonophobia and nausea). The first choice of prophylaxis of migraine in a woman of childbearing age is propranolol.

Acetazolamide is incorrect. While she does have a raised BMI, which is a risk factor for idiopathic intracranial hypertension, the headache characteristics are far more suggestive of migraines. Additionally, we are told the neurological examination is normal suggesting an absence of papilloedema.

Sumatriptan is incorrect. This is used to treat acute migraine rather than prevent migraine. Topiramate is incorrect. This can be used for prophylaxis of migraine but is potentially teratogenicand therefore less preferable in women of child-bearing age.

Zolmitriptan is incorrect. This can be used as prophylaxis for menstrual migraines. However, we are told her headaches have no predictable pattern and therefore this is not indicated.

Question 1 of 299

A 64-year-old lady presents with worsening anxiety to the emergency department. She has no history of mental health issues but her husband is worried that over the past month she has become very nervous and developed panic attacks. In addition, she is not able to carry out her daily tasks. She is retired and usually keeps active but over the past few weeks has become more disengaged and no longer is arranging to see friends or leave the house. She has terrors in the night where she screams and takes several hours of calming from her husband.

She is normally well and takes ramipril and a simvastatin for high blood pressure.

On examination, she is withdrawn but alert. She is haemodynamically stable and afebrile. Her abbreviated mental test score is 3/10 and she does not know where she is or the time of day. She has mildly increased tone in both arms with occasional myoclonic jerks and the power is 4/5 in all muscle groups. There is intact coordination and sensation.

Hb	140 g/l
Platelets	398 * 10 /l
WBC	7.6 * 10 /l
CRP	5mg/l
Na	134 mmol/l
K	4.2 mmol/l
Urea	4.3 mmol/l
Creatinine	67 µmol/l

CT head	brain atrophy, no intracranial haemorrhage or mass effect
MRI head	Hyperintense signals in the left thalamus with some similar changes in both putamen and right thalamus

What treatment should be initiated?

A. Supportive
B. Cyclophosphamide
C. Methylprednisolone
D. Intravenous antibiotics
E. Venlafaxine

Question 25 of 299

A 32-year-old man had a compressive pituitary macroadenoma surgically removed in France 4 weeks ago and has been on pituitary hormone replacement since, including growth hormone. Surgery was uncomplicated and he initially made a good recovery. He has no other past medical history. He has now developed, over the last 1-2 weeks, poor balance, with a broad-based gait. He has also become extremely forgetful. On examination, he has an ataxic gain and you also observe occasional myoclonic limb movements. His MMSE score is 22/30. Clinical examination is otherwise unremarkable, as are routine blood investigations.

Given the likely diagnosis, what might you expect to find on his MRI brain?

- A. Areas of demyelination in the cerebellum
- B. An area of high T2 signal in the right middle cerebral artery territory with restricted diffusion on diffusion-weighted sequences
- C. High T2 signal in the posterior thalamus
- D. Leptomeningeal enhancement
- E. Loss of grey-white matter differentiation

The diagnosis is Creutzfeldt-Jakob disease (CJD) from an iatrogenic source.

The use of prion-contaminated medication, grafts and instruments may result in iatrogenic CJD. The current worldwide total of growth-hormone-associated cases of CJD is 226. Most cases occurred in France (119 cases/1,880 recipients; attack rate 6.3%), the United Kingdom (65 cases/1,800 recipients; attack rate 3.6%), and the United States (29 cases/7,700 recipients; attack rate 0.4%). No new case has been identified since 2008 but would be important to recognise this condition and how it presents if it did, as it is invariably fatal -so patients need to be made aware of their prognosis.

The clinical features of the disease vary according to the route of inoculation.

Central inoculation, eg from infected neurosurgical instruments, results in a rapidly progressive neurodegenerative disease similar to sporadic CJD, characterised by ataxia, dementia, myoclonus, rigidity, and akinetic mutism. Survival is 2-12 months.

Peripheral inoculation, eg from the use of the old human growth hormone products, results in a 24% 15% 37% 13% 11%slightly less acute disease -characterised by progressive cerebellar ataxia and dementia. Survival is 8-18 months.

Question 2 of 299

A 42-year-old woman presents with a headache over the past week. She describes it as left sided, excruciating and it makes it difficult for her to sleep at night. The pain is worse when lying down and she notices that her nose is blocked on that side. She has vomited but has been feeling achy all over for the last few days. She has tried paracetamol and ibuprofen without benefit. She is otherwise well and only takes the combined oral contraceptive pill.

On examination, she appears lethargic. She has normal eye movements and fundoscopy is normal. She is able to move all her limbs with a power of 5/5 and has normal reflexes. She walks with a slow but steady gait. She is coryzal and she will not let you examine her face when you press over the frontal area.

She was seen in the emergency department a few days prior with this headache and the report is below.

CT head:- There is no evidence of bleeding, mass effect or hydrocephalus. It is noted that there is a homogeneous collection of moderately enhancing material in the frontal sinus.

What is the most likely diagnosis?

- A. Idiopathic intracranial hypertension
- B. Sinusitis
- C. Subarachnoid haemorrhage
- D. Hemicrania continua
- E. Meningioma

B. Sinusitis

Severe constant headache on a background of rhinitis is likely sinusitis

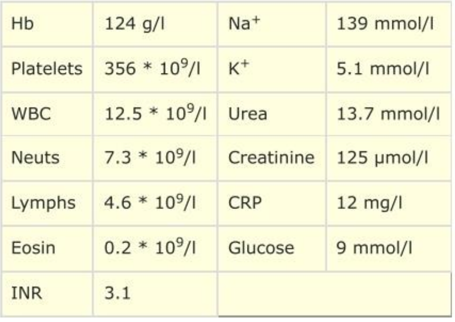
The history is an acute headache. Although there are features of raised intracranial pressure, a CT head excludes any meningioma. A subarachnoid haemorrhage typically is the most severeheadache that reaches maximal intensity over a few seconds to minutes. Hemicrania continua is a constant headache that often has autonomic features associated with it that are not seen here. Idiopathic intracranial hypertension is possible given her combined OCP use but there are no other features and fundoscopy shows no papilloedema. Examination is normal but the patient is anxious to be examined due to the exquisite tenderness of the facial sinuses in sinusitis. Furthermore, the CT head reports a collection of mucus in the sinuses seen incidentally.

Question 3 of 299

An 87-year-old lady normally resident at a nursing home is admitted with a short history of diarrhoea and vomiting, generalised malaise, stiffness, tremor, pyrexia and hallucinations. She has been previously admitted repeatedly with aspiration pneumonias, however no further details of her prior medical history are known, except her current medication including co-beneldopa, warfarin, amlodipine, amitriptyline, metformin and lactulose.

Examination is limited due to the agitated status of the patient, however chest auscultation and abdominal examination are unremarkable. A chest x-ray is unremarkable with a urine dipstick positive for ketones and containing a trace of blood.

Blood sample and blood cultures are taken and the results are provided below:



Hb	124 g/l	Na⁺	139 mmol/l
Platelets	356 * 10^9/l	K⁺	5.1 mmol/l
WBC	12.5 * 10^9/l	Urea	13.7 mmol/l
Neuts	7.3 * 10^9/l	Creatinine	125 µmol/l
Lymphs	4.6 * 10^9/l	CRP	12 mg/l
Eosin	0.2 * 10^9/l	Glucose	9 mmol/l
INR	3.1		

Taking in consideration her co-morbidities what would be your next step:

A. Initiate insulin
B. Start Tazocin
C. Prescribe rotigotine patch
D. Hold amlodipine
E. Prescribe 5 mg vitamin K orally

C. Prescribe rotigotine patch

Abrupt cessation of antiparkinsonian medication (dopamine agonists) can lead to neuroleptic malignant syndrome

This is a common situation in hospital medicine. A lady that suffers from Parkinson's disease (even though not explicitly stated - but can be assumed given the frequent aspiration pneumonias and her medication) presents dehydrated with diarrhoea and vomiting. It is possible that this lady may have gastroenteritis and it hence important to rehydrate her. It is also however important to ensure that she continues to take her anti-parkinsonian medication. Given her inability to eat and drink at the moment the most appropriate alternative would be a parenteral or topical solution. Given her blood picture and inability to isolate a source of infection, one should be cautious about starting broad spectrum antibiotics

Question 4 of 299

You are asked to review a patient on the surgical ward due to nursing concerns. The patient is a 21-year-old female who is normally fit and well and takes no medications. She was admitted three days ago for suspected appendicitis. So far she has been managed conservatively and was seemingly improving until this morning when her nurse went to perform her observations and discovered she was not responding and appeared 'stiff'.

Current management from the surgical team this admission: intravenous metronidazole, amoxicillin, and gentamicin, and regular paracetamol, oramorph, metoclopramide, and cyclizine for symptom control.

On examination, the patient's neck is in fixed extension with eyes fixed and deviated to the right. You noticed her jaw is clamped shut and limbs are rigid. Observations are stable.

What immediate medical management should be given in this situation?

A. Dantrolene
B. Naloxone
C. Diazepam
D. Adrenaline
E. Procyclidine

E. Procyclidine

Acute dystonic reactions are an adverse effect of antipsychotic medications

This patient is having an acute dystonic reaction secondary to metoclopramide. Reactions typically present with an extrapyramidal disorder and are managed with the withdrawal of the offending medication and administration of an anticholinergic such as procyclidine. Acute dystonic reactions should be considered in patients taking antipsychotic medication or other centrally acting dopamine agonists.

Question 5 of 299

A 72-year-old man presents to the emergency department. He had experienced slurring of his speech and right-sided facial drooping earlier that day following his lunch. He reports that the symptoms were mostly resolved ten minutes following their onset but took another five minutes to fully resolve.

On examination, there is no residual dysphasia or a facial droop and he has a normal neurological examination.

What imaging modality would be preferred for this patient?

A. CT angiogram head
B. Diffusion-weighted MRI head
C. Fluid attenuation inversion recovery (FLAIR) MRI head
D. T1-weighted MRI head
E. T2-weighted MRI head

B. Diffusion-weighted MRI head

MRI brain with diffusion-weighted imaging is the preferred modality in patients with suspected TIA who require brain imaging

The patient has focal neurological symptoms that lasted for only 10 minutes, consistent with a transient ischemic attack. The preferred imaging modality for TIA is a diffusion-weighted MRI head which is very sensitive to small ischaemic lesions.

CT angiogram is most commonly used to image an acute ischaemic stroke (where symptoms are ongoing). It is useful as a quick method to detect an occlusion which can then be treated. It is also used to detect intracranial aneurysms when subarachnoid hemorrhage is suspected.

FLAIR MRI head is a T2 weighted technique that dampens CSF signal and can be a superior method of detecting a white matter brain lesion and can be used to assess for leptomeningealdiseases.

T1-weighted MRI head is a sequence of MRI that provides the best contrast for paramagnetic contrast agents such as gadolinium-containing compounds. The sequence also is good for demonstrating anatomy and shows white matter as bright whilst fluid-filled compartments appear dark. It would not be the most effective imaging sequence to investigate a TIA.

T2-weighted MRI head is a sequence of MRI that lights up fluid-filled compartments, whilst white matter appears dark. Hence lesions that are associated with increased water content such as oedema will show up bright making this a good sequence to detect these lesions. It again would not be the most effective imaging sequence to investigate a TIA.

Question 6 of 299

A 57-year-old woman is seen on the acute medical take with a worsening frontal headache, nausea and distal right upper limb pins and needles.

She was born in India and emigrated 3 years ago to the United Kingdom (UK). Her past medical history includes tuberculosis treated 10 years ago and rheumatoid arthritis for which she has recently been started on methotrexate and sulfasalazine alongside a short course of oral prednisolone. Her chest X-ray was normal and quantiFERON test negative on entry to the UK.

On examination, she looks well and is alert and orientated. Her temperature is 36.8ºC, oxygen saturation 97% on air, heart rate 80 beats per minute, respiratory rate 18 breaths per minute and blood pressure 143/75 mmHg. There is symmetrical swelling in the small joints in both hands and neurological examination reveals 4/5 MRC grade of power in the distal right upper limb. Examination of the cardiovascular, respiratory and abdominal system reveals no additional abnormalities.

Her investigation results are as follows:

Hb	124 g/L
Platelets	398* 10 /L (150 - 400)
WBC	12 * 10 /L (4.0 - 11.0)
Na	135 mmol/L (135 - 145)
K	3.6 mmol/L (3.5 - 5.0)
Urea	5 mmol/L (2.0 - 7.0)
Creatinine	63 µmol/L (55 - 120)
CRP	24 (< 5)

You arrange a contrast CT head which shows the following- A 3-4cm diameter homogeneous contrast enhancing round lesion adjacent to the meningeal membrane situated in the left frontal lobe with evidence of surrounding oedema and mass effect. No additional lesions noted. No evidence of acute ischemia, haemorrhage or collection.

What is the most likely diagnosis?

A. Tuberculosis
B. Aspergilloma
C. Meningioma
D. Neuroblastoma
E. Lung metastasis

C. Meningioma

Meningioma primary brain tumors show contrast enhancement on a CT scan

The key to this question is the interpretation of the CT head findings. A meningioma will show homogeneous contrast enhancement on a CT scan.

The description and location of this space occupying lesion fit better with a meningioma than neuroblastoma.

Similarly, you may expect local or systemic signs and symptoms with metastatic lung cancer and CT findings fits better with the diagnosis of a meningioma. However, a screening CT scan of the chest, abdomen and pelvis may be appropriate to rule out this possibility.

We are told that this lady had active tuberculosis while living in India. However, on entry to the UK, there was no evidence of an active infection or a latent infection which could have been reactivated when initiated on immunosuppressive medications.

Although aspergilloma would be a risk with immunosuppression, this would be rarer and the CT head findings are more concordant with the diagnosis of a meningioma.

Question 7 of 299

A 56-year-old man is brought into the emergency department of a major stroke unit by his wife who reports that for the last 2-hours her husband has been unable to move his right side and is struggling to speak. He is known to have type 2 diabetes mellitus and hypercholesterolemia, for which he takes metformin and atorvastatin respectively. In addition, he has had a recent provoked lower limb deep vein thrombosis (DVT) for which he was started on apixaban. He works as an accountant, is an ex-smoker and drinks occasionally.

On examination, there is a dense right hemiparesis with expressive dysphasia. He scores 22 on the National Institute of Health Stroke Score (NIHSS).

Following rapid assessment, a CT brain and CT intracranial angiogram are performed, showing a proximal occlusion within the M2 segment of the middle cerebral artery with no major new ischaemic changes. An MRI head with MR angiography confirms these appearances.

Given this patient's presentation, which of the following would be the best intervention?

A. Thrombolysis immediately
B. Thrombectomy within 6 hours
C. Thrombolysis within 6 hours
D. Thrombectomy within 12 hours
E. Thrombolysis within 12 hours

B. Thrombectomy within 6 hours

The standard target time for thrombectomy in acute ischaemic stroke is 6 hours

This patient meets the criteria for a mechanical thrombectomy:

- thrombectomy can be achieved within 6 hours of symptom onset (if this cannot be achieved, consideration for thrombectomy is given in patients with sufficient salvageable brain tissue identified on imaging for up to 24 hours after symptom onset, although this is assessed on a case-by-case basis).

- he is anticoagulated, thus thrombolysis is contraindicated
- Imaging demonstrates a proximal occlusion
- There are no new major ischaemic changes on imaging
- his NIHSS is more than 5 he was independent prior to symptom onset

Question 8 of 299

You are asked to see a 57 year-old female who has presented acutely to eye clinic with deteriorating vision. On questioning she has experienced sudden blurring of the temporal field in her right eye. Her past medical history is noteworthy for hypertension and type 2 diabetes mellitus.

What is the likely diagnosis?

A. Branch retinal artery occlusion
B. Nasal retinal detachment
C. Central retinal vein occlusion
D. Temporal branch retinal vein occlusion
E. Nasal branch retinal vein occlusion

E. Nasal branch retinal vein occlusion

This case describes visual blurring and not total visual loss. Retinal artery occlusions lead to amaurosis fugax, often describes as a 'black curtain' descending over the vision. The most likely explanation for visual blurring is a retinal vein occlusion. The temporal field corresponds to the nasal retina. Both hypertension and diabetes are risk factors for a retinal vein occlusion.

Question 9 of 299

A 55-year-old man presents to the emergency department with a four-hour history of an acutely painful left eye. He also describes photophobia and reduced visual acuity associated with the pain.

On examination, diffuse redness is noted throughout the left eye. The left pupil is smaller than the left and he is unable to count fingers in the left eye although visual acuity in the right eye is unimpaired. It is also noted that there is some pus in the anterior chamber.

What treatment is most likely to be indicated?

A. Intravenous antibiotics
B. Intravenous diuretic
C. Steroid + mydriatic eye drops
D. Topical antibiotics
E. Topical beta blocker

C. Steroid + mydriatic eye drops

Anterior uveitis is most likely to be treated with a steroid + cycloplegic (mydriatic) drops

This man has presented with a case of anterior uveitis, as confirmed by the typical findings on examination. As per NICE guidance, the management of anterior uveitis is dependant on whether an infective or non-infective cause is established. As a result, all cases must be diagnosed and managed by ophthalmology in secondary care. The most common therapy is steroid + mydriatic drops and therefore this is the correct answer.

Intravenous antibiotics may be indicated in cases of infective anterior uveitis as directed by ophthalmology however treatment is more likely to be topical steroids and cycloplegics.

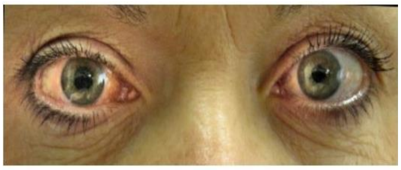
Carbonic anhydrase diuretics (for example acetazolamide) are of use in acute angle-closure glaucoma however as this is not the diagnosis here, this answer is incorrect.Topical antibiotics again may be indicated in infective cases but are not the most likely treatment.

Topical beta-blockers are again indicated in cases of acute angle-closure glaucoma which is not the diagnosis here.

Question 10 of 299

A 48-year-old woman presents to the eye casualty department with several hours of blurred vision in her right eye, accompanied by seeing 'haloes' around bright lights. She also describes nausea and numerous episodes of vomiting.

On examination, the eye appears as shown below:



What is an appropriate initial choice of treatment?

A. Topical brinzolamide
B. Topical dexamethasone
C. Topical ganciclovir
D. Topical gentamicin
E. Topical latanoprost

A. Topical brinzolamide

This patient's presentation of blurred vision, the description of 'haloes' around lights and nausea is suggestive of acute angle-closure glaucoma (AACG). This is supported by the photo of the right eye, showing erythema and a semi-dilated pupil, relative to the left eye. Immediate management involves a combination of eye drops, typically including a carbonic anhydrase inhibitor such as topical brinzolamide.

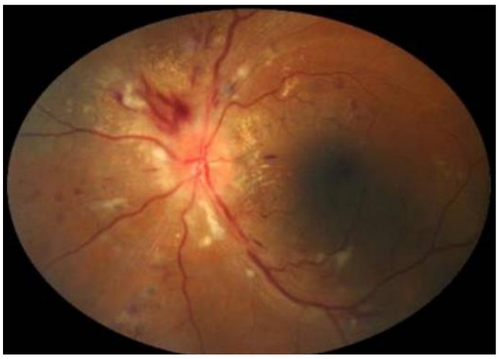
Topical dexamethasone is a corticosteroid used to reduce inflammation in a number of eye diseases. It does not routinely play a role in AACG.

Topical ganciclovir is used in the management of dendritic/herpetic keratitis. Rather than a fixed, dilated pupil, fluorescein staining would reveal a branching pattern.Topical gentamicin is used to manage bacterial infections of the eye, such as bacterial keratitis. The pupil would not be fixed and dilated as seen here, but the eye would be generally red in appearance.

Topical latanoprost may be used to treat residual angle-closure glaucoma after laser peripheral iridotomy. It is not used in the acute setting.

Question 11 of 299

A 76-year-old man is routinely reviewed as part of a health checkup. During this process, his eyes are examined using retinal photography and the following image is noted:



He reports generally reduced visual acuity and sometimes double vision.

He takes a number of medications, including amlodipine, losartan, salbutamol, metformin, paracetamol and codeine.

Given the photo above, what is the most likely diagnosis?

A. Central retinal artery occlusion
B. Central retinal vein occlusion
C. Diabetic retinopathy
D. Hypertensive retinopathy
E. Vitreous haemorrhage

D. Hypertensive retinopathy

The findings on the photo above are indicative of hypertensive retinopathy. The photo shows some generalised arterial narrowing and some evidence of silver wiring - a silvery/white appearance of retinal arterioles if they have become occluded. A flame haemorrhage is also visible in the top left area, as well as exudates scattered across the image. Together, these are all featuresof hypertensive retinopathy.

Central retinal artery occlusion classically presents with retinal whitening and a cherry-red spot opacification of the nerve fibre layer as it becomes oedematous due to ischaemia, with the cherryred spot being due to fovea sparing (no nerve fibre layer over the fovea).

Central retinal vein occlusion would also include features such as flame haemorrhages, as well as cotton-wool spots - fluffy white patches on the retina caused by damage to nerve fibres and the resulting accumulation of material within the nerve fibre layer. However, the other findings visible here, such as silver wiring and arteriovenous (AV) nicking, are more indicative of hypertensive retinopathy.

Diabetic retinopathy may have some similar findings as hypertensive retinopathy on fundoscopy and can include haemorrhages and cotton-wool spots. Hypertensive retinopathy can be distinguished by the presence of silver wiring and AV nicking, which are both present in this case. Furthermore, with advanced proliferative retinopathy, neovascularisation would be observed.

The haemorrhage visible in this case is a flame haemorrhage, rather than a vitreous haemorrhage. Vitreous haemorrhages appear as a well-defined accumulation of blood within the vitreous body, obscuring the retina, rather than on the retina itself. They normally present with a sudden, painless loss or blurring of vision.

Question 12 of 299

A 75-year-old man is referred to you for the management of tremor and mobility issues. On examination, he has a noticeable resting tremor that is worse in the right hand when compared to the left. He also is quite bradykinetic when mobilising and displays mild rigidity. His speech and cognitive function do not appear to be affected. His blood pressure is 125/80 mmHg without any significant postural drop.

You suspect idiopathic Parkinson's disease. Further history taking reveals that this gentleman has had a previous significant gambling problem which is now well controlled.

Which of the following medications, in particular, should be avoided in this patient?

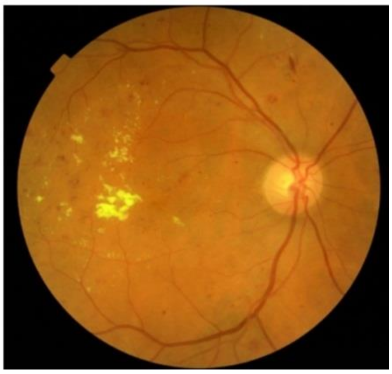
A. Rasagiline
B. Levodopa/carbidopa
C. Pramipexole
D. Entacapone
E. Amantadine

C. Pramipexole

There is an established link between the use of dopamine receptor agonists and serious impulse control disorders. For patients who have a history of habitual behaviours associated with increased risk, this group of medications should be avoided.

Question 13 of 299

A 48-year-old man with a history of type II diabetes mellitus attends the routine diabetic eye screening. He reports good compliance with his diabetes medications. His fundoscopy showed:



What is the most appropriate management for this patient?

A. Intra-vitreal VEGF inhibitor therapy
B. Optimise glycaemic control
C. Routine 2-yearly eye screening
D. Urgent trabeculectomy
E. Vitreoretinal surgery

B. Optimise glycaemic control

The fundoscopic findings of microaneurysms, hard exudates, and blot haemorrhages suggest severe non-proliferative diabetic retinopathy (NPDR). Besides optimising glycaemic control, antihypertensives and statin therapy, pan-retinal laser photocoagulation should be considered in severe NPDR.Optimise glycaemic control should be considered in all patients with non-proliferative or proliferative diabetic retinopathy. Furthermore, tight control of blood pressure and lipid levels may help slow the progression of diabetic retinopathy.

Intra-vitreal VEGF inhibitor therapy is recommended for patients with maculopathy or may be considered in combination with pan-retinal laser photocoagulation to treat severe proliferative diabetic retinopathy which may present with extensive neovascularisation around the disc or elsewhere.

Routine 2-yearly eye screening is incorrect. All patients aged 15 or over with diabetes are advised to have routine diabetic eye screening at least once a year.

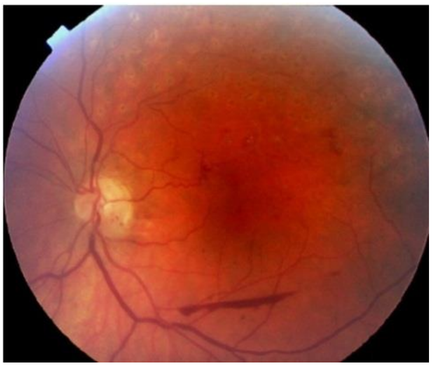
Urgent trabeculectomy , the surgical intervention used to reduce intraocular pressure in acute angle-closure glaucoma. Glaucoma leads to the classical fundoscopic appearance of cupping or increased vertical cup-to-disc ratio, which is not seen in this patient.

Vitreoretinal surgery is recommended for severe or vitreous haemorrhage, which is often a complication of extensive neovascularisation seen in proliferative diabetic retinopathy (PDR). However, this patient does not show any PDR or vitreous haemorrhage features, which may be seen as a red haze of haemorrhage into the vitreous associated with dot-blot haemorrhages, neovascularisation elsewhere or boat-shaped pre-retinal haemorrhages.

Question 14 of 299

A 60-year-old woman with history of proliferative diabetic retinopathy presents to the emergency department with a sudden painless loss of vision in the left eye. On examination, there is reduced visual acuity in the left eye.

Fundoscopy shows:



Given the fundoscopy findings, what is the most likely diagnosis?

A. Central retinal artery occlusion
B. Central retinal vein occlusion
C. Hypertensive retinopathy
D. Retinal detachment
E. Vitreous haemorrhage

E. Vitreous haemorrhage

The central red haze of haemorrhage into the vitreous is characteristic of vitreous haemorrhage. Looking closely at this patient's retina, there are dot and blot haemorrhages (seen as round blots of haemorrhages with indistinct margins) in the upper periphery of the retina. There is alsoevidence of neovascularisation which is seen best in the mid-zone with multiple fine vessels leaving the optic disc into the vitreous. Additionally, in the lower quadrant of the retina, there is a pre-retinal haemorrhage. Together, these features are suggestive of proliferative diabetic retinopathy.

Vitreous haemorrhage is characterised by a red haze of haemorrhage into the vitreous. The associated findings of dot blot haemorrhages, neovascularisation and pre-retinal haemorrhages suggest proliferative diabetic retinopathy, the most common cause of vitreous haemorrhage in adults.

Central retinal artery occlusion is characterised by retinal whitening and thin arteries. Associated findings may include sluggish blood flow (boxcar shape of the arteries), Hollenhorst plaquecholesterol (refractile lesions within the arteries) or large calcific plaques (white lesions within the arteries).

Central retinal vein occlusion results in diffuse retinal 'blood and thunder' haemorrhages. However, this is less common and is not usually associated with other features of proliferative diabetic retinopathy seen in this patient. Risk factors for retinal vein occlusion include advancing age (>55y), hypertension, diabetes, glaucoma, sickle cell anaemia, oral contraceptives and smoking.

Hypertensive retinopathy can cause retinal vascular damage, resulting in flame-shaped haemorrhages associated with arteriolar constriction, arteriovenous nicking, cotton-wool spots, yellow hard exudates, and optic disk oedema, which are not seen in this patient.

Retinal detachment appears as the retina detaches from the typical structure of the eye. In the case of rhegmatogenous retinal detachment, a large bullous separation of the retina may be seen.

Question 15 of 299

A 46-year-old Ghanaian woman was flying from Ghana to San Francisco, USA when she was noticed to be confused and behaving inappropriately on the plane. She was talking loudly to herself, complaining of a headache, and also appeared to be hearing voices. She had one episode of incontinence on the plane. During the transit in London, she was brought to the nearest hospital for investigations.

On examination, she was drowsy and slow to respond to questions. Her temperature was 37.3ºC, heart rate of 98 bpm, blood pressure of 138/92 mmHg, respiratory rate of 16, and oxygen saturations were 100% on air. Her pupils were 3mm bilaterally, equal and reactive. Her neck was supple and there was mild photophobia. Her abbreviated mental test score was 6/10.

Her investigations revealed:

C Reactive protein	24 mg/l
Haemoglobin	128 g/l
White cell count	11.6 x 10^9/L
HIV antibody serology	positive
HIV viral load	19000 copies/ml
CD4+ T lymphocyte count	35 cells/mm³
Na+	136 mmol/l
K+	4.9 mmol/l
Urea	7.2 mmol/l
Creatinine	108 µmol/l
Corrected calcium	2.32 mmol/l
Plasma glucose	5.8mmol/l

Chest X-Ray: Lung fields clear

Computer Tomography (CT) head scan: Hypodense lesions involving the medial temporal regions. Lesions enhance with contrast.

Cerebro-spinal fluid (CSF) analysis:

Opening pressure	20 cmH2O
Protein	1.2 g/L
White cell count	50 per mm³ (predominantly mononuclear cells)
Red cell count	5 per mm³
Glucose	4.8 mmol/l
Gram stain	No organisms seen

What is the next most appropriate management step?

A. Intravenous acyclovir
B. Oral prednisolone
C. Highly Active Anti-Retroviral Therapy (HAART)
D. Intravenous fluconazole
E. Pyrimethamine and Sulfadiazine

A. Intravenous acyclovir

This lady is immunocompromised with a new diagnosis of HIV, and has an altered conscious level, with psychotic symptoms suggestive of encephalitis. Her CT head scan shows the involvement of the medial temporal region, which is highly suggestive of herpes encephalitis, and this is supported by the LP results with raised protein levels, and a predominantly mononuclear white cell picture. Viral polymerase chain reaction (PCR) is the gold standard in the diagnosis of herpes encephalitis, and management for Herpes encephalitis is high-dose intravenous acyclovir to achieve central nervous system penetrance.

Although this lady has advanced HIV infection, there is some evidence that starting HAART may cause an immune reconstitution syndrome, resulting in an initial deterioration in the patient's condition as the immune system is boosted. Thus while she would require HAART, the initial management should be to decrease the burden of infection with acyclovir to prevent a deterioration in her condition.

There is limited evidence for steroid use in HSV encephalitis. There is no evidence of cryptococcal or toxoplasmosis infection from the CT and CSF results, which rules out options (d) and (e) respectively.

Question 16 of 299

A 57-year-old man presents with slurred speech. He was brought in by ambulance as his daughter was concerned when she came to visit and found his speech to be abnormal. On questioning, the patient has not noticed any changes; but the daughter has noticed that he has been drooling and been having difficulty eating for several months. She has not noticed a change in his memory or cognitive function but has been concerned that he has been laughing out of place in conversations. She feels that the changes in her father have been slowly happening over that time. On examination, the patient has slight slurred speech, mild dysarthria and the tongue appears to move abnormally. His limbs are normal on examination, as is the remainder of his cranial nerve examination.

What is the most likely diagnosis?

A. Myotonic dystrophy
B. Stroke
C. Motor neuron disease
D. Multiple sclerosis
E. Syringobulbia

C. Motor neuron disease

The correct answer is motor neuron disease. This a male patient in his 50s who has developed evidence of bulbar signs without any sensory or peripheral involvement. The chronic history makes a stroke less likely, whilst the progressive nature, his age and sex makes multiple sclerosis less likely. The absence of sensory loss or weakness of the arms makes syringobulbia less likely whilst myotonic dystrophy would have more peripheral signs. This is motor neuron disease presenting with bulbar features.

Question 17 of 299

An 82-year-old female presents to Parkinson's disease clinic with increasing number of episodes when she is unable to move at all, each lasting for around 20 minutes and up to 4 times a day. She was diagnosed with Parkinson's disease five years ago and has since been taking Sinemet 125 only.

Which of the therapies is most appropriate to reduce motor fluctuations?

A. Entacapone
B. Deep brain stimulation (DBS) of globus pallidus
C. Reducing L-dopa dose
D. Change to ropinirole
E. Change to selegiline

A. Entacapone

The patient describes increasing frequency of 'on-off' fluctuations, a common complaint in patients who have been diagnosed with PD and medicated with L-dopa for a long time. Selegiline, a monoamine oxidase B inhibitor, while useful as an adjunct, has a very poor evidence base as a monotherapy. There is little evidence that in a more elderly patient, changing to a dopamine agonist has any benefit. The patients L-dopa load should be kept as low as possible but the main problem is the lack of a smooth profile. DBS is premature. Entacapone is a catechol-Omethyltransferase (COMT) inhibitor, which reduces the peripheral breakdown of L-dopa and increases the serum half-life of L-dopa. It has little therapeutic benefit when used alone but is a successful adjunct in smoothing out motor fluctuations.

Question 18 of 299

An 80-year-old male presents to the Parkinson's disease (PD) clinic complaining of jerking and flailing movements of his arm. He says he has no control of them and finds them embarrassing and disabling. However, he reports very few other PD symptoms, with minimal problems with 'off' periods. His past medical history includes PD, diagnosed 8 years ago, and type 2 diabetes. He currently takes Sinemet 250 for Parkinson's disease 5 times a day and metformin 500mg TDS, he has been on the same dose of Sinemet for past 18 months.

What is your most appropriate management?

A. Reduce dose of Sinemet
B. Increase dose of Sinemet
C. Start entacapone
D. Start ropinirole
E. Deep brain stimulation (DBS)

A. Reduce dose of Sinemet

The patient describes involuntary movements on a background of chronic and substantial use of L-dopa, a phenomenon known as L-dopa dyskinesias (LID). The pathophysiology of LIDs remains unclear but the key is to minimise L-dopa dosage if at all possible. As the patient reports minimal other motor symptoms, this is possible in this case. Entacapone smooths the motor profile of Ldopa but does not help with LIDs. DBS is a possible treatment for LIDs changes to L-dopa dose is not possible or if symptoms remain refractory despite L-dopa dose changes.

Question 19 of 299

A 14-year-old presents to your neurology clinic reporting 9 months of subtle and gradual onset, progressive lower limb weakness. For the past 18 months, he has noticed a difficulty in keeping up with his peers in PE lessons, which he initially put down to 'not being very sporty'. However, he feels weak whenever he walks and has particular difficulty getting up from a chair.

On examination, you notice significantly hypertrophied calves on inspection. Formal examination of power reveals 4- out of 5 bilaterally in shoulder abduction, adduction and normal 5 out of 5 distally. 4- out of 5 is also noted in hip flexion and extension, 4+ in knee flexion and extension, 5 out of 5 in ankle plantar and dorsiflexion. The weaknesses demonstrated are not fatiguable and are persistent. Reflexes are present in all areas, plantars are downgoing. He has no other past medical history. His family history is unknown as he was adopted.

What is the most likely diagnosis?

A. Duchenne muscular dystrophy
B. Becker muscular dystrophy
C. McArdle syndrome
D. Spinal muscular atrophy
E. Inclusion body myositis

B. Becker muscular dystrophy

Progressive proximal muscle weakness appears to be the most important symptoms in this teenage patient. The key differentials can be separated by the age of the patient. Duchenne muscular dystrophy (DMD) is a more severe form of Becker muscular dystrophy (BMD) and patients are normally wheelchair bound by early teens. Similarly, spinal muscular atrophy produces a flaccid paralysis of proximal musculature with absent reflexes, presenting from newborn to under the age of 3.

McArdle disease is a metabolic disorder affecting proximal muscles caused by myophosphorylase deficiency. Patients frequently report a 'second wind' caused by a change in fatty acid metabolism, weakness is hence classically not persistent. Inclusion body myositis classically produces distal to proximal weakness in middle-aged patients. BMD is hence the most appropriate answer.

BMD is an X-linked disorder of dystrophin, a component of skeletal muscle that reinforces the sarcolemma-glycoprotein complex and prevents degradation. Respiratory, cardiac and bulbarmanifestations are common. Diagnosis is made on clinical suspicion, raised CK, EMG suggestive of small polyphasic potentials, a muscle biopsy suggestive of dystrophinopathy and subsequent genetic testing.

Question 20 of 299

A 76-year-old right-handed female presents with sudden onset flaccid right upper and lower paralysis with complete dysphasia. Her daughter reports her to have been well two hours ago.

On examination, the patients score 0/5 on her right upper and lower limb, at least 4/5 on both left limbs (examination was difficult due to her dysphasia), with a loud carotid bruit. She is also now in atrial fibrillation, a new diagnosis for her. She is well known to the stroke team: 6 weeks ago, she was admitted with a right middle cerebral artery ischaemic stroke, leaving her with minimal residual weakness on her discharge.

During her admission, she was found to have 85% carotid stenosis in her right internal carotid artery and 75% in her left internal carotid artery, for which she declined surgery. Her other past medical history includes hypertension, type 2 diabetes mellitus and dyslipidaemia. She does not take any anticoagulants. A CT head demonstrates a hypodensity in the left middle cerebral artery area distribution, consistent with an acute ischaemic stroke with no areas of haemorrhagic transformation.

What is the most appropriate next course of action?

A. Intravenous alteplase
B. Clopidogrel 75mg
C. Aspirin 300mg
D. Treatment dose low molecular weight heparin
E. Warfarin

C. Aspirin 300mg

This patient has clearly had a new ischaemic stroke. Her NIHSS score and presentation within 4.5 hours would be sufficient to warrant consideration of thrombolysis. However, the key here is to identify the contraindication to thrombolysis: refusing carotid surgery recently is NOT a contraindication. However, a recent stroke or head trauma within 3 months is. The appropriate management would be to load the patient with 300mg aspirin. Clopidogrel 75mg is preferred 14 days after an ischaemic stroke. Anticoagulation is typically started 14 days after the acute stroke, possibly sooner in patients with small infarct sizes and hence a low risk of haemorrhagic transformation.

Question 21 of 299

A 72-year-old admitted to hospital with VF arrest. The ambulance crew reported an out-of hospital downtime for 3 minutes before CPR was commenced. In A&E resus, CPR was successful and the patient was intubated after the return of spontaneous circulation. 3 days later, on extubation, the ITU consultant notes confusion and bilateral upper limb weakness, confirmed to be new with a collateral history. A CT head, followed by MRI head, demonstrates bilateral small areas of ischaemic change in bilateral posterior parietal lobes, between middle and posterior cerebral artery territories. CT angiography demonstrates 45% RICA stenosis, 60% L ICA stenosis. The cardiac monitor demonstrates atrial fibrillation and echocardiogram demonstrates septal akinesia, consistent with recent MI.

What is the likely cause of this patient's stroke?

A. Cardiac mural thrombus
B. Left carotid artery stenosis
C. Right carotid artery stenosis
D. Hypotension during cardiac arrest
E. Cardioembolic disease

D. Hypotension during cardiac arrest

The neuroimaging describes a posterior watershed infarct, in which the areas of ischaemia lie in the most vulnerable regions of the brain in between two cerebral artery territories. Embolic disease and cardiac thrombi can produce bilateral symptoms. However, the specific areas involved suggest regions most prone to ischaemia during the period of systemic hypoperfusion. The two broad categories of differentials to consider include cardiac pump failure and hypovolaemia. In this case, hypoperfusion due to cardiac arrest is most likely.

Question 22 of 299

A 52-year-old male is brought to the emergency department by his concerned wife after tripping and falling down a flight of 12 stairs at home, hitting his head on the way down. The patient himself is not concerned and believes he could have stayed at home.

He denies having a headache, reports no nausea or vomiting, no seizures and did not lose consciousness between the fall and when you examine him. He is not taking any regular medications including anticoagulants and remembers the whole episode except for about 20 seconds after landing at the bottom of the floor. On examination, he has no limb weakness or loss of sensation. His pupils are equal and reactive bilaterally.

What is the most appropriate management?

A. Discharge, no further investigations required
B. Discharge, outpatient CT head within 72 hours
C. Observe for 24 hours and discharge if no deterioration
D. CT head immediately
E. CT head within 8 hours of injury

E. CT head within 8 hours of injury

CT head within 8 hours of injury is the correct answer according to NICE guidelines for head injury assessment. This patient has experienced a dangerous mechanism of injury (fall down >3 steps) and has retrograde amnesia (loss of memory for 20 seconds after the event), which are both risk factors that warrant a CT head scan within 8 hours, even in the absence of other concerning features.

CT head immediately would be indicated if the patient had additional concerning features such as GCS <13, focal neurological deficit, seizure, vomiting, or was on anticoagulation. As none of these are present, scanning within 8 hours rather than immediately is appropriate.

Observe for 24 hours and discharge if no deterioration would be excessive for this patient. Inpatient observation is typically reserved for patients with more concerning features or those who have had abnormal imaging. This would be an inefficient use of resources for this patient.

Discharge, outpatient CT head within 72 hours is inappropriate as the timeframe is too long. If imaging is indicated in head injury, it should be performed within 8 hours to identify potentiallyserious pathology that may require intervention.

Discharge, no further investigations required would be unsafe. While the patient appears well, the mechanism of injury and presence of retrograde amnesia mandate further investigation as per NICE guidelines. Missing an intracranial injury could have serious consequences.

The key principle in head injury management is to identify patients who require imaging based on risk factors, even if they appear well, as early intervention for intracranial pathology leads to better outcomes.

Question 23 of 299

A 19 year old woman presents to the general medical clinic for review. She has been referred due to drooping of her eyelids, first on the right and now bilaterally. On further questioning she reveals that she has been struggling to read in dim light and recalls that two family members have required insertion of cardiac pacemakers. Examination reveals partial bilateral ptosis and a generalised ophthalmoplegia in all directions of gaze. Fundoscopy demonstrates central areas of dark pigmentation on a pale fundus.

From the options given which investigation is most likely to reveal the diagnosis?

A. Serum for anti-acetylcholine receptor antibodies

B. Serum for anti-voltage gated calcium channel receptor antibodies
C. Muscle biopsy
D. Karotyping
E. Thyroid function tests

C. Muscle biopsy

A triad of chronic progressive external ophthalmoplegia, pigmentary retinopathy and cardiac conduction defects makes Kearns-Sayer syndrome likely.

Kearns-Sayer syndrome is an example of a mitochondrial disease, a group of rare conditions which many find confusing. Despite their rarity, those candidates who do a rotation in neurology are likely to encounter mitochondrial disease in one form or another and so a basic knowledge is useful.

Kearns-Sayer syndrome is characterised by ptosis and external ophthalmoplegia occurring in the first or second decades of life. Cardiac conduction defects usually occur later and are usually in the form of atrio-ventricular nodal block, often requiring cardiac pacing. Multiple endocrinopathies may be associated and a proximal myopathy may be evident. Serum elevation of lactate and pyruvate is frequently seen, as is the case with many mitochondrial conditions.

The diagnosis should be suspected from the history and clinical features as listed above and diagnosis is confirmed by muscle biopsy which demonstrates characteristic 'ragged red fibres', this is often supplemented by polymerase chain reaction analysis of mitochondrial DNA for mutation detection.

Anti-acetylcholine receptor antibodies are seen in myasthenia gravis, and would be involved in the work-up of any patient with an unexplained bilateral ptosis, but this wouldn't explain the pigmented retinopathy or the family history of pacemaker insertion. This is also the case for antivoltage gated calcium channel antibodies, found in the Lambert-Eaton myasthenic syndrome.

Question 24 of 299

A 70-year-old man with a history of hypertension and benign prostatic hypertrophy is brought in by ambulance after a fall. He reports he felt dizzy after standing up from his arm chair, stumbled and tripped over his cat. His wife, who witnessed the fall, reports that he then hit his head on the coffee table a lost consciousness for around 1 minute.

She describes no abnormal movements or incontinence. On regaining consciousness he was oriented immediately. He remembers regaining consciousness. He has no headache, dizziness, nausea or vomiting.

On examination, he has a small laceration on his forehead. His pupils were equal and reactive to light. He had no focal neurological deficits. He was a 15 on the Glasgow Coma Scale. His abbreviated mental test score was 10/10.

ECG: Sinus rhythm. 70 beats per minute. No T wave or ST segment changes.

- Blood pressure (lying): 135/75 mmHg
- Blood pressure (standing): 110/60 mmHg
- Haemoglobin 135 g/dl
- Troponin T 1 ng/L
- Urine dip: trace of protein

What is the most appropriate course of action?

A. Admit for CT head within 1 hour
B. Admit for CT head within 8 hours
C. Admit for CT head within 24 hours
D. Discharge to return for CT head next day
E. Discharge with outpatient follow-up, no imaging required

B. Admit for CT head within 8 hours

Nice Guidelines on head injury state that: For adults who have sustained a head injury and have any of the following risk factors, perform a CT head scan within 1 hour of the risk factor being identified:

- GCS less than 13 on initial assessment in the emergency department.
- GCS less than 15 at 2 hours after the injury on assessment in the Emergency Department.
- Suspected open or depressed skull fracture.
- Any sign of basal skull fracture (haemotympanum, 'panda' eyes, cerebrospinal fluid leakage from the ear or nose, Battle's sign).
- Post-traumatic seizure.
- Focal neurological deficit.
- More than 1 episode of vomiting.'

The patient does not meet any of these criteria, so CT head within 1 hour is not mandatory. The guideline then also states:

'For adults with any of the following risk factors who have experienced some loss of consciousness or amnesia since the injury, perform a CT head scan within 8 hours of the head injury:

A. Age 65 years or older.
B. Any history of bleeding or clotting disorders.
C. Dangerous mechanism of injury (a pedestrian or cyclist struck by a motor vehicle, an occupant ejected from a motor vehicle or a fall from a height of greater than 1 metre or 5 stairs).
D. More than 30 minutes' retrograde amnesia of events immediately before the head injury.'

As this gentleman had a period of unconsciousness and is over 65, he should have a CT head within 8 hours.

Question 25 of 299

A 32-year-old man had a compressive pituitary macroadenoma surgically removed in France 4 weeks ago and has been on pituitary hormone replacement since, including growth hormone. Surgery was uncomplicated and he initially made a good recovery. He has no other past medical history. He has now developed, over the last 1-2 weeks, poor balance, with a broad-based gait. He has also become extremely forgetful. On examination, he has an ataxic gain and you also observe occasional myoclonic limb movements. His MMSE

score is 22/30. Clinical examination is otherwise unremarkable, as are routine blood investigations.

Given the likely diagnosis, what might you expect to find on his MRI brain?

A. Areas of demyelination in the cerebellum
B. An area of high T2 signal in the right middle cerebral artery territory with restricted diffusion on diffusion-weighted sequences
C. High T2 signal in the posterior thalamus
D. Leptomeningeal enhancement
E. Loss of grey-white matter differentiation

C. High T2 signal in the posterior thalamus

The diagnosis is Creutzfeldt-Jakob disease (CJD) from an iatrogenic source.

The use of prion-contaminated medication, grafts and instruments may result in iatrogenic CJD. The current worldwide total of growth-hormone-associated cases of CJD is 226. Most cases occurred in France (119 cases/1,880 recipients; attack rate 6.3%), the United Kingdom (65 cases/1,800 recipients; attack rate 3.6%), and the United States (29 cases/7,700 recipients; attack rate 0.4%). No new case has been identified since 2008 but would be important to recognise this condition and how it presents if it did, as it is invariably fatal -so patients need to be made aware of their prognosis.

The clinical features of the disease vary according to the route of inoculation.

Central inoculation, eg from infected neurosurgical instruments, results in a rapidly progressive neurodegenerative disease similar to sporadic CJD, characterised by ataxia, dementia, myoclonus, rigidity, and akinetic mutism. Survival is 2-12 months.

Peripheral inoculation, eg from the use of the old human growth hormone products, results in a slightly less acute disease - characterised by progressive cerebellar ataxia and dementia. Survival is 8-18 months.

Question 26 of 299

A 75 year old man with Parkinson's disease is brought to see you in clinic by his son. He has become increasingly concerned that his neighbours have been watching him, and have put wiring throughout his walls to monitor his movements. He has also been describing visual hallucinations of animals climbing up his walls. His son is concerned that he has become increasingly anxious. He is currently on co-careldopa, ropinirole, and rasagiline.

What is the best course of action?

A. Initiate a 'drug holiday' withholding all but co-careldopa for 1 week
B. Reduce ropinirole
C. Reduce rasagiline
D. Refer for cognitive behavioural therapy
E. Start quetiapine

B. Reduce ropinirole

This gentleman is displaying psychotic symptoms. Psychosis in Parkinson's disease (PD) can be due to the disease process itself (non-motor feature of PD), or medication side effect. It is sensible to perform a medication review and alter any potentially precipitating drugs.

Ropinirole is a dopamine agonist and is associated with psychosis, and in particular visual hallucinations. It is also important to warn all patients initiated on dopamine agonists of the potential for impulsive behaviour disorders including gambling and excessive spending.

Abrupt discontinuation of medication is never indicated in Parkinson's disease since this can lead to rapid deterioration and worsening of symptoms.

Question 27 of 299

You are asked for advice on a 57-year-old man who presented to primary care 12 weeks after an inferior myocardial infarction. He has had symptoms of persistent low mood that varies during the day, tearfulness and hopelessness. He has lost 6kg of weight in the past 3 months and his BMI is currently 19. He has fleeting thoughts of suicide but would not act on this as he does not want to hurt his family. You are told that 20 years ago, following an overdose of paracetamol, he was prescribed Citalopram and diagnosed with depression.

The GP tells you that other than the recent MI, he also has a diagnosis of Atrial Fibrillation, for which he is on warfarin and he has suffered from epigastric pain for the past 2 years. He had an OGD 1 year ago where treatment of a duodenal ulcer with adrenaline was required. Since then his symptoms of epigastric pain have decreased but are still present. There has been no repeat OGD.

What would be the safest course of action?

A. Prescribe Phenelzine
B. Prescribe Sertraline
C. Prescribe Mirtazapine
D. Prescribe Imipramine
E. Refer for 2 month wait CBT

C. Prescribe Mirtazapine

The answer is C Mirtazapine. E is an unsafe option because of the significant amount of weight loss to a point where is BMI is close to him being underweight. 2 months is too long to wait to offer an intervention

Sertraline is an SSRI. SSRIs are known to interfere with platelet aggregation and increase the risk of a GI bleed. As this individual has a history of a bleeding duodenal ulcer and continuing symptoms, Sertraline would be an unsafe option. SSRIs also interact with warfarin

Phenelzine is a MAO inhibitor and Imipramine is a TCA. TCAs have been linked to ischaemic heart disease and sudden cardiac death. TCAs are contraindicated in those with a history of ischaemic heart disease. TCAs are also dangerous in overdose which may be a significant risk for this individual. MAO inhibitors are thought to be arrhythmogenic and decrease LVF. They are notrecommended in those with cardiovascular disease.

Mirtazapine is a good choice as it is not known to cause cardiac conduction disturbances and there is good evidence of its safety post-MI. It also causes increased appetite and weight gain which would be advantageous for this individual at this time. Mirtazapine does not interact with warfarin and it does not affect platelet aggregation. Generally speaking, Mirtazapine is a safe drug and is often prescribed for the elderly and people with multiple medical problems. Mirtazapine is also relatively safe in overdose to other antidepressants.

Question 28 of 299

A 28-year-old female psychiatric nurse presents to the emergency department following a 2minute tonic-clonic generalised seizure, which self-terminated. Whilst taking the history the following morning, she tells you that over the last 48 hours she has become increasingly unwell. She has been feeling increasingly anxious and has been having insomnia and vivid nightmares which wake her from sleep. She says that everything around her no longer looks real but more like a photocopy. Bowel and bladder movements have been normal. She feels generally weak and asks the lights to be dimmed in the examination room. When the nurse bell goes off in the next cubicle, she has to cover her ears.

On examination, she appears anxious, she is perspiring, respiratory rate 16/min, blood pressure 142/86 mmHg, heart rate 115/min regular, sats 98% on air. You notice a fine tremor, especially in the hands and eyelids. GCS = 15. Oriented in time place and person. When you examine her, she tells you that it feels as if her legs are floating off the bed even though they are stationary. There is no flushing of the face

From looking at the computer records, you can see that she has a history of panic disorder treated with PRN lorazepam and sertraline 1 year ago. and has been treated for depression in the past. You also note from your records that she presented to A+E 5 days ago due to stress as she was sacked from her job.

Hb	136 g/l
Platelets	232 * 10 /l
WBC	6.9 * 10 /l
Na	142 mmol/l
K	3.8 mmol/l
Urea	6.2 mmol/l
Creatinine	81 µmol/

What is the most likely diagnosis?

A. Benzodiazepine withdrawal
B. Atypical Panic attack secondary to panic disorder
C. LSD intoxication
D. Benzodiazepine excess
E. Opiate withdrawal

A. Benzodiazepine withdrawal

Benzodiazepine withdrawal can cause physical symptoms such as tachycardia, sweating, fine tremor which is more prominent in the tongue, eyelids and hands. It can also cause nightmares and insomnia, anxiety and phobic symptoms as well as seizures, hypersensitivity to light, sounds and touch. They can also experience derealisation (an unpleasant subjective experience that the outside world does not look real to them) and kinaesthetic hallucinations. Other symptoms include malaise and tinnitus and it sometimes can present as a delirium.

Some factors in the history also point towards this as being a likely diagnosis. She has a history of panic disorder and previous prescription for benzodiazepines when she may have developed dependence. As a psychiatric nurse, she may have access to benzodiazepines off prescription. The fact that she has recently lost her job may mean that she has run out of her supply and is now suffering from withdrawal syndrome.

An overdose of benzodiazepines would not present with tachycardia, sweating and anxiety. LSD intoxication could present with hallucinations, anxiety, tachycardia and sweating, however the duration of symptoms is too long for LSD unless multiple doses were taken and LSD intoxication. LSD is not linked to causing seizures. This presentation has many features of a panic attack but would not explain the seizure or kinaesthetic hallucination.

Opiate withdrawal could present in a similar way, however, you would expect to see a marked degree of GI disturbance in this syndrome and is not linked with kinaesthetic hallucinations or derealisation. In this question, the history of previous benzodiazepine usage makes this answer less likely

Question 29 of 299

A 64 year old man presented to the Emergency Department after becoming unwell at home. His wife reported that the patient experienced a sudden onset and severe headache while watching television. Shortly afterwards she found him to have become confused and drowsy and an ambulance was called. On arrival in the Emergency Department, the patient suffered a witnessed tonic-clonic seizure, self-terminating after two minutes.

The patient had known hypertension and hypercholesterolaemia and had suffered a non-ST elevation myocardial infarction two years before, treated with a drug-eluting stent to the left anterior descending artery. Regular medications included ramipril 10 mg OD, bisoprolol 10 mg OD, bendroflumethiazide 2.5 mg OD, simvastatin 40 mg OD and aspirin 75 mg OD. The patient's wife reported that compliance with anti-hypertensive medications had been inconsistent and that controlling the patient's blood pressure had been an on-going problem over the previous two years. The patient was a retired builder and ex-smoker.

On examination, the patient was drowsy (GCS M4V2E3) but was protecting his own airway. Pupils were equal and reactive. The patient was spontaneously moving all his limbs and had downgoing plantar reflexes. Cardiovascular, respiratory and abdominal examination was unremarkable. Initial observations and investigations are listed below.

Blood pressure 220 / 115 mmHg Heart rate 89 beat / minute O2 sats (15 L O2) 100 % Respiratory rate 19 / minute Temperature 37.1ºC.

CT brain: no extra-axial bleeding or collection; no intracerebral haemorrhage; no evidence acute ischaemic stroke; no subarachnoid blood; normal ventricular system; mild small vessel disease in keeping with patient's age.

Lumbar puncture:

CSF red cells	3/ mm³
CSF white cells	3 / mm³
CSF gram stain	unremarkable
CSF glucose	60 % serum level
protein	0.5 g / L
CSF	negative for bilirubin and xanthochromia

Given persistent reduced GCS and need to obtain blood pressure control, patient was intubated and transferred to the neuro intensive care unit. Following discussion with neurological team further imaging was arranged

MR brain with angiography: structurally normal brain as per previous study; bilateral symmetric vasogenic oedema involving the subcortical white matter in the parietal-occipital, posterior temporal and posterior frontal lobes; MRA unremarkable without any area of stenosis or vasospasm.

What is the correct diagnosis?

A. Reversible cerebral vasoconstriction syndrome
B. Posterior reversible leucoencephalopathy syndrome
C. Acute disseminated encephalomyelitis
D. Cerebral venous thrombosis
E. Pituitary apoplexy

B. Posterior reversible leucoencephalopathy syndrome

Posterior reversible leucoencephalopathy syndrome may present with thunderclap headache, usually followed rapidly by confusion, seizures and visual symptoms. CT brain and lumbar puncture results are usually normal or near normal. The most common causes of PRES are hypertensive encephalopathy (as in this case) and eclampsia. Hypertension is commonly observed. Diagnosis is made by evidence of vasogenic brain oedema on MRI brain. PRES is often associated with reversible cerebrovascular vasoconstriction syndrome with vasospasms on angiography (although not in this case). Acute disseminated encephalomyelitis does not present with thunderclap headache.

Cerebral sinus thrombosis and pituitary apoplexy can both present with thunderclap headache and normal CT brain and LP although the other results and clinical picture in this case are not consistent with these diagnoses. Acute disseminated encephalomyelitis does not present with thunderclap headache.

Question 30 of 299

A 61-year-old man is referred neurology after he noticed a tremor. He has a tremor affecting both his arms and his wife has noticed he is slow with activities and has struggled with his balance more recently. Further questioning revealed the patient has had some issues with urinary incontinence and erectile dysfunction.

His past medical history includes hypertension, myocardial infarction and hypercholesterolaemia. He takes ramipril, bisoprolol, aspirin and simvastatin.

On examination, he is found to increased tone, but power was normal. However, his coordination was impaired. The rest of the physical examination was normal. His GP did some blood tests prior to the referral, the results of which are shown below:

Thyroid stimulating hormone (TSH)	0.4 mU/L	(0.5-5.5)
Free thyroxine (T4)	12 pmol/L	(9.0 - 18)
Hb	125 g/L	(135-180)
WBC	5.7 * 10 /L	(4.0 - 11.0)
Na	139 mmol/L	(135 - 145)
K	4.3 mmol/L	(3.5 - 5.0)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	148 µmol/L	(55 - 120)

What is the most likely cause of this man's presentation?

A. Idiopathic parkinson's disease
B. Multiple system atrophy
C. Progressive supranuclear palsy
D. Drug induced parkinsonism
E. Hyperthyroidism

B. Multiple system atrophy

Erectile dysfunction is an early autonomic feature of multiple system atrophy

This patient has presented with Parkinsonism (tremor, bradykinesia and rigidity). There are lots of causes of Parkinsonism.

In this case, the clues to working out the diagnosis are the balance issues, coordination problems, urinary incontinence and in particular the erectile dysfunction. This points to a diagnosis of multiple system atrophy.

In Parkinson's disease, the onset of tremor is usually unilateral at the beginning. It is typically described as being present at rest and disappears on movement. Other features include micrographia.

Progressive supranuclear palsy is a Parkinson's plus syndrome. Differentiating features are difficulty with moving the eyes vertically, slurring of speech and difficulty swallowing.

Drug-induced Parkinsonism is usually seen with antipsychotics and is reversible upon cessation of the causative drug. None of the medications listed cause drug-induced Parkinsonism.

Tremor can be a feature of hyperthyroidism. However, there are no other features in the history to support this diagnosis such as weight loss despite increased appetite, heat intolerance, sweating, diarrhoea etc.

Question 31 of 299

A 78-year-old man presents to the acute medical unit with an episode of loss of consciousness. He states that he suffered a headache earlier that day. He describes it as a sudden onset headache at the back of his head which reached 10/10 severity within a few seconds.

You organise the following investigations: CT head Blood in the sulci, fissures, basal cisterns and ventricles

What is the next most appropriate management?

A. Cerebral CT angiography

B. Lumbar puncture
C. MRI head
D. Endovascular clipping
E. Endovascular coiling

A. Cerebral CT angiography

In non-traumatic subarachnoid haemorrhages, a CT angiogram should be performed to identify intracranial aneurysms

The CT scan has confirmed a subarachnoid haemorrhage (SAH). As it is spontaneous, and not traumatic, it is likely to be an aneurysmal SAH. However to confirm this the patient needs urgent angiography - either CT or MRI. Once an aneurysm is confirmed radiologically the patient can undergo endovascular clipping or coiling.

A lumbar puncture is not indicated in this case as the CT has confirmed the diagnosis of SAH. A lumbar puncture should be performed 12 hours after the onset of headache in patients who have a negative CT scan.

MRI head would confirm a haemorrhage, however angiography is required to definitively confirm an aneurysm.

Question 32 of 299

A 18-year-old man presents to the clinic complaining of both motor and verbal tics which are causing embarrassment. He was diagnosed with Tourette syndrome when he was 14-years old. He initially tried habit reversal therapy (HRT), which partially worked however his symptoms are now the worst they have ever been. He has no other significant past medical history and takes no regular medicines.

You decide to prescribe a drug which will block the effects of dopamine in the basal ganglia.

What treatment will you prescribe?

A. Methylphenidate
B. Risperidone
C. Dextroamphetamine
D. Lamotrigine
E. Clozapine

B. Risperidone

Antipsychotics have the greatest efficacy at treating tics

Tics are classed as a hyperkinetic movement disorder consisting of repetitive, stereotyped motor or vocal movements that may be simple or complex. There is an urge to perform the movement with relief after performing the movement. They are caused by enhanced dopamine levels. Therefore dopamine antagonists such as the antipsychotics are first line pharmacological agents. Both risperidone and clozapine are antipsychotics, however due to the potentially life threatening side effects of clozapine (e.g. myocarditis and neutropaenia) it is reserved as a third line agent.

Methylphenidate, dextroamphetamine, and, lamotrigine are known drug induced causes of tics.

Question 33 of 299

A 24-year-old man presents with lower limb weakness. He states that he had an episode of food poisoning two weeks ago which consisted of severe abdominal pain and profuse non-bloody diarrhoea. Following this he noticed progressive weakness in his legs. His past medical history is largely unremarkable, however, he does admit to intravenous drug use with heroin. He last injected heroin three weeks ago.

On examination, you note weakness of ankle plantar flexion (MRC grade 3), ankle dorsiflexion (MRC grade 3), knee flexion (MRC grade 4) and knee extension (MRC grade 4). The ankle jerk and knee jerk are only present on reinforcement. There is a loss of sensation to the mid-calves. A neurological examination was otherwise unremarkable.

What is the most likely diagnosis?

A. Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
B. Acute motor axonal neuropathy (AMAN)
C. Botulism
D. Miller Fisher syndrome
E. Tetanus

A. Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)

Worsening lower limb weakness following gastroenteritis - think Guillain-Barre

Acute inflammatory demyelinating polyradiculoneuropathy (AIDP) is correct. The most likely diagnosis is Guillain-Barre syndrome. The clinical features are most in keeping with AIDP which is the most common subtype. The preceding gastroenteritis is classic of this condition with approximately 30% of cases being provoked by Campylobacter jejuni infection.

Acute motor axonal neuropathy (AMAN) is incorrect. This is a less common subtype of Guillain Barre syndrome which presents with motor involvement only. There is often early and severe respiratory involvement. The presence of sensory involvement, in this case, makes this a less likely diagnosis.

Botulism is incorrect. Botulism is characterised by a descending, flaccid paralysis, in contrast to Guillain-Barre syndrome which presents with an ascending paralysis. It is important to note that the patient is an intravenous drug user which is a risk factor for botulism. However, this method of transmission would not explain the gastroenteritis features. These can of course be related to food-borne botulism, however regardless the clinical features of an ascending paralysis are more in keeping with Guillain-Barre syndrome.

Miller Fisher syndrome is incorrect. This subtype of Guillain-Barre syndrome is characterised by areflexia, ophthalmoplegia, and ataxia. Limb weakness in this subtype is uncommon making this a less likely diagnosis.

Tetanus is incorrect. Tetanus is a life-threatening disease characterised by a descending spastic paralysis. Although the causative bacteria Clostridium tetani has been found in contaminated heroin, the clinical features of an ascending paralysis are more suggestive of Guillain-Barre syndrome.

Question 34 of 299

A 23-year-old man is brought into the Emergency Department with a severe headache.

He was awoken from sleep early this morning with the most severe headache he has ever experienced. He describes an immediate onset posterior headache that has not improved at all. He has felt his vision slightly blurred and vomited 3 times since his arrival in the department. You perform an urgent CT brain which reveals a subarachnoid haemorrhage.

What investigation is now indicated?

A. CT angiogram
B. Digital subtraction angiography
C. Lumbar puncture
D. MRI brain
E. Ophthalmoscopy

A. CT angiogram

In non-traumatic subarachnoid haemorrhages, a CT angiogram should be performed to identify intracranial aneurysms

The next step when a subarachnoid haemorrhage is confirmed is to determine whether the haemorrhage is aneurysmal or not and so the correct answer is a CT angiogram.

Subarachnoid haemorrhage has been confirmed on plain CT and so a lumbar puncture to look for xanthochromia is not necessary and therefore incorrect. This would be the correct answer if CT had not revealed a cause for the headache and you were still suspicious of a subarachnoid haemorrhage.

MRI brain is incorrect. It will not necessarily show an aneurysm so may not be helpful and anangiogram would still need to be performed.

Digital subtraction angiography is incorrect. It is sometimes performed by neurosurgeons or interventional radiology to look for an aneurysm but CT angiography is quicker and safer to confirm this.

Ophthalmoscopy is also incorrect and has little value here as the diagnosis and raised intracranial pressure are already known.

Question 35 of 299

A 35-year-old female presents to the Emergency Department with worsening lower limb weakness over a three day period. She is now unable to walk and feels that her fingers are becoming clumsy. On examination her heart rate is 65 beats per minute and regular, her blood pressure is 125/70 mmHg and her respiratory rate is 20 breaths per minute. She has absent ankle and knee jerks and reduced reflexes in the upper limbs.

Her cerebrospinal fluid (CSF) study shows an elevated protein with a normal white cell count.

Given her likely diagnosis, which of the following parameters is most important to measure throughout her admission?

A. Lower limb power
B. Serial CSF protein levels
C. Forced expiratory volume over 1st second (FEV1)
D. Postural blood pressure
E. Forced vital capacity (FVC)

E. Forced vital capacity (FVC)

FVC is used to monitor respiratory function in Guillain-Barre syndrome

The most common cause of death in patients with the severe Guillain-Barre Syndrome (GBS) is respiratory failure. This is due primarily to weakness in chest wall muscles, but may also be due to bulbar dysfunction and aspiration. Patients may require intensive care admission and ventilatory support.

For this reason, it is of great importance that forced vital capacity (FVC) is measured on a routine basis and results documented so that additional support can be sought as soon as possible. FEV1 may be preserved in early deterioration as it is not a measure of vital capacity or a marker of chest wall expansion. Therefore, a reduction in FVC is a more sensitive marker of deterioration.

Question 36 of 299

A 17-year-old man is referred by the emergency department with weakness of his lower limbs and hands, worsening over the last 2 days. He is having increasing difficulty walking and is becoming very clumsy and dropping things. He burnt his hand yesterday in the kitchen without realising until afterwards that he had done it. He also complains of feeling dizzy on standing but has no chest pain or palpitations. He is normally fit and well, although did suffer a bought of diarrhoea and vomiting 4 weeks ago. He is on no regular medication and denies any alcohol or smoking history.

On examination he is afebrile, his blood pressure is 128/79 mmHg on lying but on standing it drops to 90/60 mmHg. His respiratory rate is 20/min and his saturations are 97% on air. His cardiovascular, respiratory and abdominal examinations are normal. Neurological examination reveals symmetrical distal weakness of his lower limbs with relative proximal sparing and altered sensation to fine touch, vibration and proprioception. He has similar findings in his upper limbs. He is suspected of having Guillain-Barre syndrome and following blood tests, CT head and lumbar puncture is started on IV immunoglobulins. Despite this, he begins to become increasingly short of breath and he is referred to ITU for respiratory support.

What respiratory parameter is used to determine if invasive ventilator support is needed?

A. pO2 on ABG < 8kPa
B. FEV1:FVC ratio < 0.7
C. Saturations on 15 litres O2 less than 93%
D. FVC < 15ml/kg
E. Peak flow of less than 300ml

D. FVC < 15ml/kg

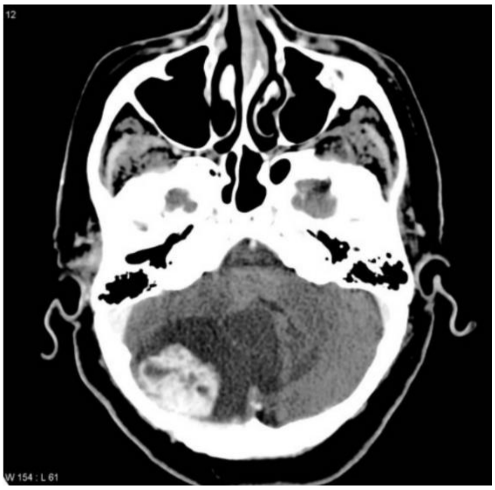
FVC is used to monitor respiratory function in Guillain-Barre syndrome

This man has Guillain-Barre syndrome with autonomic involvement and compromise to his respiratory function. The parameter used to assess whether a patient needs ventilator support is an FVC <15-20ml/kg. low pO2, low saturations and low peak flow are all indicatory of poor respiratory function but FVC is the parameter used in these cases. FEV1:FVC ratio is not used.

Question 37 of 299

A 26-year-old man is admitted for investigation after having increasing trouble walking. On admission he is found to have a severely ataxic gait and is unable to walk in a straight-line. For many weeks he has been complaining of visual problems, dizziness, headaches and clumsiness.

On examination he is noted to have horizontal nystagmus, an intention tremor and past pointing. On fundoscopy a large, erythematous retinal lesion is present surrounded by tortuous, dilated vessels.



His father had similar problems in his 20's. A CT scan is arranged:

What is the most likely underlying diagnosis?

A. Friedreich's ataxia
B. Ataxic telangiectasia
C. Neurofibromatosis
D. Tuberous sclerosis
E. Von Hippel-Lindau syndrome

E. Von Hippel-Lindau syndrome

Von Hippel-Lindau syndrome

Retinal + cerebellar haemangiomas = Von Hippel-Lindau syndrome

The correct answer is Von Hippel-Lindau syndrome. Von Hippel-Lindau (VHL) syndrome is a rare, autosomal dominant disorder characterized by the development of various benign and malignant tumours, including hemangioblastomas in the central nervous system (CNS), retinal angiomas, renal cell carcinomas, and pheochromocytomas. The patient's presentation with ataxia, nystagmus, intention tremor, past pointing, and a retinal lesion surrounded by dilated vessels is highly suggestive of CNS hemangioblastoma and retinal angioma associated with VHL. A cerebellar lesion is also clearly seen in the neuroimaging. The family history of similar problems in his father also supports this diagnosis.

Friedreich's ataxia is an autosomal recessive inherited disorder that primarily affects the spinal cord and peripheral nerves. It typically presents with progressive limb and gait ataxia, dysarthria, loss of deep tendon reflexes, sensory neuropathy, and skeletal deformities such as scoliosis. Although Friedreich's ataxia can cause some similar neurological symptoms to VHL syndrome (e.g., ataxia), it does not explain the retinal lesion or strong family history seen in this case.

Ataxic telangiectasia, also known as Louis-Bar syndrome or Ataxia-telangiectasia (A-T), is an autosomal recessive disorder characterized by cerebellar degeneration leading to progressive ataxia along with oculocutaneous telangiectasias. Patients often present with recurrent sinopulmonary infections due to immunodeficiency. While some features like ataxia overlap with VHL syndrome in this case, A-T would not account for the retinal lesion or CT scan findings.

Neurofibromatosis refers to a group of genetic disorders causing the development of benign tumours, most commonly neurofibromas, in the nervous system. There are two main types: Neurofibromatosis type 1 (NF1) and Neurofibromatosis type 2 (NF2). NF1 is characterized by multiple cafe-au-lait spots, axillary and inguinal freckling, Lisch nodules in the iris, and neurofibromas. NF2 is associated with bilateral vestibular schwannomas (acoustic neuromas), meningiomas, and ependymomas. Neither type of neurofibromatosis would explain the retinal lesion or specific neurological symptoms seen in this case.

Tuberous sclerosis is an autosomal dominant disorder characterized by the formation of benign hamartomas in multiple organs including brain, skin, kidneys, heart, lungs, and eyes. Common features include seizures, cognitive impairment, facial angiofibromas, ash leaf spots on the skin and renal angiomyolipomas. Although some aspects of this syndrome might overlap with VHL syndrome (e.g., CNS involvement), it does not account for the specific retinal lesion described or other clinical findings in this case.

Question 38 of 299

A 32-year-old man is admitted to the neurology ward with a new leg weakness. He describes progressive weakness of his legs and now also his hands, which initially started 7 months ago and has progressed very slowly. He has minimal sensory disturbance in all four limbs but on examination of the legs he has grade 3/5 power throughout with absent reflexes and tone is not raised. He has no past medical history and no recent travel. A set of bloods on admission show the following:

Hb	141 g/l (115-165 g/l)	Na	141 mmol/l (135-145 mmol/l)
Platelets	301 x 10 /l (150-450 x 10 /l)	K	4.1 mmol/l (3.5-5.2 mmol/l)
WBC	6.7 x 10 /l (2-11 x 10 /l)	Urea	4.1 mmol/l (2.5-6.5 mmol/l)
Neuts	5.1 x 10 /l (1.5-7 x 10 /l)	Creatinine	81 µmol/l (60-100 µmol/l)
Lymphs	1.2 x 10 /l (0.5-1.5 x 10 /l)	CRP	0.9 mg/l (<5 mg/l)

A non-contrast CT head and a diagnostic lumbar puncture are also performed which show the following:

CT Head	No mass lesions, haemorrhage or acute major territory infarct seen. Ventricles of normal diameter. No skull vault fractures.

CSF Protein	611 mg/l (140-450 mg/l)
CSF WBC	1 x 10 /l (<5 x 10 /l)
CSF Glucose	2.9 mmol/l (2.3-4.5 mmol/l)
CSF Electrophoresis	Normal pattern of IgG banding

Given the most likely diagnosis, which of the following treatments is most appropriate for this patient?

A. Conservative management
B. Therapeutic lumbar puncture
C. Intravenous antimicrobials
D. Intravenous immunoglobulin
E. High-dose steroids

E. High-dose steroids

CIDP is like GBS but with a more chronic onset and treated with steroids

From the history and clinical findings here, the most likely diagnosis would be chronic inflammatory demyelinating polyneuropathy or CIDP. The two main differentials would be Guillain-Barre syndrome and multiple sclerosis. Guillain-Barre syndrome would be a far more acute presentation with a rapid deterioration and multiple sclerosis would not produce such a global picture and in addition there would also be oligoclonal bands present on electrophoresis of the CSF. The chronic picture and high CSF protein are both in keeping with a diagnosis of CIDP above the others.

CIDP is an autoimmune inflammatory neuropathy which has an ongoing disease process and thus it responds well to immunosuppressive therapy. The most appropriate first line therapy therefore is high-dose steroids as this will achieve the goal of reducing inflammation and immunosuppressing a patient with a single drug. Therapeutic lumbar punctures are not indicated as there is no evidence for this being due to benign intracranial hypertension and antibiotics are also not indicated given the lack of infection markers.

Question 39 of 299

A 27-year-old man is brought to the hospital having become unwell at a party. On arrival, he is drowsy and only responds to voice. His airway appears patent and his chest is clear. Pupils are 4mm and reactive to light. Observations are as follows.

- Respiratory rate 12 breaths /min
- Oxygen saturations 95% on air
- Heart rate 84 beats /min
- Blood pressure 117/65mmHg
- Temperature 36.7ºC

Due to his reduced conscious level, you organise a CT head. While there, a friend phones the hospital and tells you he was seen taking some tablets at the party roughly 90 minutes ago and they have since found empty packets of diazepam in the house.

He returns from CT head which is reported as normal. You are asked to see him urgently as he is now unresponsive and making snoring sounds. These improve with a jaw thrust but recur if this is released. The examination is otherwise the same as on arrival.

What is the best course of action?

A. Activated charcoal
B. Flumazenil
C. Haemodialysis
D. Intubation and ventilation
E. Naloxone

D. Intubation and ventilation

Benzodiazepine overdose is best managed supportively and with airway protection and ventilation if needed. Flumazenil should be avoided unless for reversal of anaesthesia

The correct answer is intubation and ventilation. Drug ingestion leading to CNS depression is common and may be due to a variety of substances. This picture with normal observations and normal pupils should raise the suspicion of benzodiazepine use, especially with the empty packets found at the house. The mainstay of treatment in such a case is supportive, with securing the airway the main priority in the case described.

Activated charcoal is incorrect. This can bind some substances and minimise their effects if given sufficiently early after ingestion. However, its role in benzodiazepine overdose is uncertain. Toxbase advises that it can be considered within the first hour after ingestion provided the airway is protected. In this case, the patient is ou twith this timeframe and the airway is unsafe.

Flumazenil is incorrect. This antidote is effective in reversing the effects of benzodiazepine toxicity. However, reversal of an unknown quantity can lead to rebound seizures which are then refractory to benzodiazepine therapy as the receptor is blocked by the drug. Flumazenil should generally only be used in an iatrogenic overdose where the exact quantity is known. In all other cases, supportive treatment such as airway management is the mainstay.

Haemodialysis is incorrect. This is used for the removal of some toxic agents such as lithium. However, it does not remove benzodiazepines and would not be effective here.

Naloxone is incorrect. This is a highly effective antidote for opiate toxicity and acts quickly enough that it could avoid the need for intubation in such cases. However, the clinical picture is not suggestive of opiate toxicity. This generally presents with other features such as myoclonic jerks and pinpoint pupils. Opiates are also more commonly used by injection rather than as tablets.

Question 40 of 299

A 37-year-old man is being reviewed in the eye clinic for painless loss of vision bilaterally. The symptoms started 1 year ago when he initially developed central scotomas, followed by loss of colour vision and ultimately loss of all vision. He has no significant past medical history.

On examination, visual acuity is 3/60 in both eyes. Fundoscopy reveals optic atrophy in both eyes, with narrow vessels and absent macular reflexes. An MRI scan of the brain shows significantly lower optic nerve volumes than normal. His mother also lost her vision at 34 years of age. His brother and sister, who are both a few years older, developed the same symptoms several years ago.

What is the most likely diagnosis?

A. Autosomal dominant optic atrophy (ADOA)
B. DIDMOAD syndrome
C. Leber's optic atrophy
D. MELAS syndrome
E. Optic neuritis

C. Leber's optic atrophy

30-years-old, central scotoma → loss of colour vision → rapid onset of significant visual impairment ? Leber's optic atrophy

The history of central scotoma, colour blindness, and rapid onset of visual impairment point in an adult male point toward a diagnosis of Leber's optic atrophy in this scenario. A history of a similar illness in the mother and all siblings confirms the mitochondrial pattern of inheritance in which all children of an affected mother inherit the disease. Diagnosis of mitochondrial disease is confirmed by muscle biopsy showing ragged red fibres due to an increased number of mitochondria.

Although optic atrophy is a prominent feature of autosomal dominant optic atrophy (ADOA) , vision loss in ADOA occurs in late childhood or early adolescence. The onset of vision loss in ADOA is gradual and not rapid as in this scenario. The pattern of inheritance described is mitochondrial and not autosomal dominant, therefore this option is incorrect.

MELAS syndrome is characterised by mitochondrial encephalomyopathy lactic acidosis and stroke-like episodes. There is no history of seizures, weakness, metabolic disturbances, or altered consciousness and so MELAS is an unlikely diagnosis here.

The family history in this scenario demonstrates mitochondrial inheritance and effectively rules out acquired/autoimmune causes of vision loss such as optic neuritis. Optic neuritis is usually associated with multiple sclerosis, diabetes mellitus, or recent infection.

Optic atrophy and vision loss in DIDMOAD syndrome occur in childhood or adolescence. Optic atrophy in DIDMOAD syndrome is accompanied by diabetes insipidus, diabetes mellitus, and sensorineural deafness. The unremarkable past medical history of this patient rules out this diagnosis.

Question 41 of 299

A 62-year-old man develops difficulty in breathing seven hours following thyroidectomy for hyperthyroidism. He has been finding it more difficult to breathe over the last one hour and feels like his neck is tighter than it was. He has a past medical history of COPD, ischaemic heart disease and angina. He normally takes aspirin, ramipril, Symbicort, bisoprolol and atorvastatin, but has not been taking aspirin for the last week in preparation for surgery. On examination his chest is clear and heart sounds are normal. The neck wound is dressed and there is a small amount of strikethrough bleeding. His heart rate is 90 bpm, his blood pressure is 156/82mmHg and his oxygen saturations are 89% on room air. His calves are soft and non-tender.

What is the most appropriate plan?

A. Page the surgical and anaesthetic registrar urgently
B. Start salbutamol and ipratropium nebulisers
C. Give a stat dose of aspirin, clopidogrel and fondaparinux
D. Give a stat treatment dose of heparin
E. Request and urgent CT neck

A. Page the surgical and anaesthetic registrar urgently

Difficulty in breathing due to immediate heamatoma is an emergency and needs immediate action

This patient has likely a haematoma following thyroid surgery. This can cause laryngeal oedema which can be fatal. It is critical to secure the airway early, as allowing oedema to progress can make intubation more difficulty, and subsequently for the surgical team to relieve the haematoma. As the chest is clear this is unlikely to be an exacerbation of COPD, and the absence of chest pain makes acute coronary syndrome or pulmonary embolism unlikely.

Question 42 of 299

A 33-year-old female is referred to the neurology outpatient department by her general practitioner. She complains of five months of excruciating right-sided throbbing headaches, localized to the temporal region. The headaches start and stop abruptly and last for approximately 15 minutes at a time. They occur 9-12 times a day and are associated with nasal congestion and rhinorrhoea. There is no significant past medical history and she is not on any regular medications. She has a family history of migraine and smokes ten cigarettes per day. She does not drink alcohol.

Neurological examination at the time of clinic review is unremarkable.

Hb	140 g/L	Male: (135-180) Female: (115 - 160)
Platelets	176 * 10 /L	(150 - 400)
WBC	8 * 10 /L	(4.0 - 11.0)
Na	139 mmol/L	(135 - 145)
K	4 mmol/L	(3.5 - 5.0)
Urea	5 mmol/L	(2.0 - 7.0)
Creatinine	64 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)

An MRI brain is organized, which is reported as normal.

Given the likely diagnosis, which medication treatment will result in resolution of her symptoms?

A. Carbamazepine
B. High flow oxygen
C. Indomethacin
D. Prednisolone
E. Sumatriptan

C. Indomethacin

Paroxysmal hemicrania is completely responsive to treatment with indomethacin

Indomethacin is the correct answer. Paroxysmal hemicrania is characterized by relatively short-lasting, frequent unilateral headaches associated with ipsilateral autonomic features (such as rhinorrhoea and nasal congestion in this case). It shares many features with cluster headaches but can be differentiated based on its dramatic response to indomethacin, higher prevalence in females, shorter attack duration and higher attack frequency. Brain imaging is useful to exclude a secondary cause of presentation.

Carbamazepine is not the right answer. This is used as a treatment for trigeminal neuralgia. This headache is not characterized by ipsilateral autonomic features and the pain affects the lower part of the face in the distribution of the trigeminal nerve.

High flow oxygen is not the right answer. This treatment is used to abort attacks of cluster headache. Cluster headaches share many of the same features as paroxysmal hemicrania but the attacks tend to be of longer duration (45-90 minutes) and occur less frequently (1-8 times per day on average). Patients often describe circadian rhythmicity to their symptoms, with the headaches occurring at similar times each day.

Prednisolone is not the right answer. High dose prednisolone can be used to treat the temporal headache of giant cell arteritis. However, the young age of this patient essentially excludes this diagnosis.

Sumatriptan is the wrong answer. This is used as a treatment for both cluster headaches and migraines, neither of which is the correct answer here. The duration of migraine is typically longer and more classically associated with visual aura, paraesthesia, photophobia and phonophobia.

Question 43 of 299

A 55-year-old man is referred to neurology clinic by his GP with reports of a six month history of tremor affecting both hands. It worsens with emotional stress. He has no past medical history and does not take any medications. He does not smoke or drink alcohol. He works as a cooper.

On examination, there is a tremor of both hands with an frequency of 5 Hz and a medium amplitude. It is slightly more prominent on the right hand than the left but this is subtle. It is present both posturally and at rest. There are no other discriminating features.

Given the clinical presentation, which test is most appropriate to guide diagnosis?

A. Acetylcholine receptor antibodies
B. Lumbar puncture
C. MRI head
D. Nerve conduction studies
E. 123I-FP-CIT SPECT

E. 123I-FP-CIT SPECT

123I-FP-CIT SPECT can be used to help differentiate essential tremor from Parkinson's

123I-FP-CIT SPECT is the correct answer. In this scenario, there is uncertainty as to whether this tremor represents an essential tremor or a Parkinsonian tremor. The so called 'DaTSCAN' can be used to differentiate between essential tremor and a Parkinsonian tremor if there is diagnostic uncertainty. A DaTSCAN measures the density of nigrostriatial dopamine transporter sites. A radioactive tracer is injected into the blood and binds to the dopamine transporter in the brain. The imaging technique assess for the level of binding observed. In Parkinson's disease, there is a decreased level of binding between the tracer and the dopamine transporter in the brain. In essential tremor, the binding level will be normal.

Lumbar puncture is incorrect. Typically, this investigation is not necessary in differentiating between essential tremor and PD. However, if there was a suspicion of an intra-cerebral infectioncausing tremor, it may be useful.

MRI head is incorrect. This may show vascular changes if vascular parkinsonism is suspected.However, this type of Parkinsonism tends to be lower body predominant and tremor is a less common feature.

Nerve conduction studies is incorrect. This is a test that can help diagnose neuropathies but is little value in determining the cause of tremors.

Acetylcholine receptor antibodies are incorrect. This is an antibody test used to support a diagnosis of myasthenia gravis. This disorder is characterized by fatigable weakness rather than tremor.

Question 44 of 299

A 23-year-old presents to the emergency department. He has arrived with a headache however nursing staff are concerned by the appearance on the ECG taken at triage. He is usually well. He is clear that he does not have any chest pain or shortness of breath. He does report that his head is really hurting and this started suddenly in the morning when he was preparing his breakfast.

On examination, he is a young slim gentleman with normal heart sounds. His lung fields are clear and there is no visible JVP. He is difficult to examine due to agitation and he refuses to open his eyes to the light. His blood pressure is 140/80 mmHg.

ECG ST elevation in leads V4-V6

What is the likeliest cause of the ECG changes?

A. Benign early re-polarisation
B. Left ventricular hypertrophy
C. Subarachnoid haemorrhage
D. Silent myocardial infarction
E. Acute pericarditis

C. Subarachnoid haemorrhage

ST elevation can occur in subarachnoid haemorrhage

This gentleman has ST elevation but no cardiac signs. This could be benign early re-polarisation also called 'high take off' but the severe headache suggests this could be a subarachnoid haemorrhage. His slim physique may suggest a Marfan's syndrome which is a recognised cause of cerebral aneurysm. A silent myocardial infarction is rare particularly in young males and there are no other

symptoms seen like shortness of breath. Acute pericarditis has ST elevation in all leads and sharp chest pains. Left ventricular hypertrophy presents with large volume complexes but not ST elevation.

Question 45 of 299

A 25-year-old gentleman presents with a headache to the emergency department. He describes walking back from the gym and developing an occipital headache that came on suddenly and became a 9/10 severity within seconds. He started to vomit and a bystander called an ambulance.

He is normally fit and well. He takes no medication regularly and denies any recreational substance use. He has been referred to the genetics clinic due to his father having been diagnosed with a phaeochromocytoma and his maternal grandmother had kidney tumours.

On arrival to the emergency department, his glasgow coma scale has dropped from 14 to 6. He has reactive pupils and an intact corneal reflex. His neck is rigid and he screams out when you try to flex his neck. His blood pressure is 180/90mmHg, heart rate 60/min and respiratory rate is 11/min. He has two cafe-au-lait spots on his trunk but there are no palpable masses and no changes seen in the irises. He is 6 foot 5 inches and weighs 95 kilograms. Abdominal examination is unremarkable

Urine dip	blood trace, leucocytes positive
ECG	ST elevation in V1-V4
CT head	large high attenuation signal seen in the left cerebellar hemisphere with surrounding oedema, no mass effect
Lumbar puncture	xanthochromia colour, raised red cells

What is the likely unifying diagnosis?

A. Tuberous sclerosis
B. Neurofibromatosis type 1
C. Von Hippel Lindau
D. Multiple endocrine neoplasia
E. Polycystic kidney disease

C. Von Hippel Lindau

Early age SAH occur in Von Hippel Lindau

This gentleman presents with a subarachnoid haemorrhage at a young age which is likely aneurysmal. He has a family history notable for renal and adrenal malignancy and there is a suspected genetic condition present in the family. Of the above, PKD and VHL are associated with subarachnoid haemorrhage and so these should stand out as possible causes. Polycystic kidney disease usually has palpable bilateral enlarged kidneys or gross haematuria. Therefore, the answer is Von Hippel Lindau syndrome where c3p25 mutation causes 80% to develop cerebellar haemangiomas or haemangioblastomas which can bleed acutely.

Question 46 of 299

An 87-year-old lady presents to the emergency department with unilateral weakness and according to her family difficulty in naming objects. This started about six hours ago.

Examination was consistent with weakness in left arm and leg (arm > leg) with decreased sensation. You also notice that she becomes increasingly tearful and has difficulty in naming objects around her, although she is able to describe their function. A systems review indicates a Heart Rate of 72/min and a blood pressure of 110/84 mmHg. There are no precordial murmurs and no carotid bruits. An ECG is performed showing that the patient is in sinus rhythm.

An urgent CT reveals an area of grey matter differentiation in the right hemisphere. Therefore a diagnosis of Right Partial Anterior Circulation Syndrome (R PACS) is made.

She has previously been on amlodipine 5 mg and mirtazapine 30 mg once per day. She is started on aspirin.

Which other intervention would you consider regarding her treatment.

A. Atorvastatin 80 mg OD to be started 48 hours post onset of symptoms
B. Amlodipine to be raised to 10 mg
C. Anti-embolism stockings to be prescribed
D. Bisoprolol 1.25 mg OD to be initiated
E. Atorvastatin 40 mg OD to be started now

A. Atorvastatin 80 mg OD to be started 48 hours post onset of symptoms

Statins should be initiated for secondary prevention of stroke 48 hours following ischaemic event

This lady has suffered from a cerebrovascular ischaemic episode. As per NICE guidelines, and given the lack of co-morbidities secondary prevention should be started appropriately. In the case of secondary prevention in ischaemic CVA, NICE guidelines suggest the prescription of atorvastatin, 48 hours post-event. The reason behind this is that previous studies have identified the potential for haemorrhagic transformation in early administration of statins. Anti-embolism stockings are not advised to be used in stroke patients and it has been proven that they add no further benefit in the prevention of embolic events in such patients in the acute setting.

Question 47 of 299

A 45-year-old man with a history of hypertension and ischemic heart disease presents to the emergency department following a collapse. He reports that he developed weakness down his left side before suddenly collapsing to the floor. His partner reports that he lost consciousness for around two minutes before recovering. She also noted that the right side of his face was dropping. The patient's symptoms completely resolved after 60 minutes.

Current medication is amlodipine 5mg, bisoprolol 2.5mg, aspirin 75mg, simvastatin 20mg.

Which feature in the history suggests that an alternative diagnosis is more likely than a TIA?

A. Patient's age

B. Timing of symptoms
C. Crossed pattern of weakness
D. Loss of consciousness
E. Current use of anti platelets

D. Loss of consciousness

TIAs do not cause loss of consciousness

Transient ischaemic attacks (TIAs) rarely cause loss of consciousness. Whilst the patient is young for a TIA it does not completely exclude this as a possibility, especially given his risk factors. Whilst anti-platelets are a preventative measure they do not cause a complete risk reduction. Crossed patterns of weakness can occur with a posterior circulation TIA. Finally, the timing of the symptoms is actually supportive of a TIA with sudden onset and quick, complete recovery.

Question 48 of 299

A 32-year-old woman is seen in the neurology clinic with a 6-month history of intermittent headaches. The headaches typically affect her left side and are associated with paraesthesia in her left hand and occasional nausea and vomiting. She says that her symptoms resolve after a period of 4-6 hours each time. She has no past medical history of note and has no regular medications or allergies.

On examination, her observations are recorded within normal limits. There is equal power in all 4 limbs with no sensory or coordination disturbance. Her cranial nerve examination is unremarkable.

What is the most appropriate next step in the long-term management of this patient?

A. Amitriptyline
B. Aspirin
C. Propranolol
D. Sumatriptan
E. Topiramate

C. Propranolol

Propranolol is preferable to topiramate in women of childbearing age (i.e. the majority of women with migraine)

This patient's headache is likely to represent a migraine, given the unilateral presentation associated with photophobia and vomiting and normal neurological examination. To prevent the recurrence of migraines, prophylaxis can be offered to patients. Propranolol is preferred as pharmacological prophylaxis in women of childbearing age, as topiramate is teratogenic and associated with birth defects such as a cleft palate.

Amitriptyline is a third-line agent used in the prophylaxis of migraines. Typically, alternative drugs such as propranolol should be used initially, unless contraindicated. Aspirin is used in the acute treatment of migraines. However, it plays no role in the prophylaxis of migraine.

Sumatriptan is another medication used in the acute treatment of migraines. However, long-term sumatriptan is not used to prevent the recurrence of migraines.

Topiramate is used in the prophylaxis of migraines. However, as this patient is a woman of childbearing age, it is inappropriate to initiate topiramate for long-term use as it is teratogenic and associated with birth defects.

Question 49 of 299

A 60-year-old woman was referred with dizziness, nausea, and vomiting. This had come on insidiously the previous day. She described the room spinning, which was there constantly but worse with any sudden movement. She had suffered flu-like symptoms in the previous week, which were now resolving. On examination, she had horizontal nystagmus with the fast beat towards the right. Speech was normal. There was no past-pointing and finger-nose testing was normal. Gait was normal. Power was 5/5 throughout all limbs. Her hearing was normal.

What is the most likely diagnosis?

A. Benign paroxysmal positional vertigo
B. Meniere's disease
C. Vestibular neuronitis
D. Transient ischaemic attack
E. Vertebrobasilar insufficiency

C. Vestibular neuronitis

Prodromal viral illness with associated vertigo and nystagmus is suggestive of vestibular neuronitis

The presence of horizontal nystagmus in the absence of any other neurological signs suggests a vestibular origin of the acute symptoms in this case. A posterior circulation vascular event would be likely to be associated with other signs of cerebellar dysfunction or other cranial nerve palsies. The preceding probable viral illness and the persistence of the symptoms suggest a viral vestibular neuronitis as the cause of her vertigo rather than benign paroxysmal positional vertigo. There are also none of the additional features that would suggest Meniere's disease such as unilateral deafness, severe nausea, and a pressure sensation in the ear.

Question 50 of 299

A 53-year-old man presents to the emergency department with a 1-day history of bilateral leg weakness. He is now struggling to stand up from a chair. Whilst waiting to be seen in the department, the patient starts to experience finger paraesthesia.

The patient reports no medical history of note and is in good health aside from a recent bout of diarrhoea. He takes no regular medications, smokes 20 cigarettes per day and drinks up to 4 pints of beer 'most nights'. He works as a plumber.

On clinical examination, there is a marked weakness of the lower limbs, absent reflexes at the ankle, knee, and elbow with a grossly normal sensory assessment. He is dysarthric and coughs significantly on a bedside swallow assessment.

An MRI whole spine is ordered and reported as normal. Blood tests show a raised ALT, but no other abnormalities.

Given the likely diagnosis, assuming he receives standard treatment, what is the probability of long term weakness

A. 30%
B. 40%
C. 50%
D. 1%
E. 15%

E. 15%

Up to 15 percent of individuals with Guillain-Barre syndrome will experience long-term weakness

This patient presents with classical Guillain-Barre syndrome(GBS). Early recognition and treatment with intravenous immunoglobulin and/or plasma exchange both increase the speed of recovery and are important in reducing the incidence of long term sequelae.

The most common long term sequelae of GBS is fatigue, although, depending on the clinical course, pain and persistent neurological deficits may also be problematic, with long term neurological difficulties reported in 7-15% of patients.

Question 51 of 299

A 27-year-old caucasian woman is 28 weeks pregnant. She has been epileptic since the age of 7 and takes lamotrigine, which she has continued throughout the pregnancy. She has not had a seizure for 2 years.

What must you consider in pregnant patients taking lamotrigine?

A. Serum lamotrigine levels fall in the second trimester
B. She must not breastfeed while taking lamotrigine
C. She should be advised to stop lamotrigine
D. Folic acid 400mcg should be taken throughout pregnancy
E. It is protein bound and therefore drug levels increase in pregnancy

A. Serum lamotrigine levels fall in the second trimester

Due to the increased plasma volume and enhanced renal/hepatic drug clearance, lamotrigine levels decrease in the second trimester of pregnancy. It may be necessary to increase the dose of lamotrigine at this time (normally increased two or three fold). A baseline serum drug level is useful to establish compliance and inform future changes in drug doses.

Breastfeeding is not contraindicated in women taking lamotrigine. However, the infant should be monitored for signs of accumulation such as a rash or drowsiness.

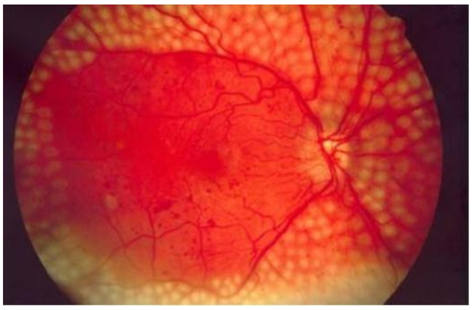
Patients should not stop their anti-epileptic medications unless a joint decision has been made in conjunction with an obstetrician/obstetric physician doctor. If a patient has been seizure-free for >2 years and is on dual therapy then it may be beneficial to reduce/stop one of the medications.

Patients on anti-epileptic medications should take folic acid 5mg throughout pregnancy.

Lamotrigine has low levels of protein binding and therefore is not affected by the decreased serum protein levels in pregnancy.

Question 52 of 299

A 52-year-old man presents for a routine eye screening appointment. He has a past medical history of hypertension, type 2 diabetes mellitus and hyperlipidaemia. The eyes are examined using an ophthalmoscope and the following view is seen of the left eye:



What is the most common complication of the treatment that this patient has received?

A. Chronic eye pain
B. Development of floaters
C. Development of infection
D. Reduced central vision
E. Reduced night vision

E. Reduced night vision

The photo shows clear evidence of diabetic retinopathy - proliferation of small vessels is present, as well as haemorrhage. Importantly, this photo also shows evidence of panretinal laser photocoagulation (PRP) - the numerous circular yellow spots around the periphery are 'burn scars' from the treatment. PRP aims to prevent further proliferation of vessels. Of the complications listed here, the most common adverse effect associated with PRP is a reduction in night vision. This is because PRP leads to scarring of peripheral retinal tissue, where rods are situated (rods being responsible for vision in low light). As such, the peripheral visual field is also often reduced.

Chronic eye pain is incorrect. Some temporary pain may arise following the procedure, but this improves within 24-48 hours.Development of floaters is incorrect. Floaters develop due to the underlying condition, and due to macular oedema that may result from diabetic eye disease. PRP itself is not generally associated with causing further floaters.

Development of infection is incorrect. PRP is not associated with the development of infection.

Reduced central vision is incorrect. As PRP targets the periphery, the central vision is typically spared.

Question 53 of 299

A 68-year-old man develops a left-sided hemiparesis and facial droop whilst out shopping with his wife at 14:35pm. His initial CT head scan is done at 15:40pm and reveals no intracranial haemorrhage or space occupying lesion. He is given alteplase in the emergency department at 15:50pm.

His post-thrombolysis CT head at 09:00 am the following morning reveals a right middle cerebral artery infarction and no evidence of intracranial haemorrhage or haemorrhagic transformation. A 12 lead ECG done in the stroke unit shows atrial fibrillation of 110 beats per minute. He has a persisting dense left-sided weakness several hours post thrombolysis.

Which of the following drugs should be added next?

A. Clopidogrel
B. Aspirin
C. Warfarin
D. Unfractionated heparin
E. Rivaroxaban

B. Aspirin

Aspirin 300mg orally for the initial two weeks should be commenced in patients with a disabling stroke and atrial fibrillation. Following this, these patients should be considered for anticoagulant treatment. The post-thrombolysis CT head revealed no acute intracranial haemorrhage or haemorrhagic transformation, therefore, it is safe to start aspirin.

Question 54 of 299

A 67 year-old woman presents to hospital after a collapse at home. One week earlier she had seen her own doctor after feeling generally unwell with fever, myalgia, and coryza. These symptoms were attributed to a viral infection and have now resolved. However, for the past few days she has felt unsteady on her feet and has had to hold on to the furniture whilst walking around the house. For the last two days in particular she has also noticed that her vision has deteriorated, and she has been seeing double. Today she tried to hold onto the sofa whilst walking around the room, but misjudged the distance and lost her grip, causing her to fall to the floor. Her daughter who is also present adds that she feels her mothers speech is slurred compared to normal, and has been so for the past three days.

Her past medical history includes hypertension, hypothyroidism, type 2 diabetes, hyperlipidaemia, angina, and recurrent urinary tract infection. She takes ramipril, amlodipine, doxazosin, laevoythyroxine, metformin, gliclazide, simvastatin, atenolol, nicorandil, and nitrofurantoin. She does not smoke but admits to enjoying a glass of sherry on most nights. Usually she is independently mobile, without aids. She lives on her own and is self-caring.

On examination, there are some bruises on the left shoulder where she fell, but no suggestion of any fracture. Observations are normal and she is afebrile. Cardiovascular, respiratory, and abdominal examination is unremarkable. She is fully alert and oriented. Pupils are equal and reactive to light. Eye movements are grossly impaired in all directions. There is no facial asymmetry. Muscle power is normal in all limbs, but finger-nose pointing is impaired and she is unable to walk in a straight line. Reflexes are unobtainable. Sensation is normal.

What is the most likely diagnosis?

A. Wernickes encephalopathy
B. Viral cerebellitis
C. Myasthenia gravis
D. Miller Fisher syndrome
E. Posterior circulation stroke

D. Miller Fisher syndrome

There has been a subacute deterioration in global cerebellar function, as suggested by gait ataxia, bilateral upper limb dysmetria, and dysarthria, progressing over a period of days. There is also complete ophthalmoplegia, and absence of reflexes. This combination of features occurring after a recent viral infection suggests a diagnosis of the Miller Fisher variant of Guillain-Barre syndrome. One might also expect to find descending weakness, which was not present in this case. Confirmation of the diagnosis is by lumbar puncture which demonstrates raised protein with normal cell count, and positive serum anti-GQ1b antibodies. Treatment is as for Guillain-Barre syndrome, with supportive care and intravenous immunoglobulin or plasmapheresis.

Wernickes encephalopathy presents with ataxia and ophthalmoplegia but also confusion, and typically occurs in malnourished alcoholics.

Viral cerebellitis is more common in children and would not explain the ophthalmoplegia and areflexia.

Myasthenia gravis would be unlikely to develop so rapidly, and though a cause of complex ophthalmoplegia, it would not explain the areflexia or the cerebellar signs.

Posterior circulation syndromes can cause acute cerebellar dysfunction but stroke of any sort is unlikely as this is a subacute presentation of neurological features not referable to one part of the brain.

Question 55 of 299

A 44 year-old man presents to the neurology clinic. He complains of weakness in the right hand, which causes difficulty with tasks such as writing and dressing, and has also noted 'twitching' in his right forearm and hand. He cannot recall exactly when the symptoms first began but feels that they have certainly been present for at least six months, and that they have got worse.

He is otherwise fit and well. His only past medical history is well-controlled asthma. There is no family history of neurological disease.

Cranial nerve examination is normal. On examination of the right hand, there is weakness of extension of the the middle and ring fingers (2/5 on the MRC scale), but no discernible muscle wasting. Fasciculations are visible in the dorsal aspect of the forearm. On examination of the left hand, there is also some subtle weakness of extension of the ring finger (4/5 on the MRC scale). There is no weakness of wrist extension on either side and power in all other muscle groups is normal. For both hands, all the fingers extend when the wrist is passively moved into palmar flexion. All reflexes are normal and there are no sensory signs.

What is the most likely diagnosis?

A. Multifocal motor neuropathy
B. Chronic inflammatory demyelinating polyneuropathy
C. Motor neuron disease (amyotrophic lateral sclerosis)
D. Inclusion body myositis
E. Ruptured tendon of extensor digitorum

A. Multifocal motor neuropathy

The history is typical for multifocal motor neuropathy (MMN). The condition presents with asymmetric muscle weakness, which is slowly progressive, and without sensory signs. Differential weakness of finger extension is a typical presentation, and reflects a pathological process which selectively affects particular motor fibres within a peripheral nerve (in this case the posterior interosseous branch of the radial nerve). Weakness without wasting is another typical feature. Nerve conduction studies show areas of conduction block outside usual areas for compression. Intravenous immunoglobulin can produce a rapid improvement in weakness.

MMN may sometimes mimic motor neuron disease (MND). Both feature weakness, wasting, and fasciculation, with relatively preserved reflexes, and normal sensation. However, certain features suggest one diagnosis over the other. For example, bulbar weakness is common in MND but rare in MMN. Depending on the form of MND, variable upper motor neuron signs may occur, contrary to MMN which is a purely lower motor neuron condition occurring in a distribution correlating with named peripheral nerves. Finally, whereas MND is usually fatal within 5 years, MMN is slowly progressive over decades and does not typically cause respiratory failure.

Chronic inflammatory demyelinating polyneuropathy(CIDP) typically causes a progressive sensory and motor neuropathy with loss of reflexes. CSF protein is elevation and nerve conduction studies show evidence of demyelination.

Inclusion body myositis characteristically causes weakness of finger flexion, as well as knee extension and ankle dorsiflexion. Affected muscles are wasted, and fasciculations do not occur as there is no denervation.

Rupture of extensor tendons often occurs in rheumatoid arthritis. The affected finger cannot be actively extended, and does not passively extend when the wrist is passively moved into palmar flexion.

Question 56 of 299

A 50-year-old man was transferred to a tertiary referral centre with dense right-sided weakness and a Glasgow Coma Score of 8. It was estimated that the onset of this event was 8 hours prior to being found. He had bilaterally up-going plantar responses. He was haemeodynamically stable and not known to have any major co-morbidities.

A CT Scan of his brain revealed a moderate area of established infarct within left middle cerebral artery (MCA) territory with massive cerebral oedema and mid-line shift.

In this circumstance, which of the following interventions may benefit the patient in the acute period?

A. Decompressive hemicraniectomy
B. Intra-arterial clot retrieval
C. Intravenous thrombolysis
D. Intravenous dexamethasone
E. Aspirin through nasogastric tube

A. Decompressive hemicraniectomy

For individuals aged up to 60 years who suffer an acute MCA territory ischaemic stroke complicated by massive cerebral oedema, surgical decompression by hemicraniectomy should be offered within 48 hours of stroke onset.

Question 57 of 299

An 86-year-old lady was admitted to the acute medical admissions unit having been referred by her GP with acute confusion. Three days ago she was treated by her GP with trimethoprim 200mg BD for a presumed urinary tract infection, her nursing home having complained of new urinary incontinence and offensive smelling urine. Unfortunately, she continued to deteriorate and on the day of admission had become rather confused and unable to mobilise, leading to the admission. Her past medical history comprised Alzheimer's disease, hypertension, hypercholesterolaemia and osteoarthritis for which she was prescribed donepezil 10mg OD, amlodipine 5mg OD, atorvastatin 20mg ON and paracetamol 1g QDS. She was usually able to mobilise independently and suffered from intermittent confusion, though she was able to hold lucid conversations with her care workers. She had a daughter who resided abroad who had not made contact with her in several years and did not have a lasting power of attorney or advanced directive in place.

Examination revealed a very unwell elderly lady. Her temperature was 39.6ºC, heart rate 122 bpm, respiratory rate 26/min and blood pressure of 97/58 mmHg. Examination of her cardiovascular system revealed the presence of a bounding peripheral pulse and a capillary refill time of three seconds. Examination of her respiratory system revealed tachypnoea. Examination of her abdomen revealed no abnormalities. She was not compliant with formal neurological examination; her GCS was 14 (E4 S4 M6). She was very confused and unable to maintain a formal conversation; her speech did not resemble any form.

When the doctor proceeded to perform venous cannulation, she became very aggressive and hostile. She refused all forms of treatment, stating that she did not require medical treatment and requested to leave the ward immediately. She did not appear to comprehend the risks of refusing medical admission and was unable to recall the information disseminated.

What is the next best management option?

A. Seek opinion from family members
B. Apply for formal Deprivation of Liberty Order and proceed with treatment once obtained
C. Respect the wishes of the patient and arrange for urgent GP follow up
D. Section under 5(2) of the Mental Health Act (MHA) and proceed with treatment

E. Proceed with treatment under the Mental Capacity Act (MCA)

A. Proceed with treatment under the Mental Capacity Act (MCA)

This lady has evidence of a life-threatening acute organic illness requiring immediate treatment, but is refusing treatment and lacks the capacity at present to make a decision regarding her medical care, and does not have an advanced directive of lasting power of attorney. Responsibility for decisions regarding medical care, therefore, is bestowed to the medical team, who are entitled to treat the patient under the Medical Capacity Act. Seeking a family opinion here is good practice but impractical here given the paucity of family contact and the emergency situation, and the Mental Health Act is not applicable here as the primary illness is most likely organic rather than relating to a mental health disorder. It is worth mentioning that under the MCA it is possible to obtain an emergency DOLS; a formal DOLS application must be made at the same time but in an emergency situation awaiting a formal DOLS should not prevent treatment.

Question 58 of 299

A 70-year-old male is evaluated at the neurology outpatient department for an episode of left sided body weakness which lasted for around 30 minutes and resolved completely. He described the episode as an inability to move the left side of his body and an associated numbness and tingling sensation in the area involved. He remained conscious throughout and was able to communicate verbally with his family members during the episode.

He suffers from hypertension and has hypercholesterolaemia. He is also a smoker with a 40 pack year history and is known to be a heavy drinker.

He has also noted a tremor in both his hands which tends to improve after he has a drink. He also feels unsteady while walking and feels the need to grip something otherwise he may lose balance. His medication includes amlodipine 5mg daily and atorvastatin 20mg daily.

On examination, his blood pressure is 150/95mmHg and his pulse is 86bpm regular. A carotid bruit is audible over both sides of the neck. Neurological examination reveals impaired sensations in a glove and stocking distribution. The remaining clinical examination is normal.

Investigations reveal:

ECG: deep S waves in lead V1-V3 and tall R waves in V4-V6

CXR: Enlarged cardiac silhouette with flecks of calcification around the aorta

Carotid artery Doppler studies reveal 85% occlusion in the right external carotid. 50% occlusion in the right internal carotid. Left internal carotid is 80% occluded while there is a 60% occlusion in the left external carotid artery.

Which of the following is the most suitable treatment option in this patient?

A. Left internal carotid endarterectomy
B. Optimizing medical management
C. Right external carotid endarterectomy
D. Percutaneous stenting of the right internal carotid artery
E. Percutaneous stenting of the left internal carotid artery

B. Optimizing medical management

In the aforementioned scenario, the patient has suffered from a right sided TIA and has recovered completely. The question aims to assess the candidates knowledge pertaining to intervention in patients with TIAs and carotid stenosis.

Carotid endarterectomy or endovascular stenting is recommended in patients with symptomatic stenosis of the affected vessel >70%. In the patient described above, the symptoms involve the left side of the body, hence the right carotid is involved. The degree of stenosis in the right internal carotid is 50 % and therefore the treatment of choice would be optimization of medical therapy with improved blood pressure control and antiplatelet agents rather than intervention.

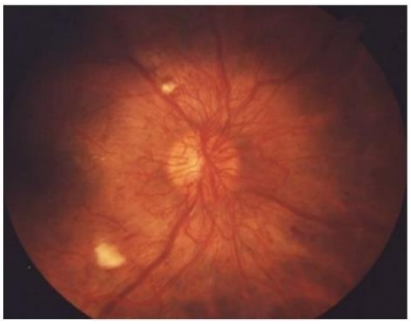
The carotid stenosis in the left internal carotid is asymptomatic therefore not an indication for endarterectomy.

The external carotids do not form part of the circle of Willis and do not contribute to the blood supply of the brain.

The reference to his benign essential tremor is of no relevance to his clinical condition

Question 59 of 299

A 50-year-old woman presents to the optician with a progressive decline in visual acuity. The optician refers her for medical review. The fundoscopic examination shows:



Given the fundoscopic findings, what is the most appropriate treatment?

A. Intra-vitreal VEGF inhibitor therapy
B. Optimise glycaemic control
C. Pan-retinal laser photocoagulation
D. Urgent trabeculectomy
E. Vitreoretinal surgery

C. Pan-retinal laser photocoagulation

The fundoscopy shows extensive neovascularisation in all four quadrants obscuring the optic disc, which is suggestive of advanced proliferative diabetic retinopathy commonly seen in type I diabetes. The soft exudates, seen as 'cotton wool spots' on the left upper and lower quadrant, represent areas of retinal infarction, suggesting advanced diabetic retinopathy.

Pan-retinal laser photocoagulation is the most appropriate treatment for this patient with extensive neovascularisation to improve retinal oxygenation and reduce the risk of retinal or vitreous haemorrhage. Pan-retinal photocoagulation aims to prevent haemorrhage and furtherneovascularisation, not to regain lost vision.

Optimise glycaemic control should be considered in all patients with non-proliferative or proliferative diabetic retinopathy. However, this patient, with extensive neovascularisation and impending haemorrhage, requires urgent photocoagulation.

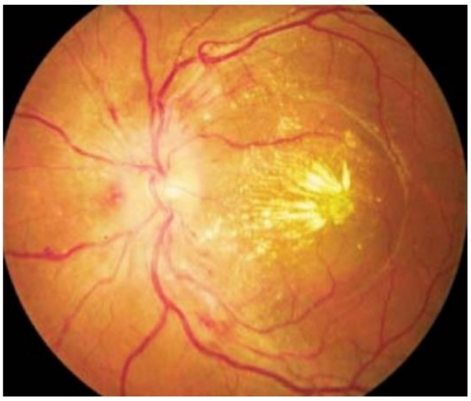
Urgent trabeculectomy is the surgical intervention used to reduce intraocular pressure in acute angle-closure glaucoma. Glaucoma leads to the classical fundoscopic appearance of cupping or increased vertical cup-to-disc ratio, which is not seen in this patient.

Intra-vitreal VEGF inhibitor therapy is recommended for patients with maculopathy or may be considered in combination with pan-retinal laser photocoagulation to treat severe proliferative diabetic retinopathy. While VEGF as an adjunctive therapy can help in the regression of neovascular vessels, definitive treatment with photocoagulation is essential to prevent impending retinal or vitreal haemorrhage.

Vitreoretinal surgery is recommended for severe or vitreous haemorrhage, which is often a complication of extensive neovascularisation. However, the fundoscopic findings in this patient do not suggest severe or vitreous haemorrhage, which may be seen as a red haze of haemorrhage into the vitreous associated with dot-blot haemorrhages, neovascularisation elsewhere or boatshaped pre-retinal haemorrhages.

Question 60 of 299

A 75-year-old man visited the optician for a progressive decline in vision in both eyes and a headache. The optician was concerned about his fundoscopic appearance and referred him to the emergency department for further workup. He has hypertension and diabetes and reports good compliance with his medications. He currently takes perindopril, amlodipine and hydrochlorothiazide for hypertension; metformin, linagliptin and dapagliflozin for diabetes management



What is the next best step in his management?

A. Add basal-bolus insulin therapy
B. Escalate antihypertensive treatment
C. Monitor visual acuity weekly
D. Refer for urgent trabeculectomy
E. Start broad-spectrum antibiotics

B. Escalate antihypertensive treatment

The flame and blot haemorrhages collected around the fovea result in a characteristic macular star pattern. The associated arteriolar narrowing and AV nipping are suggestive of hypertensive retinopathy. The more ominous sign of papilloedema indicates stage IV hypertensive retinopathy.

Escalate antihypertensive treatment is the next best step in his management. Stage IV hypertensive retinopathy is indicative of uncontrolled malignant hypertension. Prompt review and escalation of hypertensive treatment are vital in reducing ophthalmologic and systemic complications.

Add basal-bolus insulin may be considered if the patient has poorly controlled diabetes despite optimised oral therapy. Although the fundoscopic features suggest hypertensive rather than diabetic retinopathy, persistent hypertension can accelerate the progression of diabetic eye disease.

Monitor visual acuity weekly is inappropriate as this patient with stage IV hypertensive retinopathy requires prompt treatment to control blood pressure to reduce ophthalmologic and systemic complications.

Refer for urgent trabeculectomy , which is the most common surgical intervention for glaucoma, is not needed in this patient. Glaucoma leads to the classical fundoscopic appearance of cupping or increased vertical cup-to-disc ratio, which is not seen in this patient.

Start broad-spectrum antibiotics like azithromycin or ciprofloxacin would be the appropriate treatment for the cat-scratch disease, which is the most common cause of infectious neuroretinitis. Although macular star pattern and papilloedema may also be seen in neuroretinitis, the onset is typically acute and often limited to one eye.

Question 61 of 299

A 21-year-old man is referred to the ophthalmology clinic. He has a past medical history of type 1 diabetes mellitus which has been poorly controlled as he has recently started university and is living away from home for the first time. This has caused him to monitor his blood sugars less frequently as he is embarrassed about his medical problem and is keen to fit in. He has no visual symptoms but fundoscopy demonstrates microaneurysms and cotton wool spots. He has no other known medical problems and uses biphasic insulin. His observations are all within normal range visual acuity is normal.

Apart from advising and support in managing his diabetes, how should he be managed?

A. Referral for retinal laser treatment
B. Annual digital retinal photography
C. Six monthly digital retinal photography

D. Start ramipril
E. Start amlodipine

B. Annual digital retinal photography

The correct answer is annual digital retinal photography. This patient has developed preproliferative diabetic retinopathy and strict diabetic control is important. Apart from that, regular retinal photography can help find proliferative retinopathy in which case laser treatment will be needed. There is no evidence of hypertensive changes.

Diabetic retinopathy in type 1 diabetes

People with type 1 diabetes are at high risk of diabetic retinopathy. On diagnosis, they should be referred to screening services and from that point either undergo annual review or be referred to an ophthalmologist. If signs of proliferative retinopathy occur then the patient should be referred for retinal laser treatment.

Question 62 of 299

A 73-year-old patient is brought in by ambulance to the emergency department. He has had a sudden onset of right-sided weakness and dysphasia which started five hours ago. He undergoes a CT scan and an ischaemic stroke is confirmed with no evidence of acute bleeding.

Due to the delay in presentation to hospital, he is not thought to be suitable for thrombolysis.

He is started on aspirin and admitted to the stroke ward. He has significantly reduced mobility due to his weakness. He is considered to be at risk of haemorrhagic transformation.

How should his risk of venus thromboembolism be managed?

A. Low molecular weight heparin
B. Unfractionated heparin
C. Anti-embolic stockings
D. Intermittent pneumatic compression
E. Warfarin

D. Intermittent pneumatic compression

The correct answer is intermittent pneumatic compression. Patients admitted with stroke are very likely to be at high risk of developing a thromboembolic event due to reduced mobility, but low molecular weight heparin is associated with haemorrhagic transformation. NICE advises that patients admitted within three days of an acute stroke should have intermittent pneumatic compression considered. This should be provided for 30 days or until the patient is mobile or discharged.

Question 63 of 299

A 63-year-old woman returns to neurology clinic for review with her husband. She was diagnosed with Parkinson's disease two years ago and was started on ropinirole six months ago as her symptoms were becoming difficult to manage. She was mainly concerned with the rigidity of her movements. Since then she has improved remarkably, and her movements are much better, with reduced rigidity on examination. Her mood has also been improving with the relief from her symptoms.

However, her husband has become concerned that she has been increasingly spending large amounts on shopping, something which has not done before and that he feels is out of character.

What is the most likely explanation?

A. Normal behaviour
B. Progression of Parkinson's disease
C. Lewy-body dementia
D. Dopaminergic dysregulation syndrome
E. Impulse control disorder

A. Impulse control disorder

The correct answer is impulse control disorder. This is a patient recently started on a dopamine agonist who has subsequently developed reduced impulse control. This is not an unimportant symptom and can have significant implications, especially for

with a history of gambling. Before starting a dopamine antagonist this risk has to be explained to the patient. This symptom does not fit any of the other diagnoses described: there is no cognitive decline as would be expected with dementia, no worsening of Parkinsonian symptoms and no mood changes as would be expected in dopaminergic dysregulation syndrome.

Question 64 of 299

A 55-year-old man is reviewed in the psychiatric clinic. He has been referred by his GP who has been unable to manage his depression. He has a past medical history of hypertension, previous acute coronary syndrome one year ago, high cholesterol and depression. He mentions that his mood has worsened and that he is having persistent thoughts about taking his own life to the point where he is scared that he might 'do something'. There are no effects on his cognition, concentration or any sleep disturbance.

What advice should he be given in regards to driving?

A. No restrictions on driving
B. No restrictions on driving but must inform the DVLA
C. Can drive a car but not lorry or bus
D. Can drive a car but not lorry or bus and must inform the DVLA
E. Must not drive and must inform the DVLA

E. Must not drive and must inform the DVLA

The correct answer is that he must not drive and must inform the DVLA. He is a patient with depression and active suicidal thoughts and therefore should not drive.

Question 65 of 299

A 72-year-old male presents to the Parkinson's clinic with his wife, reporting increasing frequency and duration of 'off' periods. The couple finds these episodes extremely debilitating and occurs up to

11 times a day. The patient was diagnosed with Parkinson's disease 12 years ago. As a relatively young patient on diagnosis, he was commenced on ropinirole, which he continued for 5 years, before being prescribed Sinemet 6 times a day and entacapone for the following 7 years. Over past 2 years, the 'off' episodes have gradually increased in frequency in addition to the development of very mild involuntary jaw movements. He is very low in mood and has presented to the emergency department with two episodes of attempted paracetamol overdoses.

He would like a more effective treatment. What would you recommend?

A. Deep brain stimulation
B. Subcutaneous apomorphine
C. Reintroduce ropinirole at higher doses
D. Palliative care involvement
E. Trihexyl

B. Subcutaneous apomorphine

The treatment of 'off' symptoms is particularly important in patients who have been diagnosed with Parkinson's disease for a long time. The introduction of ropinirole would not help off periods. Trihexyl is an anti-cholinergic therapy for PD patients where tremor is the predominant symptom. In the context of suicidal behaviour, the patient would not be a candidate for deep brain stimulation, which for unknown reasons, increases the risk of suicide. Subcutaneous apomorphine is a reasonable option, administered as an infusion after a test bolus, which can be used to alleviate but not cure off symptoms.

Question 66 of 299

A 62-year-old male presents to the emergency department via blue light ambulance 90 minutes after sudden onset right sided weakness, expressive and receptive dysphasia. He is known to be T2DM, hypertensive on 3 agents and has a 40 pack year smoking history. On examination, you demonstrate a dense 0 out of 5 right hemiparesis. The patient has a complete expressive and receptive dysphasia, which you confirm to be new following a collateral history from his wife. The patient scores an NIHSS score of 7. He has no history of any recent surgery or head trauma. He is not on an anticoagulant and has no past medical history of coagulation disorders. His CT head demonstrates no areas of haemorrhage and a likely evolving area of ischaemic in the left middle cerebral artery territory. The radiologist calculated his ASPECT score to be 8. His observations on arrival are: temperature 36.7 degrees, heart rate 90/min and regular, blood pressure 220/150 mmHg, sats 99% on air, respiratory rate 20/min.

What is the most appropriate first-line treatment?

A. IV thrombolysis
B. Aspirin 300mg OD
C. PO amlodipine 2.5mg
D. MRI head with diffusion weighting sequences
E. IV labetalol

E. IV labetalol

The patient has multiple vascular risk factors with a sudden onset negative speech and motor syndrome this is strongly suggestive of an acute vascular event. The patient has a likely left MCA territory ischaemic infarct and is within the time window for thrombolysis (<4.5 hours in accordance with ECASS 3 trial results). The size of his infarct is also sufficiently small (calculated by ASPECT score, thrombolysis possible for all scores over 7) and his NIHSS score within range.

Thrombolysis is however not indicated in patients with blood pressures over 185/110 mmHg. Time is brain in the context of acute stroke the longer the delay to cerebral arterial reperfusion, the greater the size of infarct and subsequent functional deficits. The blood pressure is thus lowered rapidly with intravenous labetalol and not oral calcium channel blockers in this case.

Question 67 of 299

A 59-year-old male presents with 4-day history of sudden onset visual disturbance in his right eye. He reports it to be his first episode with no previous history of visual problems. His past medical history includes type 2 diabetes mellitus, hypertension and raised BMI. He is an active smoker of 40 pack years.

On examination, a right relative afferent papillary defect is detected. Pupils were equal in size. A visual field defect is demonstrated in the inferior nasal field of the right eye without a precise quadrantanopia or altitudinal pattern. Temporal arteries are non-tender and not thickened. Visual acuity on Snellen chart in left eye was 6/6, 6/18 in right. Colour vision on Ishihara plates were 17/17 on left, 5/17 on right. Fundoscopy is unremarkable. Examination of the upper and lower limbs are unremarkable, no language deficits are noted. Auscultation revealed normal heart sounds and no bruits.

His blood tests are as follows:

Hb	154 g/l
Platelets	190 * 10 /l
WBC	7.8 * 10 /l
ESR 5 mm/hr	
Na	141 mmol/l
K	3.9 mmol/l
Urea	5.6 mmol/l
Creatinine	80 µmol/l

What is the most likely diagnosis?

A. Right retinal infarct
B. Right temporal arteritis
C. Right non-arteritic ischaemic optic neuropathy
D. Left middle cerebral artery ischaemic stroke
E. Left occipital ischaemic stroke

C. Right non-arteritic ischaemic optic neuropathy

Visual field defects are a common presentation in clinical practice and MRCP part 2. The first feature to notice here is the monocular presentation, which indicates the lesion must be anterior to the optic chiasm. Next, fundoscopy is unremarkable, which would be unusual for a retinal infarct, most likely secondary to central or branch retinal artery occlusion.

Typically, an acute retinal infarct should reveal a classic cherry red spot, pale fundus and possible visualisation of the embolus. On locating the lesion to be at the optic nerve, the cause must be established: typically is this optic neuritis, arteritic or non-arteritic anterior ischaemic optic neuropathy. Optic neuropathy typically produces a correlated deficit in visual acuity with colour vision, allowing differentiation from optic neuritis, where colour vision is frequently better preserved.

Lastly, this patient has a normal ESR, is under 60 and has no local or systemic features of vasculitis, particularly temporal arteritis. In addition, he has multiple vascular risk factors, making a nonarteritic ischaemic anterior optic neuropathy most likely. Management involves optimisation of vascular risk factors and there is limited evidence for a tapering dose of oral prednisolone. Most patients can expect to improve by 3 lines of a Snellen chart by 6 months.

Question 68 of 299

A 69-year-old male presenting with a 4-month history of progressive 'droopiness' of his left eyelid. He reports that in the last 2 weeks, he has been unable to lift his eyelid at all, which he says is fortunate considering he gets double vision now when he lifts his eyelid with his fingers. He underwent a renal transplant in 1988, which continues to function well, and previously had a squamous cell and malignant melanoma resected 2 and 5 years ago respectively.

On examination, you note complete ptosis, loss of vertical eye movements and loss of adduction in his left eye. On head tilt to the right, he is unable to depress left eye. His right eye demonstrates full eye movements. The left pupil is unreactive and larger in diameter compared to the right. There is also loss of sensation at the left nasal skin fold and left forehead with sparing of his left chin. He has no facial weakness, hearing loss or palatal asymmetry. He denies headache or retroorbital pain.

Where is the likely lesion?

A. Left ocular neuromuscular junction
B. Left cavernous sinus
C. Left superior orbital fissure
D. Cerebral aqueduct
E. Left midbrain

B. Left cavernous sinus

The patient has deficits of his oculomotor nerve with parasympathetic involvement, involvement of the trochlear nerve and also the first and second branch of the trigeminal nerve, hence sparing of his left chin as supplied by the mandibular branch of the trigeminal nerve. Loss of pupillary reflexes in the left eye is a result of third nerve involvement and not necessarily retinal or optic nerve pathology. Ability to abduct the left eye suggests the abducens nerve is intact. The only anatomical location involving all these structures is the left cavernous sinus.

The possible cause for this cavernous sinus syndrome is interesting: the insidious gradual course goes against an acute cavernous sinus thrombus. A significant, expanding internal carotid aneurysm, which runs inside the cavernous sinus with the parasympathetic nerves wrapped around it, is a possibility. However, the key is the recognition that the patient is chronicallyimmunosuppressed due to his renal transplant, increasing his risk of opportunistic infections such as fungi and also dermatological malignancies.

Question 69 of 299

A 66-year-old female is brought into Emergency Department by her distraught husband, who reports that she has not been out of bed for 3 days and seems unable to recognise him. He reports no recent fevers or rigors, she has not complained of cough, dysuria, sore throat or diarrhoea and vomiting prior to being unwell. She is well known to local neurologists: she is undergoing off-label rituximab for difficult to manage relapsing-remitting progressive multiple sclerosis, with previous white matter lesions in her corpus callosum, periventricular white matter, and lower thoracic transverse myelitis.

Over the past 6 years, she had continued to relapse despite interferon beta, natalizumab, mitoxantrone and cyclophosphamide. At baseline, she is weak in her lower limbs and is able to stand only with assistance of a turning apparatus, then able to walk about 3 steps. She is normally cognitively intact and fully orientated, normally responsible for organising the couples finances. Her past medical history includes type 1 diabetes mellitus, autoimmune thyroiditis and previous deep vein thrombosis 5 years ago (warfarin since discontinued). Her medication history includes lantus, novomix, levothyroxine and 3 monthly infusions of rituximab, which had stably maintained her MS for 4 years.

On examination, she is not orientated to time or place and appears extremely irritable. Halfway through the examination, she becomes extremely tearful. There is a full range of neck movements and no photophobia.

Neurological examination is difficult due to patient cooperation: pupils are equal and reactive, there is a full range of eye movements and no obvious facial asymmetry. Power in her upper limbs were at least 3/5, lower limbs are unable to counteract gravity. Both plantar responses are upgoing. Her bloods are as follows:

Hb	134 g/l
Platelets	268 * 10 /l
WBC	7.8 * 10 /l
Na	137 mmol/l
K	4.4 mmol/l
Urea	4.5 mmol/l
Creatinine	60 µmol/l
CRP	5 mg/l
HIV	negative
Glucose	7.4 mmol/l

A lumbar puncture was performed:

WBC	16 /mm^3
RBC	150 /mm^3
Protein	0.71 g/l
Glucose	3.5 mmol/l
PCR and gram staining	awaited

What is the most appropriate management step?

A. Intravenous aciclovir
B. Intravenous methylprednisolone
C. Intravenous immunoglobulin
D. Intravenous rituximab infusion
E. Psychiatric input

A. Intravenous aciclovir

This is a difficult question regarding the side effect of rituximab and opportunistic infections. The neurological signs are difficult to interpret. Firstly, there are no hard clinical signs that her MS has deteriorated: her plantars are likely to be upgoing at baseline due to previous transverse myelitis while a symmetrical bilateral mild reduction in power is expected as a result of decompensation during acute illness. As a result, further aggressive immunosuppression would not be appropriate.

Rituximab results in B cell depletion through incompletely understood processes. An acute deterioration in cognition and agitation, in the context of an immunosuppressed, should raise strong suspicions of encephalitis or meningitis. The patient might not raise a strong immune response, hence relatively modest number of white cells in CSF and CRP, but the raised CSF protein would be consistent with viral encephalitis. A CSF:serum glucose of around 1:2 lowers the risk of bacterial CNS infection. The patient should be covered for possible herpes simplex or varicella-zoster encephalitis with intravenous aciclovir while awaiting CSF PCR.

Question 70 of 299

A 57-year-old male presents with a 3 months history of increasing clumsiness in his hands and arms. He has a complicated past medical history: 22 years ago, he underwent a renal transplant after a progressive deterioration in his renal function following diagnosis with autosomal dominant polycystic kidney disease aged 25. His transplant has functioned well since but the patient has since undergone two resections of squamous cell carcinomas and one serious lengthy hospital admission for a systemic fungal infection. He stopped working a year ago as a wine merchant, after complaining that he was no longer able to differentiate 'the smells of his wines as he got older'.

On examination, he is alert and orientated. Questioning was challenging due to his hearing impairment, despite bilateral hearing aids. He scored 17/30 on a mini-mental examination. Pupils were reactive with a full range of eye movements. Facial power and sensation were normal, with symmetrical palatal elevation and no tongue deviation. He was profoundly deaf bilaterally. Tone, power and sensation were normal, reflexes were present with downgoing plantars. However, you note significant bilateral finger-nose dysmetria and heel-shin mal co-ordination.

Which investigation is likely to produce the unifying diagnosis?

A. Lumbar puncture for cerebrospinal fluid including 14-3-3, S100
B. EEG
C. MRI head
D. Neurogenetic testing
E. Nerve conduction studies and EMG

C. MRI head

The patient has presented with anosmia, bilateral symmetrical ataxia, cognitive impairment and sensorineural hearing loss, classical symptoms of superficial siderosis, which would be demonstrated on MRI head, with siderosis typically prominent in the posterior fossa. The underlying cause for iron deposition is thought to be due to chronic or previous intracerebral haemorrhages. In the case of this patient, the association of polycystic kidney disease with brain aneurysms are likely to be significant. In other patients, previous neurosurgery or head trauma can similarly result in siderosis. There is no current treatment for superficial siderosis but case reports have demonstrated possible improvements with lipid-soluble iron chelators.

Question 71 of 299

A 78-year-old male presents to you with progressive weakness in his arms. He first saw his GP about 4 months ago complaining of a weakness in his right wrist and was told he had carpal tunnel syndrome, for which he was placed on a waiting list to see the orthopaedic surgeons. Over the next 4 months, he noticed progressive weakness in his right wrist and in bending his right elbow. He noted his right hand was becoming increasingly wasted. Two months ago, he noted similar weakness in his left wrist. He reports no changes to sensation, normal speech and swallowing. On examination, cranial nerves were unremarkable.

Both hands were markedly wasted with significant loss of musculature and fasciculations bilaterally. Reflexes were muted in both upper limbs with negative Hoffman's sign. Sensory examination in the upper limbs were unremarkable, he was unable to perform the finger-nose examination. Examination of the lower limbs was also unremarkable but the patient felt a subjective weakness in both hip flexion. MRI imaging of the patients head and spine demonstrated no significant lesions. Nerve conduction studies demonstrated f waves and H-reflexes, multiple focal areas of demyelination and motor neuropathic blocks.

What is the most appropriate management?

A. Intravenous cyclophosphamide
B. Intravenous immunoglobulin
C. Intravenous methylprednisolone
D. Plasma exchange
E. Riluzol

B. Intravenous immunoglobulin

The patient has presented with a pure motor peripheral neuropathy with multifocal areas of demyelination and motor block, with f waves and H-reflexes suggestive of late motor responses to electrical stimuli, suggestive of multifocal motor neuropathy with conduction block (MMN-CB). MMN-CB is an immune-mediated disorder, commonly associated with anti-GM1 antibodies, typically presenting with asymmetric bi-brachial motor weakness without sensory or bulbar involvement, allowing the key distinction from motor neurone disease. MMN-CB is not responsive to steroids or plasma exchange, unlike chronic demyelinating polyneuropathy (CIDP), which typically involves sensory nerves too.

Cyclophosphamide may have some efficacy but is generally not used in MMN-CB due to its toxicity profile.

Riluzole is a drug for motor neurone disease.

Question 72 of 299

A 45-year-old female presents with small multiple ischaemic infarcts in the right cerebellar hemisphere confirmed on MRI, associated with small haemorrhages within two areas of infarct. A subsequent CT angiogram 24 hours into the admission demonstrated a right vertebral artery dissection with a free flowing thrombus visualised.

What is the optimal management?

A. IV heparin infusion
B. 300mg aspirin 14 days followed by clopidogrel 75mg
C. Load with warfarin
D. Treatment dose low molecular heparin
E. Hold off antiplatelet and anticoagulation

A. IV heparin infusion

It is generally accepted that visualised thrombus requires anticoagulation to prevent it increasing in size and consequent possible embolic showering. However, the patient is still in the hyperacute phase with haemorrhagic transformation within small areas of infarct. The optimal management in this scenario is to offer anticoagulation with the greatest reversibility should intracranial haemorrhage occurs: intravenous heparin is tricky to manage but can be reversed the fastest compared to subcutaneous low molecular weight heparin and warfarin. The patient will require close hourly neurological monitoring and urgent repeat imaging if GCS decreases or new or deteriorating focal neurology presents.

Question 73 of 299

A 65-year-old lady was referred to the neurology clinic for assessment. She reported a 3-month history of progressive weakness. She had initially noticed difficulty opening jars but reported that over the past month she had also had difficulty walking up stairs. She did not have any pain and reported no changes in sensation. Past medical history included osteoporosis, type 2 diabetes mellitus and hypertension.

On neurological examination there were no fasciculations, the tone was normal and the sensation was intact. Power was reduced in finger flexion (3/5), wrist flexion (4/5), knee extension (3/5) and hip flexion (4/5) bilaterally. Other movements were relatively spared. Upper limb reflexes were present but diminished, but the knee jerk was absent. The plantar response was flexor bilaterally. There was no tenderness over any muscle groups. Cranial nerve examination was unremarkable.

Blood results are shown below:

Haemoglobin	122 g/l
White cell count	8.2 x 10^9/l
Platelets	376 x 10^9/l
C reactive protein	7 mg/l
Erythrocyte sedimentation rate	39 mm/hr
Creatine kinase	272 (24-170 U/l)

What is the most likely diagnosis?

A. Diabetic amyotrophy
B. Inclusion body myositis
C. Motor neuron disease
D. Myasthenia gravis
E. Polymyositis

B. Inclusion body myositis

Inclusion body myositis is the most common primary myopathy in this age group. It manifests as a slowly progressive weakness, usually affecting finger and wrist flexion initially. Lower limbweakness may also occur. Reflexes are usually diminished as in other myopathies. Creatine kinase levels are usually normal or only mildly raised, in contrast to polymyositis (where creatine kinase levels are usually markedly elevated). Muscles are often tender in polymyositis, and the distal muscles are usually not affected until the disease is advanced.

Motor neuron disease is an important differential to consider, but the lack of upper motor neuron signs and fasciculations goes against this. There is no description of fatigability that would lead one to consider myasthenia gravis, and no evidence of bulbar, facial or ocular weakness. Diabetic amyotrophy is characterised by painful wasting of the proximal lower limb muscles

Question 74 of 299

A 45 year old man develops weakness of the extensors in the wrist and digits of his left upper limb over a week. Over the next 2 months he also notices weakness of the small muscles of hands on the right side, and that he is progressively unable to dorsiflex his right foot. On examination, he has wasting and 2/5 power in the left wrist and digit extensors. On the right he has clawing of the right ring and little fingers along with wasting of the small muscles of the hand on that side (except the thenar eminence and the first two lumbricals, which are spared). He has a right foot drop along with wasting of the anterior tibial and perineal muscles on that side. Fasciculations are seen in all of the areas of weakness. Sensory examination and reflexes are normal, along with no clonus. Plantars are down-going. The remainder of the examination are normal. Nerve conduction studies show conduction block.

What is first-line maintenance treatment for this condition?

A. Riluzole
B. Intravenous immunoglobulin
C. Pyridostigmine
D. Steroids
E. Beta-inteferon

B. Intravenous immunoglobulin

The answer here is the condition called multifocal motor neuropathy with conduction block (MMNCB). These patients are usually younger to middle-aged men who develop focal arm weakness in the distribution of a named nerve. It usually happens quite suddenly (e.g. over a week) and they are often mistaken as a stroke at first presentation. However, over several months additional named motor nerves become involved asymmetrically such that MMNCB may eventually look like motor neurone disease (MND) - the principle differential here (specifically the lower motor neurone progressive muscular atrophy form rather than the mixed upper/lower motor neurone ALS form). For exam purposes, the key difference between these two conditions is the nerve conduction studies. MMNCB shows conduction block. MND does not. MMNCB is a demyelinating condition, much in the same way Guillain Barre or chronic inflammatory demyelinating polyneuropathy (CIDP) are. However, in MMNCB this demyelination is in segments of a nerve rather than affecting the whole nerve. Therefore, the action potentials (as well as being slowed because of demyelination) actually don't get past the areas of conduction block. The importance of doing nerve conduction studies is to decide whether a motor neuropathy is axonal (i.e. the axon itself getting damaged) or demyelinating. The demyelinating ones tend to be more easily and similarly treatable. MMNCB, Guillain Barre, and CIDP are all good examples ofdemyelinating neuropathies, all of which therefore respond to intravenous immunoglobulin (IVIG).

Note that the nerves involved in this particular case are the left radial nerve, right ulnar nerve, and right common perineal nerve.

Question 75 of 299

A 45-year-old lady has had weight loss over the last eight months. Over the last 3 months, she has become confused according to her family, forgetting things she would normally remember like telephone numbers or what she did during the day. She has now presented with a second episode of what sounds like a generalised tonic-clonic seizure in the last week. She has no other past medical history of note. Clinical examination shows MMSE of 23/30, cachexia, a bulky left adnexal region, and nil else. Routine blood tests are unremarkable. You organise a CT chest, abdomen, pelvis and head which reveal a suspicious lesion in the left ovary but are otherwise normal. You organise a biopsy of the left ovary, send off a paraneoplastic blood screen, and order an MRI of the brain.

What would you expect the paraneoplastic screen to return showing?

A. Voltage-gated potassium channel antibodies
B. Anti-Hu antibodies
C. Anti-GAD
D. Anti-Ma2 antibodies
E. NMDA receptor antibodies

E. NMDA receptor antibodies

The diagnosis is limbic encephalitis. Limbic encephalitis represents a group of autoimmune conditions characterised by inflammation of the limbic system and other parts of the brain. People with limbic encephalitis typically presents with a subacute development of memory impairment, confusion, and alteration of consciousness, often accompanied by seizures and temporal lobe signal change on MRI.

It is important to diagnose the underlying autoimmune aetiology of limbic encephalitis as this might point you toward the underlying diagnosis of cancer. This is to say that limbic encephalitis may often present as a paraneoplastic syndrome, although not always. The antibodies that cause limbic encephalitis and their associated malignancies are:

- NMDA receptor antibodies = ovarian cancer
- Voltage-gated potassium channel antibodies = Thymoma or small cell lung cancer
- Anti-Hu antibodies = Small cell lung cancer
- Anti-GAD = Thymoma

Question 76 of 299

A 47 year old female with relapsing-remitting multiple sclerosis (MS) describes increasing difficulty with fatigue, and has had to give up her work as a medical secretary. She has always been careful about ensuring a balanced diet, gentle exercise and early treatment of infection. On review and questioning her mood is good. Her most recent bloods are shown below:

Hb	120g/dl
Platelets	150 * 10 /l
WBC	5.2 * 10 /l
Na	130 mmol/l
K	3.8 mmol/l
Urea	6.0 mmol/l
Creatinine	68 µmol/l

B12, folate and TFTs are normal.

What is the best course of action?

A. Advise that she increase caffeine intake
B. Advise that increasing exercise may benefit
C. Trial of vitamin D
D. Trial of amantadine
E. Trial of ropinirole

D. Trial of amantadine

The first step in her management should be to exclude anaemia, thyroid dysfunction, sleep or mood disturbance. With the above results and knowledge that she is living a well balanced lifestyle, the next step would be a trial of amantadine.

Amantadine is an anti-viral agent that slows viral replication. It is also known to have some dopaminergic effects; the mechanism of action for reducing fatigue in MS however, remains unclear. It is currently recommended by NICE as a potential treatment, although a Cochrane review in 2006 was inconclusive.

Increasing caffeine intake and levels of exercise would not be recommended in this patient. Similarly, vitamin D has not be proven to be of benefit in MS. Ropinirole is a dopamine agonist used in parkinsons disease but not in MS.

Question 77 of 299

A 26-year-old female from the travelling community presents to A&E following a seizure. History from her family suggests that she was suffering with headaches over the last 24 hours and this morning was feverish and vomiting. Her partner says she was unwell 1 month ago with a fever and whole body rash that spontaneously resolved. There is no other significant past medical history.

On examination she appears drowsy. She has a left sided hemiparesis with bilateral nystagmus. Fundoscopy reveals papiloedema. There are no skin rashes.

What is the most likely underlying diagnosis?

A. Meningococcal septicaemia
B. Meningitis secondary to herpes simplex virus
C. Progressive multifocal leukoencephalopathy (PML)
D. Multiple sclerosis
E. Acute disseminated encephalomyelitis (ADEM)

E. Acute disseminated encephalomyelitis (ADEM)

In the case given there is no history of preceding neurological symptoms and the acute onset of the neurology points away from the diagnosis of MS. In the examination findings it is specified there is no rash making meningococcal septicaemia very unlikely. PML is only seen with significant immunosupression and presents with a subacute picture. This leaves HSV as a plausible diagnosis however ADEM secondary to measles is more likely given the previous full body rash in a member of the travelling community who may not have been vaccinated.

Question 78 of 299

A 65-year-old man, originally from Pakistan is referred to the rapid access chest clinic by his GP with a one month history of weight loss (of roughly 5 kg) and a dry, irritating cough. Over the past two days he has started to have loss of sensation in both of his feet and lower legs.

Examination reveals heart sounds 1 and 2 present with no added sounds, reduced air entry in the mid and lower left zones of the chest, a non-tender liver edge that extends 3cm below the costal margin and loss of sensation for pain, light touch and temperature in both feet up to the mid shin.

A chest X-ray is performed which shows a unilateral hilar mass, but no other consolidation or features. His past medical history includes mild hypertension and diabetes mellitus which is diet controlled. His only medication is enalapril for his hypertension. Bloods reveal no obvious abnormality.

What is the most likely diagnosis?

A. Squamous cell carcinoma
B. Small cell carcinoma
C. Adenocarcinoma
D. Tuberculosis
E. Sarcoidosis

B. Small cell carcinoma

Small cell carcinoma is the correct diagnosis in this case. The presentation of rapid onset neurological symptoms (sensory neuropathy) alongside constitutional symptoms and a hilar mass on chest X-ray is highly suggestive of small cell lung cancer (SCLC) with paraneoplastic syndrome. SCLC is strongly associated with paraneoplastic syndromes, particularly Lambert-Eaton myasthenic syndrome and peripheral neuropathies. The rapid progression of symptoms is also characteristic of SCLC, which typically has a more aggressive course than other lung cancers.

Squamous cell carcinoma typically presents as a central mass and can cause hilar lymphadenopathy, but it is less commonly associated with paraneoplastic syndromes. While it can present with constitutional symptoms like weight loss, the neurological manifestations would be unusual for this type.

Adenocarcinoma is typically peripherally located in the lung and would be less likely to present as a hilar mass. While it can metastasise to cause neurological symptoms, these would more commonly be due to direct spread rather than paraneoplastic phenomena.

Tuberculosis, while common in patients from Pakistan and capable of causing hilar lymphadenopathy, typically presents with more systemic symptoms such as night sweats and haemoptysis. The neurological symptoms would be unusual for TB unless there was direct CNS involvement, which would typically present differently.

Sarcoidosis can present with hilar lymphadenopathy but is typically bilateral rather than unilateral. While neurological involvement can occur in sarcoidosis, it typically affects the cranial nerves rather than causing a peripheral neuropathy. The weight loss and rapid progression would also be unusual for sarcoidosis.

Question 79 of 299

A 64-year-old man is referred to you from a psychiatrist for a second opinion. He initially presented with a 3-month history of low mood, apathy and suicidal ideation. In addition he was asked to retire early from his job as an accountant as he was performing poorly at work. He is also sleeping an average of 14 hours per day.

When the psychiatrist assessed him he noted abnormal jerky movements in the lower limbs as well as a broad based gait. An MMSE was performed and he scored 15/30. This is corroborated by your examination and you also note hyperreflexia in the lower limbs and nystagmus.

He has no history of cognitive impairment or any psychiatric history. There is no family history of any neurological or psychiatric conditions and his only past medical history is an appendectomy 20 years ago which was complicated by a large intraperitoneal bleed.

Which findings are you most likely to find on investigation?

A. Increased T2 and FLAIR signal intensity in the putamen and head of the caudate on T2 weighted MRI, 14-3-3 protein on CSF
B. CAG trinucleotide repeats on the short arm of chromosome 4
C. Increased T2 and FLAIR signal intensity in the putamen and head of caudate on T2 weighted MRI and oligoclonal bands on CSF
D. CAG trinucleotide repeats on the short arm of chromosome 12
E. Cortical atrophy, most prominent in the frontal lobes

A. Increased T2 and FLAIR signal intensity in the putamen and head of the caudate on T2 weighted MRI, 14-3-3 protein on CSF

The diagnosis here is Sporadic Creutzfeld Jakob Disease. CJD is characterised by a rapidly progressive dementia along with neuropsychiatric changes. Death usually occurs within a year of diagnosis. Most common psychiatric symptoms are depression and apathy although euphoria, anxiety and emotional lability can also be seen. Myoclonus, ataxia, nystagmus and hyperreflexia are the most common neurological symptoms.

A represents the most likely findings for sporadic CJD. Sporadic CJD normally has a longer clinical course than nvCJD and is normally seen in older people (although nvCJD is possible in this individual as he may have has a blood transfusion 20).B represents a finding seen in Huntingtons chorea. The lack of family history makes this diagnosis less likely. The oligoclonal bands in C are seen in association with Multiple Sclerosis not CJD. D is not a recognised investigation finding and E would be more consistent with a diagnosis of Picks Disease. The very rapid onset of symptoms and presence of myoclonic jerks make this answer less likely

Question 80 of 299

A 55-year-old man presents to the Accident and Emergency department and a medical referral is requested. He reports that for the past week he has been hearing voices. He states that he cannot recognise who the voices are as they are whispering quietly but he thinks that they are making derogatory comments about him. He denies any visual hallucinations and you cannot elicit any delusional beliefs. His mood appears euthymic.

He tells you that he has a long history of alcohol dependence lasting for 30 years drinking approximately 10 units of alcohol a day on average. He tells you that in the past he has tried to stop drinking alcohol but this has caused admission to hospital due to seizures. He is particularly worried because he has cut down on alcohol since the hallucinations because he is worried that he is going mad. He is now only drinking 2 units a day and has not drunk any alcohol for 24 hours. On one previous occasion where he abstained from alcohol, he said that he had hallucinations and had to be admitted to hospital for a few days and put on a drip and was told that he almost died.

Na	144 mmol/l
K	3.6 mmol/l
Urea	14.1 mmol/l
Creatinine	119 µmol/l
Bilirubin	36 µmol/l
ALP	199 u/l
ALT	92 u/l
γGT	271 u/l
Albumin	36 g/l

He has a family history of alcohol dependence and depression but no other psychiatric problems. His medications include Omeprazole, Vitamin B, Thiamine and Diazepam.

On examination his GCS is 15, there is no tremor or sweating Pulse 80 regular BP 138 / 74 chest clear, abdo soft non tender, no peripheral focal neurology MMSE 28/30 He is commenced on chlordiazepoxide and observed for 24 hours. His GCS remains at 15 and his repeat physical examination remains unchanged and the hallucinations are still present

What is the most likely diagnosis?

A. Late onset schizophrenia
B. Delerium tremens
C. Alcohol withdrawal syndrome
D. Alcoholic hallucinosis
E. Hepatic encephalopathy grade 2

D. Alcoholic hallucinosis

Alcoholic hallucinosis is a rare condition that can occur during intoxication or withdrawal, but occurs without a clouding of consciousness. Characteristically there are auditory hallucinations which can be vague at first but then can develop into clear voices with a derogatory or persecutory content. The hallucinations normally resolve after less than 6 months.

Delirium tremens will present with a clouding of consciousness and a fluctuating or reduced GCS should be seen when the patient is observed. Also in Delirium Tremens, visual hallucinations are more common, with Lilliputian hallucinations being characteristic of this condition.

Alcohol withdrawal syndrome does not typically cause auditory hallucinations. In addition there is no evidence of a withdrawal syndrome as his pulse is normal there is no sweating or tremulousness. It is possible he has been self medicating with diazepam during his period of abstinence from alcohol.

Schizophrenia is unlikely as a diagnosis as the symptoms are too acute. In addition, affective changes and delusions and family and personal history would be more likely with a diagnosis of schizophrenia.

Hepatic encephalopathy is not the diagnosis. Although there are deranged LFTS, there is no reduction in GCS and there is no liver flap .In grade 2 encephalopathy there should be definite impairment of concentration and attention. However, this is not seen in this individual as evidenced by the high score on the MMSE

Question 81 of 299

A 65-year-old man was referred to neurology outpatient clinic with a six month history of double vision. He had first noticed this when reading before going to bed but had more recently been occurring earlier during the day whenever the patient concentrated on an activity. The patients wife also reported that she had been struggling to hear the patient when he spoke to her and that on several occasions the patients eyelids had drooped during late in the day. The patient denied experiencing any weakness in his arms or legs but stated that his general mobility was normally very limited due to osteoarthritis of both his knees. Other past medical history included hypercholesterolaemia, hypertension and diverticular disease. Regular medications included bendroflumethiazide 2.5 mg OD, simvastatin 40 mg OD, co-dydramol as required. The patient was a retired builder and lived alone with his wife. He was an ex-smoker who rarely consumed alcohol.

Examination showed normal pupillary reflexes, visual acuity and visual fields. No ptosis was observed. Assessment of eye movements demonstrated a complex ophthalmoplegia with diplopia in all directions of gaze. There was significant weakness of bilateral facial muscles with bilateral involvement of the forehead. Examination of the tongue and palette was normal. Peripheral nerve examination was unremarkable except for evidence of fatiguable muscle weakness in the upper limbs.

Chest x-ray: clear lung fields with no effusion; no cardiomegaly; possible mediastinal widening

Haemoglobin	13.5 g / dL
White cell count	8.9 * 10 /l

Platelets	409 * 10 /l
Urea	4.7 mmol / L
Creatinine	95 micromol / L
Sodium	137 mmol / L
Potassium	4.8 mmol / L
Calcium (adjusted)	2.5 mmol / L

What is the single most sensitive investigation for the likely diagnosis?

A. Repetitive nerve stimulation neurophysiology
B. Serum acetylcholine receptor antibodies
C. Serum muscle specific tyrosine kinase antibodies
D. CT mediastinum
E. Single fibre electromyography

E. Single fibre electromyography

The patient is presenting with symptoms and signs consistent with myasthenia gravis. All of the above investigations would be appropriate in this context but have variable sensitivities for myasthenia gravis as listed below:

- Single fibre electromyography: sensitivity 92-100 %
- Repetitive nerve stimulation neurophysiology: sensitivity 70 %
- Serum acetylcholine receptor antibodies: sensitivity 85 %
- Serum muscle specific tyrosine kinase antibodies: sensitivity 40-70 %

The Edrophonium (Tensilon) test has a high sensitivity for myasthenia gravis but is no longer used due to risk of fatal cardiac arrhythmia. Around 10 % of patients with myasthenia gravis also have a thymoma and therefore CT scanning is an important part of assessment of these patients. However, this investigation will no yield a diagnosis.

Question 82 of 299

A 65-year-old man underwent an elective inguinal hernia repair. Due to the list running late into the evening, the patient was admitted for an overnight stay. During the night after the operation the patient was observed to have an increasing oxygen requirement and the following morning was referred to the oncall medical registrar.

The patient reported feeling progressively more short of breath since the operation, particularly when he had tried to lie down to sleep. He denied any cough, chest pain, leg swelling or palpitations. Prior to the operation the patient had been generally well although he had found that he frequently experienced double vision when reading especially in the evening. He also had noticed some difficulties when chewing tough foods in recent weeks. Past medical history was unremarkable and the patient took no regular medications.

Examination revealed a regular pulse, no elevation of jugular venous pressure and normal heart sounds. Both calves were soft and non-tender. The patient had a shallow respiratory effort and was unable to speak in full sentences. Chest expansion was reduced bilaterally, chest was resonant with vesicular breath sounds throughout. The patient had bilateral weakness of facial muscles and ptosis on prolonged upward gaze. Power of neck flexion and extension was reduced, graded as 4/5.

Basic observations:

- Blood pressure: 120 / 76 mmHg
- Heart rate: 115 beats / min
- Respiratory rate: 32 breaths / min
- Temperature: 36.8ºC

Portable CXR: technically poor film due to poor inspiratory effort; clear lung fields; no pleural effusion; no upper lobe blood diversion; no free air under diaphragm.

Arterial blood gas analysis (35 % O2)

pH	7.29
PaCO2	6.6 kPa
PaO2	8.7 kPa
Bicarbonate	18 mmol / L (reference 20.0-26.0)
Lactate	2.1 mmol / L

Bedside forced vital capacity: 1.9 L

What is the most important next step in management?

A. Pyridostigmine
B. Referral to intensive care unit
C. Reduce percentage of supplemental oxygen
D. High-dose corticosteroids
E. Intravenous immunoglobulin

B. Referral to intensive care unit

The patient has symptoms and signs of previously unrecognised myasthenia gravis. The physiological stress of surgery has precipitated a myasthenic crisis associated with type 2 respiratory failure, tachycardia, tachypnoea and reduced forced vital capacity. The priority in management is to refer the patient to an intensive care unit for respiratory support.

Corticosteroids and pyridostigmine are mainstays of treatment of myasthenia gravis with intravenous immunoglobulin also used in severe cases. However, these treatments cannot be expected to restore respiratory muscle function rapidly in this emergency situation.

The patient has no history of obstructive lung disease with type 2 respiratory failure due instead to failure of ventilation due to respiratory muscle weakness. Therefore, reducing percentage of supplemental oxygen would not be beneficial and would cause additional hypoxia.

Question 83 of 299

A 48-year-old woman presented to the emergency department with a severe headache. Symptoms had started early that day while the patient had been walking around her office with the headache reaching maximal intensity within a few minutes. The pain was felt across the entirety of the patient's head and was much improved when she lay down flat. There were no associated symptoms and the patient had been constitutionally well in the preceding days.

The patient had no past medical history and was nulliparous. She was a non-smoker who consumed 15 units of alcohol per week.

Clinical examination demonstrated no evidence of focal neurological deficit and no signs of meningism. Simple analgesia given in the emergency department had limited impact on the patient's headache.

CT brain with venogram: no evidence of intra-axial or extra-axial bleeding; no space occupying lesion; no hydrocephalus; no evidence of venous sinus thrombosis

Lumbar puncture: opening pressure 5 mmHg; red cells 8 mm³; white cells 1 / mm³; no xanthrochromia

What is the next best investigation to confirm the likely diagnosis?

A. Digital subtraction myelography
B. Cerebral angiography
C. CT brain with contrast
D. MRI whole spine with STIR
E. MRI brain with gadolinium

E. MRI brain with gadolinium

The clinical presentation and initial investigations are suggestive of spontaneous intracranial hypotension. The key aspect of the history is the strong postural relationship to pain with the headache worsening within a few seconds of upright posture and easing within a minute of lying horizontal. Spontaneous intracranial hypotension can cause either a headache of insidious or rapid onset. A low opening pressure on lumbar puncture (< 6 cmCSF) is one of the diagnostic criteria.

Diagnosis is confirmed by MRI with gadolinium that demonstrates distinctive dural gadolinium enhancement and downward displacement of brain on sagittal views.

In some cases of spontaneous intracranial hypotension, investigations such as MRI whole spine with STIR sequences or digital subtraction myelography may be used to identify the location of CSF leak in order to guide blood patch treatment.

Question 84 of 299

A 55-year-old male attends the clinic with low mood. He also describes anhedonia and anergia. On mental state examination you note passive suicidal ideation, psychomotor agitation, and poverty of thought. He was recently started on a new medication for treatment of Huntington's chorea.

What drug may have been the cause of this presentation?

A. Citalopram
B. Venlafaxine
C. Mirtazapine
D. Risperidone
E. Reserpine

E. Reserpine

VMAT inhibitors such as reserpine can cause drug induced depression

Important for me Less important

The clinical features are suggestive of depression. Before diagnosing a mental health disorder it is extremely important to rule out organic and drug induced causes. For example, organic pathology such as hypothyroidism can cause depression. Several drugs have been implicated in drug induced depression including isotretinoin and vesicular monoamine transporter (VMAT) inhibitors (e.g. reserpine).

Therapeutic options for Huntington's chorea include dopamine-depleting agents (e.g. reserpine, tetrabenazine) and dopamine-receptor antagonists (e.g. neuroleptics). It is likely that the patient has been started on reserpine which has resulted in drug induced depression.

Question 85 of 299

A 68-year-old man presents with a weak left leg. He states that he first noticed it a few weeks ago. On examination you note weakness of left ankle plantar flexion.

Nerve conduction studies of the tibial nerve are as follows:

- Conduction velocity 25 metres per second (normal >50) Amplitude of 21mV (normal >17)

What is the most likely cause?

A. Uraemia
B. Multiple myeloma
C. HIV
D. Vitamin B12 deficiency
E. Diabetes mellitus

B. Multiple myeloma

When interpreting NCS, a reduced conduction velocity but normal amplitude is indicative of demyelinating pathology

Peripheral neuropathies can result from axonal degeneration, demyelination, or a combination of the two. Generally, axonal neuropathies are caused by metabolic, toxic or heritable causes. Demyelinating neuropathies are generally caused by autoimmune processes, paraproteinaemia or the result of an inherited disorder of myelin

It is very difficult to distinguish between the two on clinical grounds, hence why nerve conduction studies (NCS) are very useful for making the distinction.

When interpreting NCS, a reduced amplitude but normal conduction velocity is indicative of axonal pathology. Causes of a predominant sensory axonal peripheral neuropathy include diabetes mellitus (commonest cause), B12 deficiency, uraemia, carcinoma (paraneoplastic) and HIV.

The NCS in this case confirm a demyelinating process. Multiple myeloma is the only given option which causes demyelination. The other options are causes of an axonal peripheral neuropathy.

Question 86 of 299

A 54-year-old man presents with seizures. His wife states that they recently returned from Kenya. Observations are as follows: heart rate 96 beats per minute, blood pressure 130/85 mmHg, respiratory rate 16 breaths per minute, SpO2 96% (on air), temperature 38.6ºC.

An MRI scan is performed:

MRI head General oedema of the medial temporal lobes on T1

What is the most likely pathogen?

A. Coxsackie
B. Herpes simplex virus type 1
C. Herpes simplex virus type 2
D. Varicella zoster virus
E. West Nile virus

B. Herpes simplex virus type 1

CT head showing temporal lobe changes - think herpes simplex encephalitis

Herpes simplex virus type 1 is correct. The clinical ad radiological features are consistent with herpes simplex encephalitis. HSV-1 is responsible for 95% of cases of viral encephalitis in adults.

Coxsackie is incorrect. Coxsackie or Echovirus groups of enteroviruses are the most common cause of viral meningitis. The patient in this clinical case has clinical features of encephalitis (e.g. seizures) rather than meningitis (headache, neck stiffness, and photophobia).

Herpes simplex virus type 2 is incorrect. It is herpes simplex virus type 1 which is more commonly implicated in viral encephalitis.

Varicella zoster virus is incorrect. Although this remains within the differential diagnosis, the most common cause of viral encephalitis is herpes simplex virus type 1 making this the preferred answer.

West Nile virus is incorrect. Although this virus remains within the differential diagnosis given the travel history, it is a rare infection in travellers, and thus a less likely diagnosis. However, a consult with infectious diseases and appropriate testing should be conducted in order to exclude it.

Question 87 of 299

A 22-year-old man attends with a 3-month history of low mood. He also states that he has reduced energy levels and does not get enjoyment from things that he usually would. On mental state examination, he has no evidence of delusions or thoughts of self-harm. He is started on sertraline.

When should the patient be reviewed?

A. 1 week
B. 2 weeks
C. 3 months
D. 4 weeks
E. 6 months

A. 1 week

Patients ≤ 25 years who have been started on an SSRI should be reviewed after 1 week

1 week is correct. Patients under the age of 25 years or who are at increased risk of suicide (e.g. psychosis, previous self-harm) should be reviewed after 1-week following the initiation of antidepressant therapy. This is because some evidence suggests that selective serotonin reuptake inhibitors (SSRIs) may cause worsening of suicidal ideas in vulnerable patients, particularly in the very early stages of treatment..

Question 88 of 299

A 54-year-old woman presents to the Emergency Department with a five hour history of headache and visual disturbance. She states the headache came on quickly and she has vomited ten times since this pain started. She denies any past medical history and states she wears glasses for reading.

On examination there is a mid-dilated pupil in the left eye. The right eye direct pupillary reaction was satisfactory. There is no tenderness over the left temporal artery and there is no other neurological deficit.

Her observations revealed a blood pressure of 141/90 mmHg, heart rate 90 bpm, temperature 36.4ºC, oxygen saturation 96% on room air and respiratory rate 12/min.

Her blood results are as follows:

Hb	140 g/L	Male: (135-180) Female: (115 - 160)
Platelets	450 * 10 /L	(150 - 400)
WBC	11.0 * 10 /L	(4.0 - 11.0)
Na	135 mmol/L	(135 - 145)
K	4.6 mmol/L	(3.5 - 5.0)
Urea	5 mmol/L	(2.0 - 7.0)
Creatinine	80 µmol/L	(55 - 120)
CRP	8 mg/L	(< 5)

Topical pilocarpine was the applied to the eye.

What other medication should be given urgently to help manage this condition?

A. Intravenous acetazolamide
B. Topical cyclopentolate
C. Oral nimodipine
D. Topical tropicamide
E. Oral beta blocker

A. Intravenous acetazolamide

Alongside eye drops, IV acetazolamide is used in the initial emergency medical management of acute angle-closure glaucoma

The answer here is acetazolamide. This patient presents with acute angle-closure glaucoma. The acute onset headache, mid-dilated pupil with no other neurological deficit makes acute angle closure glaucoma the most likely pathology. After administering eye drops such as timolol and pilocarpine the optimal intravenous treatment is acetazolamide; a carbonic anhydrase inhibitor which decreases the level of aqueous humour in the eye.

Cyclopentolate is and acetylcholine receptor antagonist antagonist which allows mydriasis, this would cause further closure of the iridocorneal angle and therefore worsening this patients symptoms.

Nimodipine is a calcium channel blocker used in the treatment of subarachnoid haemorrhage to combat the effects of cerebral vasospasm.

Tropicamide is a dilating eye drop which is used may reduced the iridocorneal angle and therefore drainage of aqueous humour, potentially worsening the acute angle closure glaucoma.

Pilocarpine and timolol are used in the treatment of acute angle-closure glaucoma but are used as eye drops rather than intravenously. Pilocarpine causes miosis, thereby increasing the rate at which aqueous humour leaves the eye and decreasing intraocular pressure. The exact mechanism of timolol is not known but it is thought that through inhibition of beta receptors, the production of aqueous humour is reduced. Timolol is a beta blocker but is used topically, there is no known role for oral beta blockers in acute angle closure glaucoma.

Question 89 of 299

A 27-year-old lady was admitted to the Emergency Department due to acute shortness of breath. She had been completely normal that morning. Her sister mentioned that this was not the first time she had suffered such an attack and she improved every time after staying in hospital for a couple of hours and taking some nebulisers. The patient is not known to have any medical condition. Her father is on long term prednisone tablets and nebulisers for chronic obstructive pulmonary disease.

On examination: blood pressure 123/86 mmHg, pulse rate 110/min, respiratory rate 35/min. Oxygen saturation 98%. The chest was clear with good air entry.

Blood investigations showed:

Hb	128 g/l
Platelets	320 * 10 /l
WBC	8 * 10 /l
Na	137 mmol/l
K	4.2 mmol/l
Urea	6 mmol/l
Creatinine	100 µmol/l

A 3-month-old pulmonary function test was normal.

What is the next step in management?

A. Discharge home
B. Refer to repeat pulmonary function tests
C. Nijmegen questionnaire
D. Serial ECG
E. Psychiatric review

C. Nijmegen questionnaire

Normal patient observations and examination ruled out any significant pathology. The history of repeated admissions without a diagnosis and rapid recovery are all pointers towards hyperventilation syndrome (HVS). If a doctor encounters such presentation, the Nijmegen questionnaire can be used to test whether or not the patient has HVS. This questionnaire involves asking about 16 different symptoms such as chest pain and tingling fingers. Each one of these symptoms should be assigned a number from 0 to 4 according to how often it is felt. A score of more than 23 out of 64 is diagnostic of HVS.

Question 90 of 299

A 62-year-old woman presents with a blurring of the vision in her left eye and associated pain. She has not experienced this before but does recall that, 5 years prior, she experienced reduced sensation of the left leg, which eventually completely recovered spontaneously.

On examination, her vision is markedly worse in the left eye, with worse colour discrimination also. She has pain on eye movement in all planes. Neurological examination of the limbs is unremarkable.

Which of the following is associated with a poor prognosis in this patient's most likely diagnosis?

A. Female sex
B. Long interval between relapses
C. Older age of onset
D. Relapsing-remitting course
E. Sensory symptoms only

C. Older age of onset

Older age of onset is associated with a poor prognosis in multiple sclerosis

The diagnosis here is likely to be multiple sclerosis, given the two distinct episodes over time. The first episode presented with weakness of the left leg some years ago, recovered fully, and the recent episode is indicative of optic neuritis. It is worth remembering that the 'typical' patient carries a good prognosis - of the feature of this patient her age on diagnosis is atypical; older age is associated with a poorer prognosis. Usually, patients would present in their 20s or 30s.

Female sex is associated with a good prognosis in multiple sclerosis.

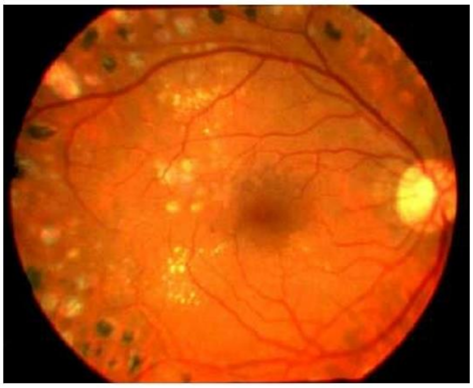
A 5-year interval between episodes, as seen here, is a significant amount of time between the first two episodes and is considered a marker of good prognosis, not poor.

This patient also demonstrates a relapsing-remitting course - complete recovery between episodes. This is also indicative of a good prognosis, not poor.

The presence of only symptoms, as opposed to motor symptoms too, is also considered to be a sign of good prognosis, not poor.

Question 91 of 299

A 64-year-old man presents with visual loss. He is on holiday in the United Kingdom; his English is limited and obtaining a history is difficult. He appears generally well in himself and does not appear to be in any obvious pain. Retinal photography is undertaken and shown below:



Which of the following is the most likely diagnosis?

A. Age-related macular degeneration
B. Central retinal artery occlusion
C. Central retinal vein occlusion
D. Diabetic retinopathy
E. Anterior ischaemic optic neuropathy

D. Diabetic retinopathy

The correct answer is diabetic retinopathy. This photo is classic of the condition. Microaneurysms are visible, as well as some central macular oedema. A number of exudative areas - 'cotton-wool spots' - are also visible. As the condition progresses, more neovascularization is expected.

Age-related macular degeneration is incorrect. The 'dry' form would characteristically appear with deposits of drusen around the macula, rather than the vascular changes seen here. The 'wet' form will have some vascular changes, but this will appear as choroidal neovascularisation rather thanthe various microaneurysms seen here.

Central retinal artery occlusion is not consistent with the photo above - it would typically show a cherry red spot, where the centre of the macula is red, but surrounding retina is pale due to lack of blood flow. The retina in general may appear pale.

Central retinal vein occlusion would present with widespread flame haemorrhages rather than the smaller changes seen here, as well as dilated and tortuous veins, which are not really seen in this photo.

Ischaemic optic neuropathy would also look different to the photo above, presenting with a pale, oedematous optic disc. The vascular changes and exudates seen here would not be present.

Question 92 of 299

A 45-year-old teacher is reviewed in a routine nephrology clinic. She has end stage renal failure with focal segmental glomerular sclerosis (FSGS) on biopsy and is receiving renal replacement via haemodialysis. She requires hearing aids for bilateral sensorineural hearing loss and is of short stature. She mentions that she has been feeling more tired and lethargic in the last few months. A fasting blood sugar taken by her GP is 8.0mmol/l. She has a family history of diabetes in her mother and maternal grandmother, both of whom also required hearing aids at an early age.

Given the above features, what is the most likely cause of her end stage renal failure?

A. Autosomal dominant polycystic kidney disease
B. Alport syndrome
C. Liddle syndrome
D. Maternally inherited diabetes and deafness (MIDD)
E. Granulomatosis with polyangiitis (Wegener granulomatosis)

D. Maternally inherited diabetes and deafness (MIDD)

Alport syndrome and GPA could also cause end stage renal failure and deafness. However, diabetes is not a feature of Alport syndrome and GPA is not a directly heritable disease.

ADPKD causes end stage renal failure with an autosomal dominant pattern of inheritance but would not explain the other features.

Liddle syndrome is a genetic cause of hypertension due to mutations in the epithelial sodium channel in the distal convoluted tubule.

Question 93 of 299

A 55-year-old female is referred to the neurology clinic with fatigue and muscle weakness, particularly affecting the lower limbs causing difficulty walking. The patient has had several similar episodes in the past with one such episode associated with painful, reduced visual acuity. Previous episodes would typically last a few weeks before spontaneously resolving.

On examination today the patient has spasticity weakness of the lower limbs with reduced sensation distally. Cranial nerve and spinal examination are both normal.

An MRI brain is performed showing evidence of disseminated brain lesions and further tests confirm unpaired oligoclonal bands in the CSF, but not in the serum.

Which of the following is associated with a poor prognosis in the patient's most likely diagnosis?

A. Female sex
B. Long interval between first two relapses
C. Older age of onset
D. Presence of oligoclonal bands in the CSF at time of diagnosis
E. Relapsing-remitting disease

C. Older age of onset

Older age of onset is associated with a poor prognosis in multiple sclerosis

This patient meets the definition for multiple sclerosis (MS) with the dissemination of lesions of the CNS, brain and/or spinal cord (motor and sensory disruption, optic neuritis, etc.) in time and space with characteristic findings on MRI and of unpaired oligoclonal bands in the CSF. Older age onset is associated with a poorer prognosis in MS when compared to patients who present at a younger age.

Females generally have a better prognosis in MS, this patient's likely diagnosis, when compared to male patients.

Longer intervals between a patient's first two relapses are associated with an improved prognosis in MS.The presence of CSF oligoclonal bands at the time of MS diagnosis has not been linked to the condition's progression or prognosis.

Of the four MS subtypes/patterns, relapsing-remitting is associated with the best prognosis (other subtypes: secondary progressive disease, primary progressive disease, progressive-relapsing disease).

Question 94 of 299

An eighty-year-old lady is reviewed. She has a complex past medical history of chronic kidney disease, hypertension, type II diabetes, osteoporosis, Paget's disease and epilepsy, taking ramipril, atorvastatin, sodium bicarbonate, linagliptin, zoledronic acid and phenytoin. On examination, she has asymptomatic cervical lymphadenopathy, with no other abnormal findings.

Which medication could be causing this?

A. Phenytoin
B. Sodium bicarbonate
C. Atorvastatin
D. Linagliptin
E. Zoledronic acid

A. Phenytoin

Phenytoin can cause lymphadenopathy

Phenytoin is known to be an iatrogenic cause of lymphadenopathy, as well as carbamazepine, allopurinol and sulphonamides. Be aware, that a more systemic drug reaction is more often noted with medications, with lymphadenopathy as an associated, but not isolated, sign e.g. DRESS and serum sickness.

Sodium bicarbonate, atorvastatin, linagliptin and zoledronic acid are not commonly associated with lymphadenopathy.

Question 95 of 299

A 62-year-old man is reviewed following a thyroidectomy for follicular thyroid cancer without metastatic spread. He started developing first twitching and then cramps following the procedure, primarily affecting his legs. He finds this to be quite painful and has never experienced anything like this previously. He reports that the surgical registrar told him that the procedure went well without complication. He also has a past medical history of hypertension, vitamin D deficiency, depression and gout. He was taking ramipril, cholecalciferol with calcium and allopurinol. All his regular medication have been held for one day due to surgery.

What is the most likely cause of his cramps?

A. Hypocalcaemia
B. Hypercalcaemia
C. Hypophosphataemia
D. Hyperphosphataemia
E. Hypokalaemia

A. Hypocalcaemia

Following thyroid removal, checking calcium is important to assess for hypoparathyroidism

The patient has undergone an thyroidectomy and developed symptoms consistent with hypocalcaemia soon after. This is most likely due to iatrogenic primary hypoparathyroidism as the parathyroid glands can easily be removed or have vascular damage from thyroid surgery. The patient would likely have low parathyroid levels, as well as low calcium and high phosphate. The low calcium would need to be replaced and then symptoms would resolve.

Question 96 of 299

An 82-year-old female is brought into your falls clinic by her daughter after her third fall this year. No fractures were sustained and she appears to have no significant head injuries. The fall appears mechanical in nature. She currently lives with her daughter, who reports the patient's mobility to be progressively deteriorating, from full independence and no exercise limitations 1 year ago to restrictions at 50-70 yards now, limited by knee pain secondary to osteoarthritis. Her other past medical history includes hypertension, type 2 diabetes mellitus, chronic kidney disease and previous gallstones.

You note she is withdrawn and makes little eye contact. Her voice is quiet. When you ask her whether she is low in mood, she does not respond. She reports no suicidal ideations but has little hope for the future. She asks you to 'not worry about it', as she 'has been the same way for several months now'. However, the patient does seem amenable to some kind of treatment.

On the Beck depression scale, she scores 11/63 (0-13 = no or minimal depression), on the geriatric depression scale, she scores 11/15 (greater than 10 = indicative of depression) and mini-mental state examination, she scores 19/30 (20-26 = mild cognitive impairment, 10-19 = moderate cognitive impairment). Routine investigations including B12, folate, thyroid function, liver function tests and bone profile are unremarkable.

What is the most appropriate treatment pathway?

A. Citalopram
B. Amitriptyline
C. Mirtazapine
D. Donepezil
E. No treatment required

A. Citalopram

Depression in elderly can depress cognitive function, hence cognition may be inaccurately depressed on measurement scales. Donepezil is thus not indicated on this measure alone. In elderly patients, GDS is more appropriate than Becks depression scale, as

the latter focuses heavily on somatic symptoms that frequently under-score depression in elderly patients. This patient is describing depression without suicidal ideations. Tricyclic antidepressants and SSRIs are similarly efficacious in elderly patients but the first line of treatment for depression in the elderly is a SSRI such as citalopram, mainly due to the lack of interactions with primarily P450 enzymes . TCAs produce significantly greater anticholinergic side effects. MIrtazapine and sertraline failed to demonstrate a significant benefit compared to placebo in Alzheimers patients with depression

Question 97 of 299

A 46-year-old white Caucasian female presents to the Emergency Department after waking up unable to walk and complains about problems with vision in her right eye. The patient says she is normally extremely healthy and the only time she has ever visited her GP was when she had an episode of diarrhoea and vomiting about a week ago. She is understandably distressed as she has not experienced any symptoms before and has not been previously diagnosed with any medical conditions. She has no drug or family history. Nursing staff report to you that she has been given a pad on her bed as she is incontinent of urine, which she is tearfully embarrassed by.

On examination of her cranial nerves, a right relative afferent papillary defect is noted. Visual acuity and colour vision are 6/6 with 17/17 Ishihara plates on the left, 6/60 with 0/17 Ishihara plates on the right. She reports no diplopia with a full range of eye movements and normal facial sensation. Facial movements are normal. Fundoscopy was unremarkable. Examination of the patient's upper and lower limb power demonstrated normal tone with 2-/5 power on the left arm and leg in all movements; and 4-/5 all movements in right arm and leg. There is a patchy loss of sensation to cotton wool on right lateral wrist and anterior aspect left lateral shin. Both plantars are upgoing. Reflexes are brisk at knee and ankles bilaterally. Anal tone and saddle sensation are intact. The patient's cognitive state is normal on superficial examination.

An urgent MRI head and whole spine demonstrates abnormal high signal in the cervical cord from C3 to C7. Her blood tests were mislabelled and hence unavailable. A lumbar puncture was performed with the following results:

WCC	12 mm³
RBC	<1 mm³
Protein	0.9 g/l
Glucose	5.2 mmol/l (10.2 mmol/l serum)
Oligoclonal bands	awaited
Viral PCR	awaited

What is the most likely diagnosis?

A. Idiopathic intracranial hypertension
B. Transverse myelitis
C. Miller-Fisher syndrome
D. Multiple sclerosis
E. Devic's disease

E. Devic's disease

A first episode of an optic neuritis and myelitis occurring together is suggestive of a central neuroinflammatory cause. A full range of eye movements makes Miller-Fisher syndrome unlikely (and any ataxia demonstrated is likely secondary to limb weakness). Although there is the temptation of diagnosing multiple sclerosis in a patient with features disseminated in place, the keys to the answer are the sites of the lesion (optic nerve and cervical cord) and the long length of cord involvement beyond 3 vertebral levels, much more suggestive of neuromyelitis optic or Devic's disease. The diagnosis would be clinched by a positive aquaporin 4 antibody.

Question 98 of 299

A 42-year-old woman presents with 6 days of drowsiness and a gradual onset headache, initially starting in the occipital region and radiating to the apex. She has recently returned from Australia in holiday one week ago but has complained of poor appetite after a cough and cold since landing. She has no past medical history, takes no regular medications except the oral contraceptive pill. She is a non-smoker and drinks minimally. On examination, the patient has a full range of neck movements and no photophobia. Examination of her limbs is unremarkable. You request a CT head without contrast, which demonstrates two small areas of subarachnoid blood in right convexity. She denies any recent head trauma.

Which investigation will most likely provide the conclusive diagnosis?

A. CT head with contrast
B. MRI head
C. MR venogram
D. Lumbar puncture with xanthochromia
E. CT angiography

C. MR venogram

MR Venogram is the gold standard test for diagnosing venous sinus thrombosis

The patient presents with a non-specific headache on a background of a number of different risk factors for venous thromboembolic disease: recent long-haul flight, likely dehydration from poor oral intake, oral contraceptive pill. A generalised headache is present in almost 90% of all patients with cerebral venous thrombosis (CVT) . The headache is caused by impaired absorption of cerebrospinal fluid due to the sinus thrombus, resulting in increased intracranial pressure. CVTs can also present with seizures, encephalopathy and focal symptoms, but be aware that the presenting clinical features can be extremely variable.

A plain CT head can sometimes demonstrate signs of CVT in one-third of patients. A dense triangle sign is often seen in the posterior superior sagittal sinus. In addition, the empty or negative delta sign due to thrombus obstruction. However, MR venogram (CT venogram in the hands of highly skilled radiologists) is the most sensitive imaging modality.

This scenario is a useful demonstration that not all subarachnoid blood equates to a spontaneously ruptured aneurysm. Cerebral venous thrombosis is a classic cause of intraparenchymal and subarachnoid haemorrhages, particularly if around the convexity . In addition, the description of the headache is atypical for an aneurysmal subarachnoid haemorrhage: the headache is of gradual onset, persists for days, with no meningism. Although it may seem illogical, treatment with anticoagulation will treat the sinus thrombus, resulting in improved CSF flow, while the subarachnoid blood will slowly resolve.

Question 99 of 299

A 57-year-old gentleman was brought to the emergency department by ambulance following a collapse 2 hours earlier. His partner witnessed him fall to the floor and stated that he had not been moving his right arm and leg since. She said that he had been well before this episode. The ambulance crew reported that he had had a generalised tonic-clonic seizure, which was terminated after 6 minutes with 5mg of diazepam. On examination, he was drowsy, with a Glasgow coma score of 10 out of 15, and his blood pressure was 165/92mmHg. He had a right sided facial droop and there was no movement in his right arm or leg. He was known to be a smoker, and he took amlodipine for hypertension. He was not on any other medications.

An urgent CT head scan was performed immediately which demonstrated loss of differentiation between the grey and white matter in the left frontal and parietal lobes, but no acute haemorrhage.

What is the most appropriate initial management?

A. Aspirin 300mg for 2 weeks
B. Intravenous alteplase 900 micrograms/kg
C. Aspirin + dipyridamole 25/200mg
D. Clopidogrel 75mg
E. Warfarin

A. Aspirin 300mg for 2 weeks

This patient presents with a sudden onset of neurological deficit, with lateralising signs. This history is strongly suggestive of a stroke, and the CT head findings suggest an ischaemic cause.

Acute management of ischaemic stroke involves keeping the patient nil by mouth until swallow assessment is performed, nasogastric tube insertion if dysphagia is problematic, and admission to a high dependency stroke unit for close monitoring.

If the presentation is within 4.5 hours of onset thrombolysis with a recombinant tissue plasminogen-activator (such as alteplase) can be considered, which has been shown to improve neurological outcome. This patient presents at 2 hours, but his seizure at the onset of stroke precludes the use of thrombolytic therapy (see table).If the presentation is beyond 4.5 hours, or thrombolysis is contraindicated, aspirin should be commenced at a dose of 300mg for 2 weeks as soon as possible. Lifelong anti-platelet therapy should be continued thereafter. Aspirin in combination with dipyridamole is only recommended if clopidogrel is contraindicated. Warfarin is not indicated in the immediate management of stroke, though may be started if the patient is shown to have atrial fibrillation. This is usually delayed for 2 weeks, due to the risk of haemorrhagic transformation if given before this.

Question 100 of 299

A 45-year-old woman has been brought to the Emergency Department by ambulance. Her 20year-old son found her collapsed on the floor with a note stating that she wished to take her own life. The paramedics have brought all the medication packages that they could find. This included sertraline, atorvastatin and diazepam. Previous medical history includes depression with suicidal ideation and a paracetamol overdose 3 years ago that required admission.

Her 50mg sertraline package shows five empty slots. Her 10mg diazepam package shows 30 empty slots.

On assessment of the patient:

- A - Airway is supported by the anaesthetist with a bag valve mask.
- B - Respiratory rate is being supported up to 12/min. Saturations are maintained at 98% however, the patient desaturates and hyperventilates without assistance.
- C - BP 102/74 mmHg, pulse 94 bpm.
- D - GCS 9, (E1, M5, V3), pupils 4mm bilaterally and reactive.

What is the next step in the management of this patient?

A. Activated charcoal
B. Flumazenil
C. High dose insulin therapy
D. Intubation and ventilation
E. Naloxone infusion

D. Intubation and ventilation

Benzodiazepine overdose is best managed supportively and with airway protection and ventilation if needed. Flumazenil should be avoided unless for reversal of anaesthesia

Intubation and ventilation is correct. The patient is hypoventilating and unable to protect their airway. The cause is likely an overdose of benzodiazepines which requires organ support whilst the drug is metabolised. Further investigations such as CT head, ECG, paracetamol and salicylate levels will also be important to ensure there is no alternative cause for the sudden drop in GCS.Activated charcoal is incorrect because the patient has a low GCS. Although activated charcoal can be used in overdose if the patient presents within 60 minutes of ingestion, it should not be administered to a patient with a decreased GCS. Charcoal is an emetic and increases the risk of aspiration in a patient with a low GCS. In this case, the time of consumption of medication is also unknown.

Flumazenil is incorrect because it is not known if this is an isolated benzodiazepine overdose and the patient may have a dependence on benzodiazepines. Flumazenil is rarely used outside of the operating theatre. It is the antidote to benzodiazepines but must not be used in mixed overdoses. If the patient has any risk of seizures then administration of flumazenil will prevent benzodiazepines from providing seizure control. In this case, the patient has likely ingested a considerable dose of benzodiazepines but may have taken a mixed overdose.

High dose insulin therapy is incorrect because this is used in beta-blocker and calcium channel blocker overdose. High dose insulin therapy is the administration of insulin at 1unit/kg. This therapy may overcome myocardial starvation and increase myocardial function without an increase in oxygen demand.

Naloxone infusion is incorrect because there is no suspicion of an opioid overdose. Naloxone is the antidote to opioid toxicity. Although it is entirely appropriate to trial naloxone in suspected mixed overdose and suspicion of opioids, a naloxone infusion should only be started if the patient has shown a response to an initial naloxone bolus. The initial dose is 400mcg, however experienced clinicians may titrate this to affect in chronic opioid users as this can lead to sudden and severe withdrawal symptoms.

Question 101 of 299

A 72-year-old man is referred to the neurology outpatient department with an insidious onset of tremor by his general practitioner. He has a past medical history of hypertension and recurrent falls. He is on regular amlodipine. He does not smoke or drink alcohol.

On examination, there is bradykinesia and rigidity and a pill-rolling tremor of the right hand. He is unable to make vertical saccades with his eyes when tested. He appears to lung forward when walking.

What is the likely diagnosis?

A. Corticobasal degeneration
B. Dementia with Lewy Bodies
C. Multiple system atrophy
D. Parkinson's disease
E. Progressive supranuclear palsy

E. Progressive supranuclear palsy

Progressive supranuclear palsy: postural instability, impairment of vertical gaze, parkinsonism, frontal lobe dysfunction

Progressive supranuclear palsy is the correct answer. This patient presents with parkinsonism, postural instability and impairment of vertical gaze, which is characteristic of this condition.

Dementia with Lewy Bodies is incorrect. While this can cause parkinsonism, it does not cause gaze palsies and dementia is a prominent feature.

Multiple system atrophy is incorrect. This is another 'parkinson-plus' syndrome but is characterized by autonomic dysfunction and postural instability rather than gaze palsies.

Corticobasal degeneration is incorrect. This is characterized by parkinsonism, apraxia, aphasia and classically 'alien hand syndrome', which results in the failure of the individual to control the movements of their limb resulting from the sensation that the limb is 'foreign'.

Question 102 of 299

A 65-year-old gentleman presents with left sided arm pain that originates in the shoulder and spreads into the ring and little fingers. This has worsened over the past three weeks to the point that he cannot sleep at night. His GP has trialled co-codamol without any benefit.

He is a previous smoker of 40 pack years, has hypertension and a myocardial infarction 5 years previously. He is currently well but on further questioning reveals that he has lost 2 stone in weight over the last 3 months despite increasing his food intake. He has a productive cough which has occasional streaks of blood in.

On examination, he is able to move his left shoulder, elbow and wrist with a full range of motion and no tenderness but reports that the pain is present whilst not moving. He has some weakness of his left biceps with a diminished reflex and sensation is reduced to the fourth and fifth in response to light touch. The limb has normal pulses and capillary refill time with no swelling. There are crepitations on the left upper zone and he has clubbing present.

Hb	103 g/l	Na	137 mmol/l
Platelets	456 * 10 /l	K	4.2 mmol/l
WBC	13.1 * 10 /l	Urea	5.6 mmol/l
Neuts	9.8 * 10 /l	Creatinine	98 µmol/l
Lymphs	0.89 * 10 /l	CRP	89 mg/l
Eosin	0.25 * 10 /l		

Chest x-ray	consolidation seen in the left upper zon

What is the likely diagnosis?

A. Bronchial carcinoma
B. Pneumonia
C. Cervical rib
D. Multiple sclerosis
E. Tuberculosis

A. Bronchial carcinoma

Lung carcinoma can present with a brachial neuritis

This gentleman presents with a neuralgia pain in the left arm and altered neurology in the dermatome of C8. Of these, pneumonia is unlikely to ever cause this. He does have respiratory symptoms and an extensive smoking history and this excludes multiple sclerosis as there are no other areas of altered neurology. The diminished reflexes suggest a lower motor neuron lesion and C8 is classically affected in a Pancoast tumour. Tuberculosis can rarely infiltrate the brachial plexus but bronchial carcinoma is the most likely. A cervical rib is unlikely to present at this age.

Question 103 of 299

A 46-year-old lady is admitted to emergency department with a 2 hour history of dysphasia, visual disturbance and weakness. Examination reveals left homonymous hemianopia, left sided hemiparesis with sensory loss and dysphasia. Observations show she is apyrexial with a heart rate of 102/min and blood pressure of 145/82 mmHg.

An urgent CT head and angiography are booked indicating a large infarct in the territory of the middle cerebral artery in the right cerebrum, while the CT angiography is indicative of proximal occlusion.

There is no significant past medical history and the blood investigations for this lady are normal. Her modified Rankin score is 1 and her national institutes of health stroke scale (NIHSS) is 12.

What is the next most appropriate course of action in her management given that we are now four hours from presentation?

A. Offer intravenous thrombolysis alone
B. Reduce blood pressure via the administration of nifedipine
C. Offer thrombectomy with intravenous thrombolysis cover
D. Load with clopidogrel
E. Treat conservatively with aspirin and secondary prevention

C. Offer thrombectomy with intravenous thrombolysis cover

A combination of thrombolysis AND thrombectomy is recommend for patients with an acute ischaemic stroke who present within 4.5 hours

This question highlights the importance of understanding the timing scales applicable to stroke management. The time limit for offering thrombolysis is 4.5 hours currently, while the thrombectomy window (provided that certain anatomical and functional criteria are met) is that of 6 hours.

This young lady fulfils the criteria for thrombectomy and thrombolysis and it is important to note that thrombolysis is not contra-indicated but actually encouraged en-route to thrombectomy.There is no indication in reducing this lady's blood pressure as it is well below 180/110 mmHg.

There is no place for clopidogrel loading in the acute management of stroke, with the exception of aspirin allergy.

As this lady fulfils all the criteria, has a reasonable pre-stroke score (modified Rankin score <3) and a high stroke score indicating the impact of the occlusion to her functioning (NIHSS >5), thrombectomy with thrombolysis cover is the most appropriate course of action.

Question 104 of 299

A 32-year-old male patient presents with a 1-day history of painful rash on the forehead. The patient does not have any past medical history of note. On examination, there is a vesicular rash in the distribution of the ophthalmic nerve on the right side. There is no pus or discharge. There is currently no ocular involvement.

What is the appropriate treatment?

A. Topical steroid cream for 7-10 days
B. Topical acyclovir for 7-10 days
C. Oral acyclovir for 7-10 days
D. Oral steroid for 7-10 days
E. Topical mupirocin for 7-10 days

C. Oral acyclovir for 7-10 days

Topical antiviral treatment is not given in herpes zoster ophthalmicus

This patient has herpes zoster ophthalmicus. First line treatment is oral acyclovir, started as soon as possible, for 7-10 days. Topical antiviral treatment is not given in herpes zoster ophthalmicus. This patient has no ocular involvement so far, however, if there is any sign of ocular involvement, he should be referred to ophthalmology urgently.

Steroid can be given concurrently but it does not reduce the risk of post-herpetic neuralgia. Topical mupirocin is not a suitable treatment.

Question 105 of 299

A 28-year-old man is admitted to the respiratory ward with sudden onset chest pain and shortness of breath. He has no past medical history of note. On examination, there is reduced air entry in the left lung that is hyper-resonant to percussion. The likely diagnosis is confirmed on a chest x-ray and he is treated with a pleural aspiration and observed on the ward for 24 hours.

During this period of observation, he remains well with normal observations and resolution of his chest pain and shortness of breath. A repeat chest x-ray is taken that appears normal and he is medically fit for discharge.

The patient mentions that he is due to fly to Brazil for a holiday in 2 days and wants to know if this will be safe.

What is the most appropriate advice to give this patient?

A. Able to fly following pleurodesis
B. Able to fly immediately
C. Able to fly in 1 week
D. Able to fly in 6 weeks
E. Unable to fly for life

A. Able to fly in 1 week

Pneumothorax -> can fly 1 week after treatment if chest x-ray shows resolution

This patient's clinical history, examination and investigation findings are in keeping with a pneumothorax. Given that this patient is young with no other past medical history, it is likely that he has had a spontaneous, primary pneumothorax which, if large enough, should be treated with needle aspiration. Current guidance from the British thoracic society states that following complete resolution of the pneumothorax, patients are able to fly 1 week after treatment. If a pneumothorax arises following a traumatic injury, then flying 2 weeks after chest x-ray confirmation of resolution is advised.

A pleurodesis is usually required for recurrent pneumothoraces and can be either chemical or surgical. Given that this patient's chest x-ray shows resolution of the pneumothorax, pleurodesis isnot necessary and would not be an indication for this patient to travel by air.

It is too soon for the patient to fly immediately as guidelines state that patients not air travel until 1 week from the complete resolution of pneumothorax on chest x-ray.

Previous guidelines advised that air travel would be safe following 6 weeks from the resolution of pneumothorax. However, this has since been changed to 1 week.

Unable to fly for life is incorrect. Following a pneumothorax, guidance is given to avoid deep-sea diving for life. However, air travel is still possible following pneumothorax resolution.

Question 106 of 299

A 68-year-old man presents to the acute medical unit with an episode of loss of consciousness. He states that he suffered a headache earlier that day. He describes it as a sudden onset headache at the back of his head which reached 10/10 severity within a few seconds.

You organise the following investigations:

CT head Blood in the sulci, fissures, basal cisterns and ventricles

Cerebral CT angiogram Evidence of ruptured posterior cerebral artery aneurysm

What is the most appropriate initial management?

A. Triple H therapy (hypertension, hypervolaemia, and haemodilution)
B. Labetalol
C. Magnesium sulphate
D. Amlodipine
E. Nimodipine

E. Nimodipine

Nimodipine is used to prevent vasospasm in aneurysmal subarachnoid haemorrhages

The patient has suffered from a subarachnoid haemorrhage (SAH) as confirmed on CT brain. A CT angiography has confirmed that it is aneurysmal. He is now at significant risk of re-bleeding and vasospasm.

To prevent re-bleeding he needs urgent endovascular clipping or coiling.

The gold standard for preventing vasospasm is nimodipine. Alternative calcium channel blockers can be used but the strongest evidence favours nimodipine.

The combination of induced hypertension, hypervolaemia, and haemodilution (triple H therapy) isoften used to prevent and treat cerebral vasospasm after aneurysmal SAH, however the evidence for this approach is inconclusive.

Question 107 of 299

The emergency department registrar asks for your advice regarding a 67 year-old female patient who presented with an acutely painful right eye. On examination the right pupil is fixed in middilation and not responsive to light. The conjunctiva is injected. The patient is clearly in considerable pain and has vomited twice in the department. The emergency department physicians have given intravenous analgesia and anti-emetics. You refer urgently to ophthalmology.

What is appropriate initial treatment?

A. Topical pilocarpine
B. Urgent iridotomy
C. IV acetazolamide
D. Topical latanoprost
E. Topical brimonidine

C. IV acetazolamide

The diagnosis here is acute angle closure glaucoma, an ophthalmological emergency. The correct urgent management is as follows:

- IV analgesia and antiemetics, lie patient supine.
- Topical beta blockers and steroids.
- IV acetazolamide.
- After initial treatment, pilocarpine will induce meiosis and open the angle. This is initially ineffective due to pressure induced ischaemic paralysis of the iris.
- Iridotomy 24-48 hours after intra-ocular pressure is controlled to prevent recurrence.

Question 108 of 299

A 20-year-old female with multiple sclerosis (MS) attends the emergency department following a seizure. She was diagnosed with MS at age 16 and has received different immunomodulatory regimes in the past, including azathioprine. She commenced natalizumab 2 years ago. This is her first seizure however once recovered, she tells you that she has noticed she has been increasingly clumsy over the last 6 months, she drops things easily. In addition, she has had several episodes where her speech has been slurred and people have commented that she sounds tired. On examination, you find that her tone is normal throughout, power in all muscles groups in both upper and lower limbs is normal. On cranial nerve examination, you identify a right homonymous superior quadrantanopia however she does have a full range of eye movements and no ptosis. She has an ataxic gait. Her speech is normal throughout the history.

She is concerned, what is the diagnosis?

A. Progressive multifocal leukoencephalopathy
B. Transient ischaemic attacks
C. Progression of multiple sclerosis
D. Newly diagnosed epilepsy
E. Myasthenia gravis

A. Progressive multifocal leukoencephalopathy

Natalizumab is a humanised monoclonal antibody against the cell adhesion molecule 4-integrin and is licensed as a monotherapy for the treatment of multiple sclerosis in Europe.

Progressive multifocal leukoencephalopathy (PML) is an opportunistic infection caused by the JC virus that only occurs in patients who are immunocompromised and has a risk of 2.1 in every 1,000 using natalizumab. Patients who have taken immunosuppressants before the initiation of natalizumab therapy have the highest risk of developing PML

Question 109 of 299

A 22-year-old, recently married woman presents to the first seizure clinic and is diagnosed with idiopathic generalised epilepsy. She tells you that she is keen to start a family soon.

Which first line anti epileptic drug should be avoided?

A. Levetiracetam
B. Topiramate
C. Lamotrigine
D. Carbamazepine
E. Valproate

E. Valproate

All antiepileptic drugs are associated with a risk of major congenital malformations in the offspring. However, the potential for the mother to develop tonic clonic seizures, which can result in significant adverse health outcomes for the fetus, means that discontinuing antiepileptic drug therapy during pregnancy is still discouraged by most practitioners.The largest randomised trials of newer generation versus older generation antiepileptic drugs (SANAD trials) found that valproate is superior to both lamotrigine and topiramate for the treatment of idiopathic generalised epilepsy. However, valproate is associated with teratogenicity and a risk of low IQ and should therefore be avoided in women of childbearing potential. The risk of teratogenecitiy for the newer generation antiepileptics drugs remains largely unknown, due to small sample sizes and polytherapy exposures. The data for lamotrigine is limited but is believed to be less teratogenic than valproate.

Carbamazepine is associated with a higher risk of developing major congenital malformations. For Levetiracetam, although pregnancy exposure data is limited, the UK epilepsy and pregnancy registry have not identified any major congenital malformations in association with its use.

Question 110 of 299

A 45-year-old male patient presents with an inaugural seizure. During surgery, it is found that he has an aggressive glioma, and on further histological analysis the most aggressive form of glioma is diagnosed.

Given the aggressive nature of this tumour, which of the following is the next step in the standard of care for this tumour?

A. Chemotherapy
B. Radiotherapy
C. Chemo-radiotherapy
D. No further therapy needed
E. Biological agents

C. Chemo-radiotherapy

Glioblastoma multiforme is by far the most common and most malignant/aggressive of the glial tumours. It kills virtually every patient that is affected by it, and until a trial in 2007 was published, the standard of care was surgery and radiotherapy.

Currently, the standard of care is surgery followed by chemo-radiotherapy with temozolomide, an alkylating chemotherapy agent. The key is that the temozolomide and the radiotherapy have a synergistic effect on killing tumour cells.

Question 1 of 189

A house officer is asked to review a patient on her ward as the nurses are concerned about the patients speech. The house officer reports that the patient has unilateral weakness of her right face, arm and leg, dysphasia and a visual field defect. She reports that reflexes are brisk on the right and that the tone of the limbs is increased. There is no disdiadokokinesis on the left, but she is unable to assess on the right arm. The patient's heart rate is 65, blood pressure 198/100 mmHg and respiratory rate 14. Jugular venous pressure is 2cm above the sternal notch. Pupils react to light and are consensual. The patients family are present who report that the symptoms were sudden in onset. The family are unsure about past medical history, but a list of medications includes warfarin, bendroflumethiazide, ramipril, atorvastatin and allopurinol. A CT head reveals a cerebral infarct.

How would this stroke be classified?

A. Partial anterior circulation stroke
B. Total anterior circulation stroke
C. Posterior circulation stroke
D. Lacunar syndrome
E. Thalamic stroke

B. Total anterior circulation stroke

The correct answer is Total anterior circulation stroke. A total anterior circulation stroke (TACS) is characterised by the presence of all three features: motor or sensory deficit affecting at least two out of three areas (face, arm and leg), homonymous hemianopia, and higher cerebral dysfunction (e.g. dysphasia). In this case, the patient presents with unilateral weakness of her right face, arm and leg, dysphasia and a visual field defect which are indicative of a TACS.

A Partial anterior circulation stroke is incorrect because it does not involve all three areas mentioned above. It typically involves at least two out of the three areas but not all. The patient's presentation indicates involvement of all these areas hence suggesting a total rather than partial anterior circulation stroke.

Posterior circulation stroke is also incorrect as it usually results in symptoms such as vertigo, nausea/vomiting, nystagmus and cranial nerve palsy which are not reported in this case. Theposterior circulation supplies the brainstem, cerebellum and occipital lobes so deficits would be expected in these areas rather than the unilateral motor/sensory loss described.

Lacunar syndrome is another incorrect option. Lacunar strokes result from the occlusion of small penetrating arteries that provide blood to the brain's deep structures. They typically present with pure motor or sensory symptoms and do not include cortical signs such as dysphasia or visual field defects.

Lastly, Thalamic stroke is also an incorrect choice. Thalamic strokes can present with various symptoms including sensory loss, weakness, speech difficulties and behavioural changes depending on which part of the thalamus was affected. However, they do not generally cause widespread motor deficits as seen in this patient's presentation.

Question 2 of 189

A 65-year-old man attends neurology clinic for review of his long-standing trigeminal neuralgia. He had first experienced symptoms five years previously and been troubled by his illness ever since despite frequent neurology review. The patient experiences attacks of severe shooting pain affecting the right side of his lower face, each episode usually lasting about one hour. The interval between attacks has steadily reduced over the years so that at the present time the patient experiences four to five episodes per week. The patient describes that his symptoms are profoundly limiting his life and that he rarely leaves his house for fear of an attack.

Four years previously, treatment with carbamazepine had been introduced with an initially good response to symptoms. However, patient proved to be intolerant of carbamazepine due to drowsiness. Subsequent trials of treatment with oxcarbazepine, lamotrigine and baclofen had not given lasting relief.

The patient had recently been diagnosed with depression and initiated on treatment with sertraline. He was also suffered from type 2 diabetes currently managed with diet and metformin 500 mg TDS. The patient lived with his wife and had been unable to work as a school-teacher for the past two years due to his symptoms.

Having previously been reluctant to consider surgical intervention, the patient now felt he would be willing to try any options that could improve his symptoms.

MRI brain with / without contrast: sinuses unremarkable without evidence of inflammation; no space occupying lesion; no extra-cranial mass along course of trigeminal nerves; no evidence of widespread demyelination plaque; no evidence of previous infarction; no abnormal enhancement of the trigeminal nerves.

What is the appropriate surgical intervention for this patient?

A. Stereotactic radiosurgery
B. Balloon compression
C. Microvascular decompression
D. Radiofrequency lesioning
E. Glycerol rhizolysis

C. Microvascular decompression

The patient has long-standing and severe trigeminal neuralgia with life-limiting symptoms despite appropriate medical treatment. Surgical intervention should therefore be considered.

In around 95 % of cases, trigeminal neuralgia is believed to be caused by compression of the trigeminal nerve by adjacent blood vessels, although the exact mechanism of the pathophysiology is incompletely understood. In a minority of cases, trigeminal neuralgia can be due to an alternative diagnosis such as sinusitis, extra-cranial or intra-cranial masses, multiple sclerosis or infarction of the thalamus or brainstem.

The MRI brain undergone by the patient does not provide evidence for any of the rare causes of trigeminal neuralgia with the patient's symptoms therefore very likely due to vascular compression. Using specialist techniques not included in the standard protocol, MRI can detect vascular contact with the trigeminal nerve. However, vascular contact with cranial nerves is also a normal variant in some individuals so these techniques are not routinely used.

Microvascular decompression is therefore the surgical technique of choice and is effective treatment in 95 % of such cases of trigeminal neuralgia. The other possible answers refer to methods of palliative destruction of the trigeminal nerve root, therefore carrying the risk of causing facial numbness. However, they are effective in the minority of trigeminal neuralgia cases not caused by vascular compression.

Question 3 of 189

A 42-year-old woman attends neurology clinic for review of her treatment strategy for multiple sclerosis. The patient had first developed symptoms of multiple sclerosis five years previously. Her first episode had involved sensory loss and motor weakness affecting her left leg. An MRI brain scan conducted at this time had demonstrated multiple lesions suggestive of multiple sclerosis. At this point in time, the patient had decided against receiving disease modifying therapy.

One year after her first episode, the patient suffered an episode of optic neuritis. A repeat MRI scan had demonstrated a progression of the previously observed radiographic lesions. Subsequently, the patient had been initiated on treatment with interferon beta. This treatment was continued for two years during which time the patient suffered no further relapses of multiple sclerosis. However, the patient found the unwanted effects of interferon beta to be progressively harder to tolerate and she eventually decided against continuing with this treatment. A subsequent trial of glatiramer acetate was quickly halted due to the patient experiencing severe symptoms of flushing.

Following the cessation of disease-modifying therapy, the patient had experienced multiple further relapses, including one episode where she had required hospitalisation due to cranial nerve involvement. Further assessment during this period found that the patient met the local criteria for aggressive or highly active multiple sclerosis. Accordingly, later line therapies were discussed with the patient who was keen to proceed.

Aside from her history of multiple sclerosis the patient suffered from no other significant medical problems and took no regular medications. The patient was a science teacher that had been unable to work for the past year due to her multiple relapses.

The later line therapy recommended for the patient is natalizumab.

What is the essential investigation that must be completed prior to initiation of treatment with natalizumab?

A. Transthoracic echocardiogram
B. JCV antibody status
C. Pulmonary function tests
D. Thyroid function tests
E. CMV antibody status

B. JCV antibody status

The patient has highly active multiple sclerosis causing significant morbidity. While she had obtained benefit from the standard initial therapies interferon beta and glatiramer acetate, these treatments were ultimately not tolerated. In this situation, consideration of escalation to secondline disease-modifying therapy is appropriate. Observational studies have reported that escalation from a first-line therapy to a second-line drug reduces relapse rate at one year.

Evidence suggests that alemtuzumab, natalizumab and fingolimod outperformed other disease modifying therapies at preventing relapse at 2 years. In addition, natalizumab also reduced 2-year disability progression rates.

Natalizumab is strongly associated with progressive multifocal leukoencephalopathy, an infection of the central nervous system with the John Cunningham virus (JCV). Therefore, JCV antibody status is an essential part of assessing an individual for treatment with natalizumab. Patient's who are seropositive for JCV are not treated with natalizumab or switched to another drug.

Question 4 of 189

A 45-year-old lady presented to the emergency department with prolonged fever and malaise, She had a new murmur and clinical signs clearly indicating subacute bacterial endocarditis. ECHO confirms vegetations on her aortic valve and blood culture is still pending. She is a known case of myasthenia gravis and has been warned against taking some groups of antibiotics.

Which of the following antibiotics can worsen the symptoms of myasthenia gravis?

A. Gentamicin
B. Augmentin
C. Meropenem
D. Benzylpenicillin
E. Trimethoprim sulphamethoxazole

A. Gentamicin

Answer: Gentamicin.

Aminoglycosides are known to worsen myasthenia gravis. Other medications that have this effect include: ciprofloxacin, verapamil, beta blockers like propranolol, lithium, D-penicillamine and muscle relaxants like Botox.

Question 5 of 189

A 36-year-old female presents to clinic with transient visual loss. She reports three episodes over the last few months where her vision 'turns black' in both eyes despite being alert. This lasts for a few seconds and is then followed by a unilateral throbbing headache associated with nausea and phonophobia. It is worse on exertion and lasts for a couple of days. On examination her visual acuity is 20/20 bilaterally, her visual fields are normal and fundoscopy is unremarkable.

What is the most likely diagnosis?

A. Transient ischaemic attack
B. Amaurosis fugax
C. Anterior ischaemic optic neuropathy
D. Temporal arteritis
E. Migraine with aura

E. Migraine with aura

The headache in this patient is very typical of migraine which can be preceded by an aura lasting between 5 minutes to an hour usually. This patient's visual loss was relatively brief and in the context of unilateral vision loss would certainly raise the possibility of transient ischaemic attack (TIA) However, she reports her vision turned black in both eyes which would be very unlikely with a TIA as there would have needed to be simultaneous involvement of both anterior visual pathways. Since there is isolated bilateral transient visual loss if this was a TIA it would be of the occipital cortex from occlusion of the posterior cerebral artery although this is very unlikely given it does not appear to be a homonymous hemianopia she describes, and there is a characteristic history of migraine which is the most common cause of transient bilateral visual loss in young adults. Amaurosis fugax specifies a type of TIA, which typically causes a unilateral visual disturbance.

Temporal arteritis represents an arteritic form of anterior ischaemic optic neuropathy. Temporal arteritis tends to present later in life and may be associated with other symptoms like scalp tenderness, and jaw claudication. The non-arteritic form of anterior ischaemic optic neuropathy tends to be related to cardiovascular factors, and therefore again presents later in life and more commonly restricted to one eye.

Question 6 of 189

A 54-year-old female attends her GP with sudden onset reduced vision. This is particular to the left eye. The patient has a background of type 2 diabetes mellitus and hypertension. The GP is unable to adequately see the optic fundi on fundoscopy but thinks the left side appears pale.

What is the most likely diagnosis?

A. Retinal vein occlusion
B. Hypertensive retinopathy
C. Giant cell arteritis
D. Stroke
E. Retinal artery occlusion

E. Retinal artery occlusion

Retinal artery occlusion is associated with cardiovascular risk factors as in this case. It causes sudden onset painless visual loss. Fundoscopy may reveal a pale retina and the macula can appear as a 'cherry red spot'.

Retinal vein occlusion may present with distorted and blurred vision rather than visual loss. Additionally, fundoscopy may reveal vascular dilatation with associated haemorrhages.

Hypertensive retinopathy tends to be asymptomatic and is instead generally an indicator of endorgan damage due to long-term effects of hypertension.

Giant cell arteritis may be expected to have preceding symptoms of headache, jaw pain and scalp tenderness before abrupt visual loss.

Question 7 of 189

A 25 year-old woman with ataxia telangiectasia undergoes open biopsy of an enlarged cervical lymph node. Microscopic examination reveals changes consistent with nodular sclerosing Hodgkins disease. Unfortunately, she develops spreading cellulitis around the biopsy site which fails to respond to intravenous antibiotics and ultimately requires surgical debridement.

What is the most common reason for the increased susceptibility to infections in ataxia telangiectasia?

A. Hypogammaglobulinaemia
B. Neutropaenia
C. Hyposplenism
D. Defect in phagocyte
E. NADPH oxidase Complement deficiency

A. Hypogammaglobulinaemia

Ataxia telangiectasia is an autosomal recessive condition resulting in cerebellar ataxia with ocular telangiectasia. Individuals are often immunocompromised, typically due to hypogammaglobulinaemia. Lymphopaenia may also contribute.

There is also an increased risk of malignancy, typically lymphoma or leukaemia. A defect in phagocyte NADPH oxidase is responsible for chronic granulomatous disease.

Question 8 of 189

A 42 year-old man presents with an acute of onset of weakness in the left face, arm, and leg, which has not resolved. On examination there is upper motor neuron facial weakness on the left, with dense weakness of the left arm and leg. There is no evidence of sensory neglect, hemianopia, or dysphasia.

He past medical history includes migraine with visual aura, for which he takes propranolol and sumatriptan. His last migraine attack was a month ago. He has suffered two transient ischaemic attacks in the last year, and now also takes clopidogrel. His father also suffered from migraine with aura and died in his 50s after suffering a series of strokes.

Plain computed tomography shows multiple round lesions in the white matter, which appear the same density as cerebrospinal fluid. Magnetic resonance imaging shows scattered well-circumscribed lesions in the subcortical white matter which appear hypointense on T1 and hyperintense on T2-weighted sequences. On DWI (diffusion-weighted imaging) there is a hyperintense lesion in the right internal capsule, with a corresponding hypointense area on the ADC (apparent diffusion coefficient) map.

What is the most likely underlying diagnosis?

A. Patent foramen ovale
B. Progressive multifocal leukoencephalopathy
C. Migrainous infarction
D. Cerebral amyloid angiopathy
E. CADASIL

E. CADASIL

The clinical and radiological description fits with a lacunar infarction in the right internal capsule resulting in a pure motor hemiparesis. The area of acute infarction is not visible on the CT in the hyperacute phase, but is visible on the diffusion-weighted MR as described. The other white matter lesions are most likely old lacunar infarcts which may have been clinically silent.

The personal history of migraine with aura coupled with the family history make this most likely CADASIL (cerebral autosominal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). The conditions results from mutations in the NOTCH3 gene onchromosome 19. Individuals typically develop migraine with aura around age 30, transient ischaemic attacks and ischaemic strokes in their 40s, and dementia around the 50s. Strokes are typically lacunar.

There is an association between patent foramen ovale, migraine with aura, and stroke. Stroke in this context is embolic, which characteristically produces wedge-shaped infarcts involving cortex and white matter, rather than the small lesions seen in lacunar stroke. Emboli may arise in the venous circulation and cross over into the arterial circulation via the shunt (paradoxical embolism).

Progressive multifocal leukoencephalopthy is a demyelinating disease of the central nervous system caused by reactivation of the JC virus, most typically seen in patients with AIDS and low CD4 counts.

In migranous infarction the neurological deficit develops during an attack of migraine.

Cerebral amyloid angiopathy is an important cause of primary lobar intracerebral haemhorrage in the elderly.

Question 9 of 189

A 43-year-old man is apprehended by the police after a violent assault outside a pub. He is brought to the attention of the duty psychiatrist because he is extremely confused and agitated. He repeatedly says that his wife is having an affair with the Prime Minister. He believes this to be true because of a message encoded in the traffic lights. He also mentions that he has not slept in the last two days.

The psychiatric assessment is interrupted when he has a tonic-clonic seizure, which self-terminates in 3 minutes. He is taken to the local Accident and Emergency department and reviewed by the medical team.

The medical SHO manages to contact his wife, who reports that he is normally fit and well and she last saw him when he left for work five days ago. At that time he appeared normal but complained of a headache, and took some ibuprofen.

During the clerking, he is noted to have repetitive chewing movements of the mouth. Again, the assessment is interrupted by a tonic-clonic seizure which does not terminate after 10mg of intravenous diazepam. After 15 minutes he is loaded with phenytoin. He continues to fit so is intubated and transferred to the Intensive

Care Unit. Termination of seizure activity is only achieved after induction of general anaesthesia with thiopentone.

What is the most likely diagnosis?

A. Schizophrenia
B. Fronto-temporal dementia
C. Acute intermittent porphyria
D. Post-ictal psychosis
E. Autoimmune limbic encephalitis

E. Autoimmune limbic encephalitis

Autoimmune limbic encephalitis presents with acute or sub-acute cognitive dysfunction, behavioural changes, and seizures. A number of specific antibody-related syndromes have been described. The description given here is suggestive of anti-NMDA receptor encephalitis, with a prodromal headache followed by prominent psychiatric features, with orofacial dyskinesias, insomnia, and progression to seizures.

Schizophrenia is a common cause of psychosis but the seizures should point away from a psychiatric disorder towards an organic brain pathology.

Fronto-temporal dementia is a slowly progressive condition.

Acute intermittent porphyria may cause a range of neurological manifestation including psychosis and seizures, but there are no features here that point specifically to this diagnosis.

Post-ictal psychosis is a rare manifestation of the post-ictal state, typically in patients who have had epilepsy for some time. The rapid development of psychosis and seizures in a previously well person should prompt the search for an alternative diagnosis.

Question 10 of 189

A 45 year-old man is referred to the nephrologists for investigation of chronic kidney disease. He has a past medical history of hypertension, type 2 diabetes, and Parkinsons disease, and his medication comprises ramipril, metformin, and bromocriptine.

Review of blood tests shows that the glomerular filtration rate (GFR) has steadily fallen from 85 to 44ml/min/1.73m^2 over the last year.

On questioning, his only symptom is chronic back pain which has been getting worse over the last year. On examination, both kidneys are easily palpable.

Routine investigations are as follows:

Abdominal ultrasound shows bilateral hydronephrosis.

Hb	12.1 g/dl
MCV	94.2 fl
Platelets	264 x10^9/l
WCC	7.1 x10^9/l
Na	137mmol/l
K	4.6 mmol/l
Urea	13.8 mmol/l
Creatinine	157 mol/l
eGFR	44 ml/min/1.73m^2
ALT	24 IU/l
ALP	78 IU/l
Bilirubin	6 mol/l
Albumin	37 g/l
Total protein	64 g/l
Serum protein electrophoresis	pending
Urine dipstick	negative for blood, protein, leucocytes, and nitrites

What is the most likely cause of his chronic kidney disease?

A. Multiple myeloma
B. Diabetic nephropathy
C. Bladder cancer
D. Retroperitoneal fibrosis
E. Autosomal dominant polycystic kidney disease

D. Retroperitoneal fibrosis

Bilateral hydronephrosis suggests that there is an obstruction to the outflow of both kidneys. This typically occurs at the bladder outlet, raising the possibility of a bladder or prostate cancer. The absence of haematuria makes bladder cancer less likely, and the absence of lower urinary tract symptoms makes prostate cancer less likely. However, if another diagnosis were not more forthcoming it would be appropriate to investigate for these conditions.

Bilateral hydronephrosis can more unusually result from obstruction of both ureters. This occurs in retroperitoneal fibrosis, where the ureters are encased in dense fibrous tissue. Back pain is a common symptom. The condition may be idiopathic, or may occur in association with an abdominal aortic aneurysm, or secondary to long-term use of ergot derived dopamine agonists such as bromocriptine, cabergoline, or pergolide.

In the context of back pain and chronic kidney disease, multiple myeloma is a distinct possibility. Serum protein electrophoresis is required to detect the presence of a paraprotein. However, subtracting total protein from albumin (64-37) suggests that the total immunoglobulin level is 27 g/L, and therefore there is unlikely to be a significant level of paraprotein. Equally, there is unlikely to be any urinary Bence Jones protein in the absence of dipstick proteinuria. Finally, one would not expect to see hydronephrosis in myeloma kidney.

The absence of proteinuria makes diabetic nephropathy less likely, and also one would not expect to see evidence of urinary tract obstruction in this condition.

At the age of 45, autosomal dominant polycystic kidney disease can be excluded by the absence of renal cysts on ultrasound.

Question 11 of 189

A 77-year-old female was brought into hospital after waking with left arm weakness predominantly affecting the hand with a left sided facial droop in an upper motor neuron pattern. Her blood pressure on admission was 175/90 mmHg and her heart rate was 80 beats per minute and in sinus rhythm. Her blood glucose level on admission was 7.2 mmol/L.

Her initial CT brain showed some mild bi-temporal atrophic change and some chronic small vessel ischaemia without any acute ischaemic changes and in particular, no haemorrhage.

She was admitted with a suspected diagnosis of minor ischaemic stroke.

Which of the following imaging modalities will confirm the diagnosis?

A. CT cerebral angiogram (CTA)
B. Fluid attenuated inversion recovery (FLAIR)
C. MRI Thin slice non-contrast enhanced CT brain scan
D. Diffusion weighted imaging (DWI) MRI
E. Formal cerebral digital subtraction angiogram (DSA)

D. Diffusion weighted imaging (DWI) MRI

DWI-MRI is the most sensitive and specific imaging modality for diagnosing acute stroke. FLAIR MRI is sensitive for chronic ischaemic changes.

Both CTA and DSA may identify significant intravascular stenoses or thrombosis but are insensitive for small areas of acute ischaemic change.

Thin slice CT scans may identify established ischaemia with more sensitivity than a standard CT scan but is still inferior to DWI MRI.

In general, the purpose of the initial CT scan in accident and emergency for suspected ischaemic stroke patients is to exclude a haemorrhage.

Question 12 of 189

A 37-year-old woman has been diagnosed with relapsing remitting multiple sclerosis and is considering further therapeutic options including natalizumab. She has had two severe relapses despite treatment with glatiramer acetate. She is currently still able to work, but is very fatigued and feels her mobility is limited.

On examination, she has brisk reflexes bilaterally, with mild weakness in her proximal left leg and reduced sensation in the left foot.

She has highly active disease on her brain MRI with multiple acute and sub-acute plaques present. She also has a single lower cervical cord lesion.

Before considering a new therapy, aside from HIV and general immunological status, which of the following investigation results is of greatest importance?

A. Cytomegalovirus status
B. Syphilis serology
C. Hepatitis C serology
D. EBV serology
E. JC virus status

E. JC virus status

Natalizumab is a therapy approved for the management of highly active relapsing-remitting multiple sclerosis (RRMS) and is given as a once-monthly infusion. Natalizumab has been shown to greatly reduce relapse rates in RRMS.

It is a humanised monoclonal antibody against the cell adhesion molecule (CAM) 4-integrin. Natalizumab prevents leukocyte adhesion to endothelial VCAM1, thus preventing the migration of immune cells into the CNS.

An extremely rare, severe and almost universally fatal adverse side effect of Natalizumab is progressive multifocal leukoencephalopathy (PML). Only patients who are seropositive for JC virus are at risk of developing PML with exposure to natalizumab, and therefore checking the JC virus status of patients who are considering natalizumab therapy is mandatory.It is also worth noting that some patients with low titres of JC virus are still commenced on natalizumab under close monitoring and that duration of natalizumab therapy is proportional to the risk of developing PML, i.e..short duration therapy (1-2 years) carries a very low risk of developing PML, even in those with a low positive JC virus titre. Ultimately, patients who are JC virus positive should not receive natalizumab and another therapy should be considered.

Question 13 of 189

A 45-year-old male presents with ascending weakness. He first noticed that he was tripping over more easily, but now has trouble getting out of a chair. He feels otherwise well. Of note, he did have moderate diarrhoea which had completely resolved a week prior to developing this weakness.

On examination, he is haemodynamically stable with a heart rate of 68 beats per minute and a blood pressure of 135/80 mmHg. His respiratory rate is 18 breaths per minute. He has reduced power in ankle plantar and dorsiflexion bilaterally, absent ankle jerks and reduced knee jerks. His plantar responses are downwards.

Acutely, which of the following results will most assist you with a diagnosis?

A. MRI showing inflammation of the lumbo-sacral spinal cord
B. Elevated white cell count on cerebrospinal fluid (CSF) analysis
C. Abnormal nerve conduction tests of the lower limbs
D. Elevated CSF protein
E. Raised erythrocyte sedimentation rate (ESR)

D. Elevated CSF protein

Acutely, an elevated CSF protein level may be the only indication of an inflammatory aetiology, highly suggestive of Guillain-Barre Syndrome (GBS) or Acute Inflammatory Demyelinating Polyradiculoneuropathy in this clinical setting. The CSF white cell count is not elevated in GBS.

In relation to nerve conduction studies, these often provide normal results within the acute setting and the classic demyelination findings may not be detectable for at least a week.

Question 14 of 189

A 65-year-old male with a 60 pack year smoking history has been diagnosed with small cell lung cancer. He is currently undergoing chemotherapy. Over the last few months, he has noticed his vision deteriorating and complains of diplopia. He also feels weaker in his upper limbs although his symptoms do fluctuate.

On examination, he has mild ptosis of the eyelids bilaterally and a complex ophthalmoparesis affecting both eyes. He also has reduced power proximally in the upper limbs.

In this clinical syndrome, in addition to electrophysiological studies, which of the following blood test results is likely to assist with the diagnosis?

A. Presence of anti-muscle specific kinase antibodies
B. Presence of anti-neuronal antibodies
C. Presence of voltage gated potassium channel antibodies
D. Presence of sodium channel antibodies
E. Presence of voltage gated calcium channel antibodies

E. Presence of voltage gated calcium channel antibodies

The paraneoplastic myasthenic syndrome described above associated with small-cell lung cancer is Lambert-Eaton myasthenic syndrome (LEMS).

Antibodies to voltage-gated calcium channels (VGCCs) have been reported in 75-100% of LEMS patients who have small cell lung cancer (SCLC) and in 50-90% of LEMS patients who do not have underlying cancer.

Question 15 of 189

A 75-year-old female on aspirin for known ischaemic heart disease is being investigated for the cause of a recent transient ischaemic attack (TIA) which caused brief left sided weakness. She does not have a history of atrial fibrillation, nor has any been detected on routine telemetry.

Her MRI brain scan does not provide any evidence for acute stroke and her transthoracic echocardiogram does not demonstrate any intra-cardiac thrombus.

A carotid ultrasound study revealed a 75-85% stenosis of the right internal carotid artery.

In addition to ordering a CT carotid angiogram to further investigate the lesion, the next best step in her management would be to?

A. Add clopidogrel
B. Commence best medical management and re-image in 6 months
C. Commence an unfractionated heparin infusion
D. Commence best medical therapy and refer for a carotid endarterectomy in 6-8 weeks
E. Commence best medical therapy and refer for a carotid endarterectomy within 14 days

E. Commence best medical therapy and refer for a carotid endarterectomy within 14 days

Patients with a TIA or small ischaemic stroke with evidence of significant carotid artery stenosis (male patients with a carotid artery stenosis of 50-99% or female patients with a carotid artery stenosis of 70-99%) that corresponds to the same side as the stroke/TIA should be considered for an urgent carotid endarterectomy (CEA) within 14 days.

Question 16 of 189

An 81-year-old lady with a history of congestive cardiac failure was assessed in accident and emergency and clinically diagnosed with an acute ischaemic stroke. Her main deficits were slurred speech and left sided facial droop with some loss of fine motor control in the left hand. On admission, her blood pressure was 185/70mmHg with a heart rate of 95 beats per minute in sinus rhythm.

The initial CT scan of her brain showed some evidence of chronic small vessel ischaemia, but no acute pathology, in particular no haemorrhage was seen.

Which of the following combinations of investigations should be carried out during the acute admission?

A. MRI, transthoracic echocardiogram (TTE), cardiac telemetry and carotid duplex study
B. Transoesophageal echocardiogram (TOE), CT cerebral angiogram and carotid duplex study
C. CT scan, fasting lipids and a video fluoroscopy swallow study
D. Fasting glucose, Electroencephalogram (EEG), MRI and thrombophilia screen
E. Thrombophilia screen, MRI and a TTE

A. MRI, transthoracic echocardiogram (TTE), cardiac telemetry and carotid duplex study

Question 17 of 189

A 42-year-old man presented with a partial left Horner's syndrome (ptosis with miosis, no anhidrosis), ipsilateral neck pain and reduced visual acuity on the same side.

He reported that the first symptom was neck pain and that his vision worsened over the next two hours. On admission, his blood pressure was 145/80 mmHg and heart rate was 80 beats per minute in sinus rhythm. His chest was clear.

His initial non-contrast enhanced CT brain scan showed a very small area of gliosis in the left frontal area possibly related to a distant injury, but no acute pathology.

Which of the following tests is likely to give you a diagnosis?

A. MRI of the brain
B. CT carotid angiogram
C. Chest X-Ray
D. Erythrocyte sedimentation rate (ESR) and temporal artery biopsy

E. CT venogram of the neck and brain

B. CT carotid angiogram

The oculosympathetic pathway leads a course from the posterior hypothalamus, through the brainstem followed by the spinal cord, over the apex of the lung to the superior cervical ganglion, and then finally ascends along with the internal carotid artery to ultimately reach the pupillary dilator muscle and Mueller's muscle of the lid. These post ganglionic fibres within the carotid sheath are vulnerable to the compressive effects of a mural haematoma or pseudoaneurysm resulting from a carotid artery dissection. Such compression can result in a partial Horner's syndrome.

In addition to this, patients with both carotid and vertebral artery dissections often present with neck pain.

Finally, in patients with a carotid dissection retinal ischaemia is often as a result of thrombi produced within the dissected portion of the vessel that then embolize distally towards the brain or in this case, the ophthalmic artery, a branch of the internal carotid artery.The investigation of choice to diagnose a carotid dissection is a CT carotid angiogram, however, other such as MR angiograms of the neck are also adequate.

Question 18 of 189

A 62 year-old man with a history of osteoarthritis, type II diabetes and mild dementia is seen in neurology clinic. He has a 2 month history of weakness in his right arm. He has also noticed that his voice has become softer. He is finding it hard to use door handles and open jars. On two occasions his wife has noticed him stumbling whilst walking.

On examination he has fasciculations over his right deltoid muscle and wasting of the interossei muscles of the right hand. There is 4/5 strength in right shoulder abduction on the Medical Research Council (MRC) scale. Limb reflexes are absent in the right arm but detectable elsewhere. Coordination is normal. Sensation is normal and Romberg's test is negative.

What is the most likely diagnosis?

A. Compressive Cervical myelopathy
B. Diabetic peripheral neuropathy
C. Motor neurone disease
D. Multiple sclerosis
E. Thoracic outlet syndrome

C. Motor neurone disease

Arm weakness can have many causes, but in this case the voice is also affected as are the lower limbs.

Fasciculations imply lower motor neurone involvement and would make a diagnosis of multiple sclerosis unlikely. Cervical myelopathy or diabetic neuropathy would not explain the voice change.

Thoracic outlet syndrome would not affect the patients legs so the most likely diagnosis in this case is motor neurone disease.

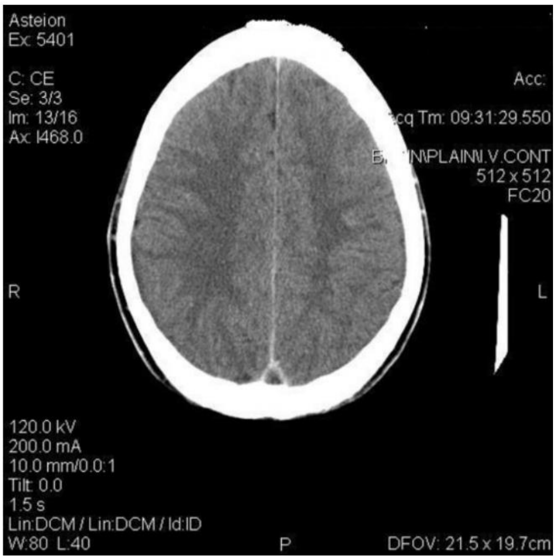
Motor neurone disease is associated with fronto-temporal dementia.

Question 19 of 189

A 19-year-old female is admitted to the Emergency Department after suffering a seizure. Her friends report that she is normally fit and well but had been complaining of a bad headache for the past few hours.

On examination her GCS is 13/15 (M6 V4 E3). No focal neurological deficit is noted. She appears slightly confused and is holding her head in her hands. Her pulse rate is 90/min with a temperature of 37.2º. No neck stiffness is noted.

A CT scan with contrast is requested:

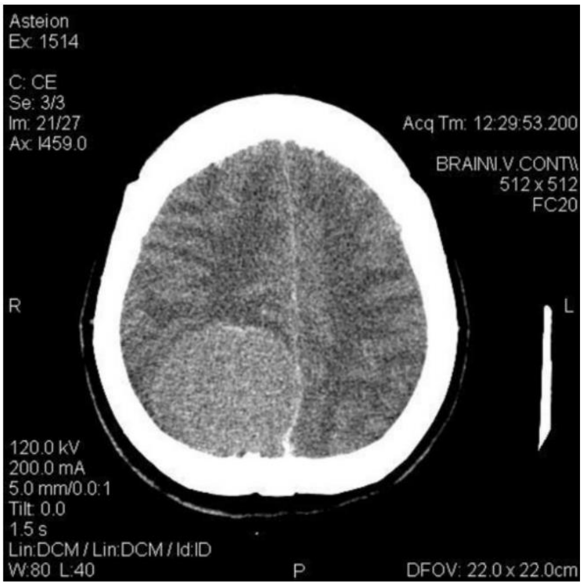


What is the most likely diagnosis?

A. Extradural haemorrhage
B. Superior sagittal sinus thrombosis
C. Herpes simplex encephalitis
D. Subrarachnoid haemorrhage
E. Meningioma

B. Superior sagittal sinus thrombosis

The CT with contrast demonstates a superior sagittal sinus thrombosis showing the typical empty delta sign. Look at the 'bottom' of the scan for the triangular shaped dural sinus. This should normally be white due to it being filled with contrast. The empty delta sign occurs when the thrombus fails to enhance within the dural sinus and is outlined by enhanced collateral channels in the falx. This sign is seen in only about 25%-30% of cases but is highly diagnostic for sagittal sinus thrombosis.

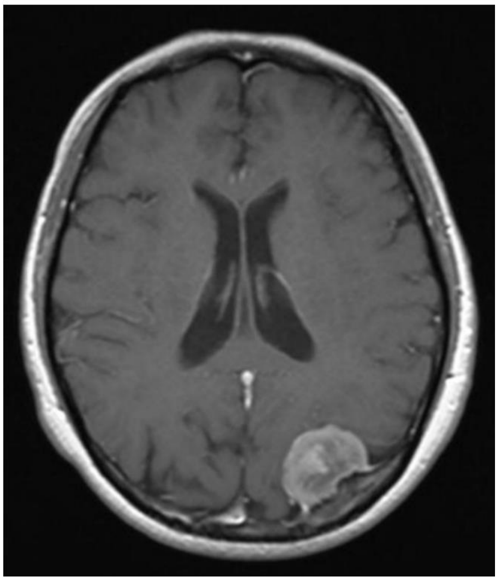


Question 20 of 189

A 54-year-old woman is admitted to the Emergency Department after having a seizure. This occured whilst she was a passenger in a car. There is no history of trauma. By the time of her admission she is alert with a GCS of 15/15. Her partner describes a generalised seizure with a postictal phase lasting around 30 minutes.

On examination her heart rate is 90/min, blood pressure 102/60 mmHg and temperature 37.1ºC. There are no focal neurological signs.

A MRI scan is requested:



What is the most likely diagnosis?

A. Extradural haematoma
B. Gliolastoma multiforme
C. Subdural haematoma
D. Meningioma
E. Oligodendroma

D. Meningioma

The MRI shows the typical well-circumscribed appearance of a meningioma. A dural tail can be where the tumour 'connects' to the dura. It is seen in around 65% of meningiomas.

Question 21 of 189

A 45-year-old woman presents to the Emergency Department due to a headache. This has been getting gradually worse over the past 3 months. Her GP has tried a number of therapies including a triptan, amitriptyline and standard analgesia with limited effect. She is a non-smoker and drinks around 30 units of alcohol per week.

Neurological examination is unremarkable. A CT scan is arranged:

What is the most likely diagnosis?

A. Extradural haematoma
B. Meningioma
C. Glioblastoma multifome
D. Herpes simplex encephalitis
E. Subdural haematoma

B. Meningioma

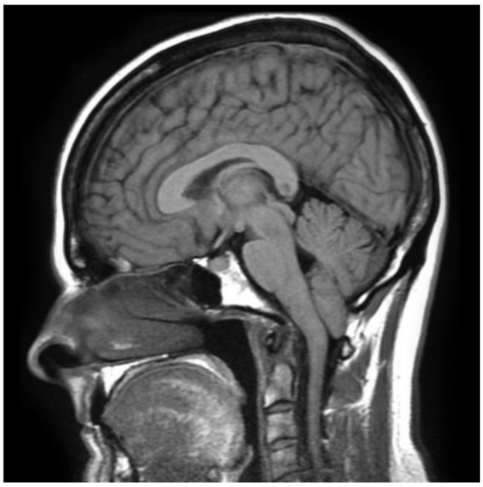
The CT shows a well defined spherical mass in the right posterior falx cerebri consistent with a meningioma. There is mild oedema and mass effect on the right lateral ventricle. The tumour is straddling the inferior surface of the falx.

A glioblastoma multifome would normally have a more heterogenous appearance than shown here.

Question 22 of 189

A 34-year-old woman is referred to the neurology clinic for a 6 month history of progressively worsening headaches. The headaches tend to be occipital in nature and are worsened by coughing.

Neurological examination is unremarkable. Her MRI is shown below:



What finding is shown on the MRI?

A. Brainstem cavernous angioma
B. Pituitary adenoma
C. Arnold-Chiari malformation
D. Arachnoid cyst
E. Spina bifida

C. Arnold-Chiari malformation

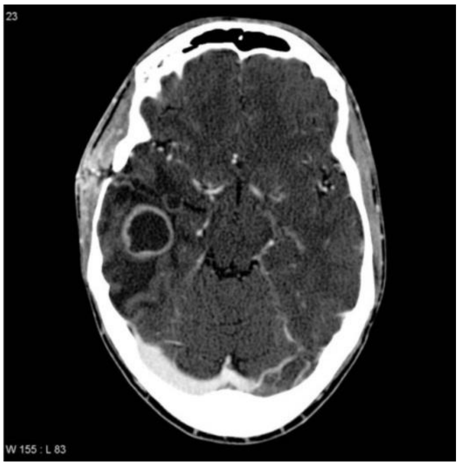
The MRI shows herniation of the cerebellar tonsils through the foramen magnum consistent with a Chiari type I malformation.

Question 23 of 189

A 23-year-old man is admitted to ITU after arriving from India on a medical transfer plane. He had been travelling in India for around 4 weeks before starting to complain of feeling unwell. His girlfriend describes acting out of character and having numerous seizures prior to being admitted to hospital in Patna, east India.

His girlfriend describes him having a scan in India as well as a procedure in theatre which was abandoned.

A CT head with contrast is performed:



What is the most likely diagnosis?

A. Neurocysticercosis
B. Meningioma
C. Glioblastoma multiforme
D. Cerebral abscess
E. Herpes simplex encephalitis

D. Cerebral abscess

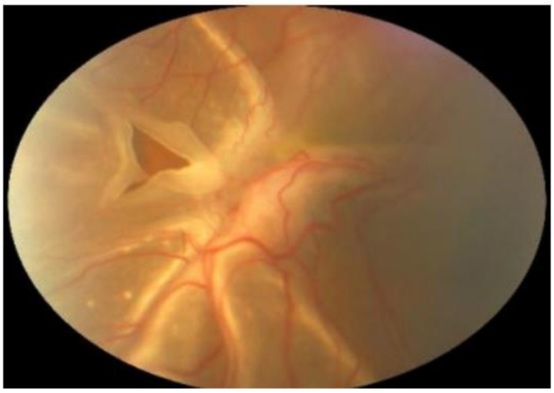
CT demonstrating a cerebral abscess. CT demonstrates a rounded lesions with vast amounts of surrounding vasogenic oedema resulting in mass effect and distortion of the cerebral peduncle. Contrast confirms the presence of a smooth ring of enhancement, characteristic of an abscess.

The scan shows signs of overlying surgical change consistent with a prior attempted drainage via a burr hole.

This patient underwent repeat surgery with successful drainage of the abscess. He made a slow but uneventful recovery.

Question 24 of 189

A woman presents with reduced vision in her right eye. She is unsure when it started but can now only make out hand movements with the right eye. Fundoscopy of the affected eye shows the following



What is the diagnosis?

A. Penetrating foreign body
B. Myelinated optic disc
C. Papilloedema
D. Choroidoretinitis
E. Retinal detachment

E. Retinal detachment

The correct diagnosis is Retinal detachment. This condition presents with symptoms such as sudden or gradual reduction in vision, often described by patients as a 'curtain coming down'. Fundoscopy reveals an elevated retina with folds and a visible retinal tear.

Penetrating foreign body is incorrect because it would typically present with a history of trauma, and the patient would likely experience pain. On examination, there might be visible injury to the cornea or sclera, hyphaema (blood in the anterior chamber), irregular pupil, or low intraocular pressure.

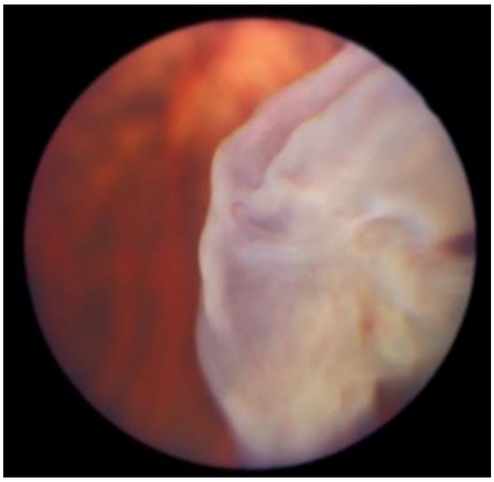
Myelinated optic disc, also known as medullated nerve fibres, is incorrect because it does not typically affect vision. It appears on fundoscopy as whitish patches extending from the optic disc but does not cause elevation or detachment of the retina.

Papilloedema is incorrect because this condition involves swelling of the optic disc due to increased intracranial pressure. Symptoms can include transient visual obscurations and headache. On fundoscopy, there would be blurring of the optic disc margins and elevation of the disc itself rather than the retina.

Finally, Choroidoretinitis, inflammation of the choroid and retina usually due to infection such as by Toxoplasma gondii or Cytomegalovirus, is incorrect because it typically presents with floaters, photopsia (flashes of light), and blurred vision due to inflammatory lesions in the retina. These lesions appear as yellow-white patches during fundoscopy but do not cause retinal detachment unless severe and chronic.

Question 25 of 189

A 71-year-old man presents with sudden painless loss of vision in his left eye: Fundoscopy shows the following



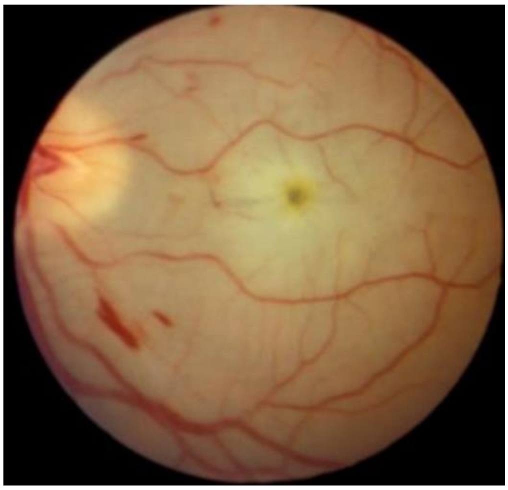
What is the most likely diagnosis?

A. Ciliary body rupture with lens dislocation
B. Vitreous haemorrhage
C. Ischaemic optic neuropathy
D. Central retinal artery occlusion
E. Retinal detachment

E. Retinal detachment

Question 26 of 189

This man presents with unilateral visual loss. On examination he has a relative afferent pupillary defect. Fundoscopy shows the following



What is the most likely diagnosis?

A. Central retinal vein occlusion
B. Subhyaloid haemorrhage
C. Solar retinopathy C
D. entral retinal artery occlusion
E. Optic neuritis

A. Central retinal vein occlusion

The correct answer is **Central retinal artery occlusion.** This condition presents with sudden, painless, unilateral vision loss. On examination, there may be a relative afferent pupillary defect (RAPD), also known as Marcus Gunn pupil, which is an abnormal response to light in the affected eye due to a severe decrease in the number of functioning retinal ganglion cells. Fundoscopy typically reveals a pale retina with a cherry-red spot at the fovea due to obstruction of blood flow in the central retinal artery.

Central retinal vein occlusion is incorrect because it presents differently. Patients often complain of sudden or gradual vision loss. On fundoscopy, there are widespread retinal haemorrhages ('blood and thunder' appearance) and cotton wool spots due to blockage of the central retinal vein leading to increased pressure and subsequent leakage from other vessels.

Subhyaloid haemorrhage is also incorrect. It presents with sudden visual loss or floaters but does not typically cause RAPD. On fundoscopy, you would see a pre-retinal (subhyaloid) haemorrhage which appears as a dark red, boat-shaped mass located between the retina and vitreous humour.

The diagnosis of **Solar retinopathy** is unlikely in this case as it results from direct solar radiation damage to the macula leading to central scotoma (blind spot). The typical fundoscopic finding is yellowish dots at the level of RPE in fovea.

Lastly, **Optic neuritis**, commonly associated with multiple sclerosis, typically presents with painful vision loss over days accompanied by dyschromatopsia (impaired colour vision). However, fundoscopy may initially appear normal or show mild disc swelling rather than the findings described here.

Question 27 of 189

A 19-year-old university student is reviewed in the general medical clinic with bilateral ptosis. It has developed gradually over the last few months and has now progressed to the extent that he has to tilt his head upwards during lectures. He denies diurnal variation in his symptoms.

His past medical history is unremarkable and he takes no regular medications. He tells you that his mother had a pacemaker fitted due to frequent 'blackouts'.

On examination, you note the presence of bilateral ptosis. He also has impaired abduction and adduction of both eyes. Direct fundoscopy shows black spicules in the periphery of both eyes. An ECG is taken and shows sinus rhythm with first-degree heart block.

Given the likely diagnosis, which additional symptom is he most likely to describe?

A. Night blindness
B. Syncope
C. Tremor
D. Flank pain
E. Diplopia

A. Night blindness

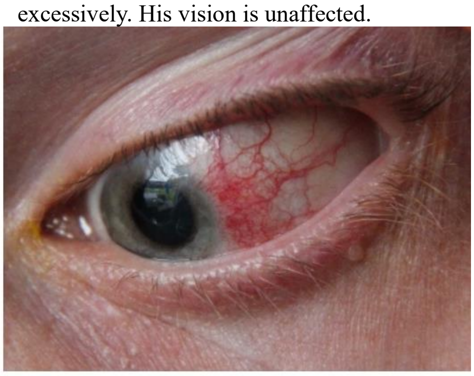
The most likely diagnosis is Kearns-Sayre syndrome, a mitochondrial disorder. Individuals usually present <20 years-of-age with progressive external ophthalmoplegia. Ptosis usually develops first, followed by difficulties with horizontal gaze. Patients don't usually complain of diplopia as the extraocular muscle weakness is symmetrical.

Affected patients also usually suffer from pigmentary retinopathy, which causes atrophy of the retinal pigment with bony spicule formation typical of retinitis pigmentosa. As the changes progress, patients often complain of funnel-vision and night blindness.

Cardiac conduction defects usually develop after the onset of ophthalmoplegia and sudden death may occur as a result. Regular cardiac follow-up is essential. Other abnormalities include cerebellar ataxia, sensorineural deafness, muscle weakness and diabetes mellitus..

Question 28 of 189

A 44-year-old man attends after waking up with a red eye and some slight crusting. He describes mild pain and finds the eye is tearing excessively. His vision is unaffected.



Slit lamp examination shows congestive vessels with a radial distribution pattern. He works as a carpenter and has a background of ulcerative colitis but is otherwise fit and well.

What is the most likely diagnosis?

A. Conjunctivitis
B. Episcleritis
C. Exposure keratopathy
D. Ocular foreign body
E. Scleritis

B. Episcleritis

This is a presentation of episcleritis. **Episcleritis** is usually painless or with mild pain, there are prominent surface vessels that are mobile and blanch with phenylephrine drops.

Episcleritis is correct. It is an inflammatory condition affecting the episclera and is usually self-limiting. It is not classically associated with severe pain and vision is preserved.

Conjunctivitis is incorrect. This usually presents with purulent discharge and extensive crusting around the eyes. The conjunctiva is often inflamed. It commonly initially affects one eye but can spread easily to affect both. In this case, there is no purulent discharge and so conjunctivitis is less likely.

Exposure keratopathy is incorrect. This is when the cornea is exposed for prolonged periods of time. It can present with a gritty or foreign body sensation and the damaged areas of the cornea will stain with fluorescein. In this case, there is no foreign body sensation and no staining on the cornea.

Ocular foreign body is incorrect. This would commonly be associated with discomfort and a foreign body would be seen on slit lamp examination. This is not seen here.

Scleritis is incorrect. This is also an inflammatory condition but is more classically associated with pain, photophobia, and blurring of the vision. Slit lamp examination usually shows new vessel formation and abnormal vessel distribution. These features are not present for the patient in the stem.

Question 29 of 189

A 45-year-old lady was admitted to the Medical Admission Unit with a 16-hour history of weakness. Two days prior to the admission she experienced a sensation of double vision and shortly afterwards had become more unsteady when walking. The weakness developed initially in her arms and was shortly followed by weakness in her legs. Her past medical history included a history of coeliac disease for which she adhered to a strict gluten-free diet, but she was otherwise fit and well.

On examination, she was not distressed and was fully orientated to her surroundings. She had a temperature of 37.6ºC, a heart rate of 88/min, a respiratory rate of 18/min and a blood pressure of 182/82 mmHg. The cardiovascular and respiratory examination was otherwise unremarkable. Examination of the abdomen revealed a mass arising from the symphysis pubis. Examination of her cranial nerves revealed a failure of bilateral external gaze, as well as diplopia on asking the patient to fixate down and in. Her pupils were dilated but reactive. Fundoscopy revealed no abnormalities, and cranial nerve examination was otherwise unremarkable. The tone was reduced in all muscle groups, with a power of grade 3/5 in all muscle groups. Reflexes were absent in all limbs and plantar responses were normal. She was unable to mobilise independently and an ataxia was noted.

Initial investigations revealed the following:

Hb	132 g/l
Platelets	222
WBC	5.8
ESR	16 mm/hr
Na	139 mmol/l
K	3.7 mmol/l
Urea	4.3 mmol/l
Creatinine	77 µmol/l
Bilirubin	11 µmol/l
ALP	101 u/l
ALT	22 u/l
Glucose	6.0 mmol/l
CRP	22 mg/l

CSF

Appearance	Clear
Glucose	4.5 mmol/l
Protein	0.6 g/l
White cells	3 / mm³

CT brain scan: normal appearances, no evidence of haemorrhage, midline shift or space occupying lesion.

What is the single investigation most likely to lead to a diagnosis?

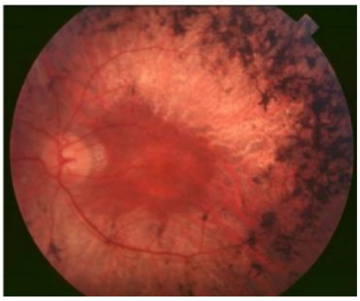
A. Anti Jo1 antibodies
B. Anticholinesterase antibodies
C. Anti GQ1b antibodies
D. Anti GM1 antibodies
E. Antinuclear antibodies

C. Anti GQ1b antibodies

The combination of ophthalmoplegia, ataxia and areflexia is strongly suggestive of Miller-Fisher syndrome, a variant of Guillain-Barre syndrome (GBS). Anti GQ1b antibodies are present in 90% of cases. Anti GM1 antibodies are present in axonal neuropathies including GBS but also other conditions and are not specific to Miller Fisher syndrome. Anti Jo1 antibodies are found in polymyositis whilst anticholinesterase antibodies are found in myasthenia gravis.

Question 30 of 189

A 35-year-old man with a vague history of vision problems is reviewed in the ophthalmology clinic. He has not seen a doctor in years and does not report a record of any medical illness.



Fundoscopic examination revealed the following:

What is the most likely cause of the fundoscopic findings?

A. Hereditary retinal degeneration
B. Hypertensive retinopathy
C. Non-proliferative diabetic retinopathy
D. Proliferative diabetic retinopathy
E. Vitreous haemorrhage

A. Hereditary retinal degeneration

The black bone spicule-shaped pigmentation in the peripheral retina and the mottling of the retinal pigment epithelium seen in this fundoscopic image suggest retinitis pigmentosa.

Retinitis pigmentosa is a hereditary condition characterised by retinal degeneration, affecting predominantly the rods and the peripheral retina. Night blindness is often the initial sign, and tunnel vision is due to the loss of the peripheral retina.

Hypertensive retinopathy is characterised by arteriolar narrowing and AV nipping in the early stages. The flame and blot haemorrhages collected around the fovea can result in a characteristic macular star pattern. Papilloedema is seen in advanced disease.

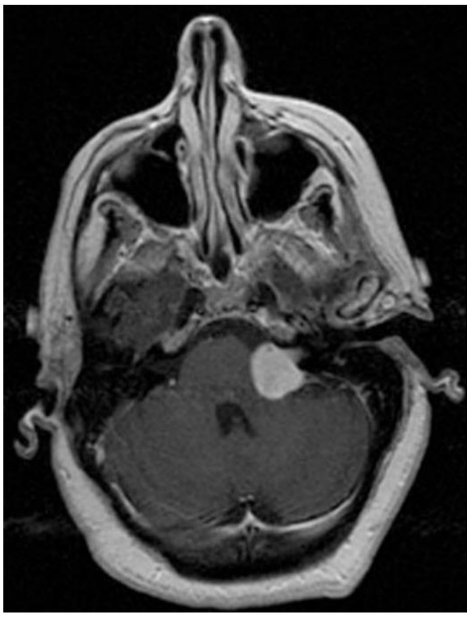
Non-proliferative diabetic retinopathy is characterised by microaneurysms, blot haemorrhages, hard exudates, cotton wool spots and venous beading or looping with no evidence of retinal neovascularisation or fibrous tissue.

Proliferative diabetic retinopathy is characterised by retinal neovascularisation predominantly around the optic disc or can be seen as neovascularisation elsewhere (NVE). Occasionally fibrous tissue may be seen anterior to the retinal layer.

Vitreous haemorrhage is seen as a red haze of haemorrhage into the vitreous. Dot blot haemorrhages, neovascularisation or boat-shaped retinal tears may also be seen.

Question 31 of 189

A 55-year-old man presents with six weeks history of tinnitus. He has noted some changes in hearing lately. There is no record of any medical illness, and he does not take any regular medications. He is a chronic smoker and has 40 pack year history. His MRI brain showed:



What is the next best step in his management?

- A. Computed tomography (CT) of thorax
- B. Intratympanic steroid therapy
- C. Systemic steroid therapy
- D. Urgent audiogram
- E. Urgent referral to ENT

E. Urgent referral to ENT

The MRI brain shows an intracanalicular solid nodular mass with an intense contrast enhancement in the right internal auditory meatus (IAM), which is suggestive of vestibular schwannoma.

Urgent referral to ENT is the correct answer. The patient's presentation and the MRI findings are in keeping with vestibular schwannoma, and the patient requires an urgent referral to ENT for further management.

Computed Tomography of thorax is incorrect. While a metastatic lesion of the cerebellopontine angle is a likely differential given the smoking history, the patient may benefit from a chest radiograph and/or a CT of the thorax to assess for lung neoplasms. However, the presentation and the MRI findings are characteristic of vestibular schwannoma, and the patient needs an urgent referral to ENT.

Intratympanic steroid therapy is incorrect. Intratympanic steroid injection treats vestibulocochlear symptoms of inner ear disease, such as Meniere's disease or idiopathic sudden sensorineural hearing loss. However, this patient's MRI suggests vestibular schwannoma as the likely cause for his hearing loss and requires urgent referral to ENT.

Systemic steroid therapy is incorrect. While systemic steroid therapy may be considered in treating sensorineural hearing loss associated with vestibular schwannoma, there is no adequate evidence to support its routine use in patients with vestibular schwannoma. The patient should be referred to ENT.

Urgent audiogram is incorrect. Patients with sensorineural hearing loss, tinnitus and vertigo should have an audiogram and MRI brain to assess for vestibular schwannoma. However, this patient's MRI brain is diagnostic of vestibular schwannoma and requires urgent ENT referral.

Question 32 of 189

An 82-year-old man is referred to neurology clinic with slowness. He presented with his wife who reported that he has been becoming progressively slower in his movements and his facial expressions have become more limited. His symptoms have progressed rapidly following the onset of dizziness a few weeks ago. He has a past medical history of type two diabetes, hypertension, high cholesterol, previous hemicolectomy for diverticulitis. His current medications include ramipril, atorvastatin, paracetamol, amlodipine, metformin, prochlorperazine and gliclazide.

On examination, he has a coarse bilateral tremor at rest, and rigidity in both arms. He has a slow gait as well.

What is the most likely diagnosis?

- A. Parkinson's disease
- B. Drug-induced parkinsonism
- C. Multi-system atrophy
- D. Vascular parkinsonism
- E. Wilson's disease

B. Drug-induced parkinsonism

The answer is drug-induced parkinsonism. There are several hints to why this is more likely. A bilateral tremor of rapid onset makes drug-induced parkinsonism a more probable cause when compared to Parkinson's disease. The recent dizziness suggests that prochlorperazine was only recently introduced, making it more suspicious that it may the cause of the current symptoms. Vascular parkinsonism would have a more step-wise progression with definitive days of significant deterioration, which are not described here. Multi-system atrophy generally has greater autonomic involvement, as well more cerebellar dysfunction. Wilson's disease typically occurs in younger patients, and is also assoaciated with liver dysfunction.

Question 33 of 189

A 28-year-old woman presents with a gradually worsening headache, nausea and vomiting.

The headache started about 3 days ago coming on over about 3-4 hours and is worse on coughing and lying flat. She has been complaining of some nausea and vomiting which she had attributed to some reheated curry she had the night before.

She is usually fit and well but did suffer a spontaneous below-knee deep vein thrombosis (DVT) 3 years ago which was treated with warfarin for 6 months. She has been taking over-the-counter paracetamol and ibuprofen for the headache and currently has a Mirena intrauterine coil in-situ for contraception. She has no known drug allergies.

She currently works as a sales associate. She smokes 10 cigarettes a day and drink 21 units of alcohol a week.

On examination she looks unwell, pale and nauseated. Her blood pressure was 140/98 mmHg, heart rate 100 bpm, oxygen saturations of 98% on air. Her temperature was 36.1 degrees Celsius.

Heart sounds were normal, and her calves soft and non-tender with no evidence of thromboembolism.

Her chest was clear and her abdominal examination was unremarkable.

On neurological examination there was no cranial nerve abnormalities noted. She had normal tone, power, reflexes and sensation in both her upper and lower limbs. Coordination was intact. Bloods taken by the Emergency Department were as follows:

Na+	136 mmol/L
K+	3.9 mmol/L
Urea	4.8 mmol/L
Creatinine	76 µmol/L
Hb	12.5 g/dL
WBC	11.0 x 10^9/L
Platelets	350 x 10^9/L
INR	0.9
aPTT	30 seconds
LFTs	Normal

CT head was performed and reported as normal. Following this a lumbar puncture was performed:

CSF colour	Clear
Opening pressure	250 mmH20
White cell count	5.0 x 10^6/L (all lymphocytes)
Red cell count	15 x 10^6/L
Protein	0.3 g/L
Glucose	4.4mmol/L (Serum glucose 5.3mmol/L)

What is the most likely diagnosis?

A. Intracranial venous thrombosis
B. Subarachnoid haemorrhage
C. Migraine
D. Intracerebral malignancy
E. Subdural empyema

A. Intracranial venous thrombosis

This lady has had a previous venous thromboembolism and presents with a gradually worsening headache with multiple red flags. The history and examination is rather non-specific but it is the CSF opening pressure in the context of previous venous thrombus that most points towards the diagnosis of an intracranial venous thrombosis. This can present with a gradual or severe headache, signs of raised intracranial pressure and cranial nerve palsies.

Subarachnoid haemorrhage is unlikely in the context of the gradual onset of symptoms. This patient has no previous history of migraine and the investigations are not consistent with this.

She is apyrexial and there is nothing in her presentation to indicate an intracerebral abscess, furthermore the CT is normal.

A normal CT also rules out intracerebral malignancy.

Question 34 of 189

You are the medical registrar on call. While reviewing another patient, you notice an 82-year-old female inpatient on the same ward, currently treated for community-acquired pneumonia sitting in a chair. You notice a persistent movement of her head, in a nodding motion, associated with a tremor of both hands, worse in the left than the right. Reading through her notes, she has previously been treated for epilepsy and was started on oral phenytoin by her GP 4 months ago. On examination, the hand tremor appears to worsen when her arms are outstretched. She performs finger-nose dysmetria testing without difficulty with no speech. She demonstrates no cogwheeling. The patient appears unconcerned by the symptoms 'I have learned to live with it for years doctors!' she tells you.

What is the most likely diagnosis?

A. Tremor-predominant
B. Parkinson's disease
C. Phenytoin induced cerebellar tremor
D. Essential tremor
E. Physiological tremor
F. Orthostatic tremor

D. Essential tremor

The patient's examination is one of isolated tremor with no other cerebellar or neurological features. The clinical features of worsening on posture, head nodding and lack of cerebellar symptoms suggest a diagnosis of essential tremor. She demonstrates no signs of Parkinson's disease, a tremor that does not alleviate with movement and the history describes onset beyond the start of phenytoin. Orthostatic tremor onsets in the trunk and legs when the patient stands. The described features are perhaps too severe for a physiological tremor, which is typically low in amplitude and barely visible. It is unlikely the patient would have received a beta agonist for a community-acquired pneumonia in the absence of obstructive airways disease, hence a druginduced tremor is also unlikely.

Question 35 of 189

A 48-year-old male presents with a sudden onset occipital headache onset 2 and half hours ago, associated with slurred speech, vomiting and unsteadiness in all movements. In the 90 minutes after admission to the emergency department, it was noted that the patient became increasingly drowsy, deteriorating from a GCS of 15 on admission to E3 V4 M5. On examination, pupils are equal, his speech is dysarthric and bilateral plantars are downgoing. You are unable to elicit more formal power, tone or sensation examination in the patient. An initial CT head is unremarkable but a subsequent MRI head with diffusion weighting sequences demonstrates restricted diffusion in bilateral cerebellar hemispheres with significant swelling around the cerebellum, brainstem and aqueduct. GCS currently 14/15 at 10 hours post-event. You have initiated aspirin 300mg and inserted a nasogastric tube.

What is the appropriate management?

A. Add clopidogrel 300mg
B. Start warfarinisation
C. Thrombolysis

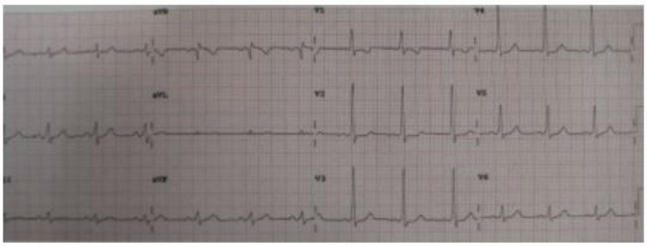
D. Discuss with neurosurgery for decompressive posterior craniectomy
E. Hourly neuro observations with empirical anti-seizure medications

D. Discuss with neurosurgery for decompressive posterior craniectomy

This patient is critically unwell. He has presented with a posterior circulation infarct significant oedema around a very tight part of the neuro-anatomy. Although pupils are currently equal and reactive, the drop in GCS is a major concern. It may not be possible to illicit upper motor neurone signs in the hyperacute phase after a stroke. The most concerning complication at this stage is a progression towards obstructive hydrocephalus from CSF flow blockage at the aqueduct or 3rd or 4th ventricle. Prophylactic posterior craniectomy must be considered in such a young patient, discussion with neurosurgery is essential.

Question 36 of 189

A 14-year-old boy presents his third generalised seizure over the past 72 hours, despite recently being started on sodium valproate by a neurologist for recurrent seizures 6 weeks ago, with worsening vision at night and hearing loss bilaterally. The patient has a number of myoclonic jerks as you arrive. On examination, his heart sounds are unremarkable but you notice a tachycardia at 140 and regular. The ECG is shown below:



The patient is uncooperative to further neurological examination but you notice sluggishly reactive pupils of equal size. His mother reports that he has been educated in a special needs school for the past 5 years but had been attending the local primary school until aged 9, when he dropped further behind than his peers.

Which investigation produces the underlying diagnosis?

A. MRI
B. Lumbar puncture
C. Electroencephalogram (EEG)
D. Cardiac electrophysiology studies
E. Muscle biopsy

E. Muscle biopsy

The patient is a young male presenting with cognitive impairment developing after a period of normal development, seizures, myoclonic jerks, Wolff-Parkinson-White syndrome and worsening vision (consistent with optic atrophy). The unifying diagnosis is that of myoclonic epilepsy with ragged red fibres (MERRF), which is a mitochondrial DNA disorder diagnosed by ragged red fibres on muscle biopsy.

Question 37 of 189

A 61-year-old male presents with his sixth episode of binocular visual phenomenon over the past 14 months. He describes these episodes as 'lights' and 'white dots' in his field of vision. He denies any limb or facial weakness or sensory loss. He denies having a headache. He is an active smoker, with a 60 pack year smoking history and has known hypertension on ramipril 5mg OD. Your neurological exam is unremarkable; CT head demonstrates no acute infarct or haemorrhage. MRI head is unremarkable.

What is the most likely diagnosis?

A. Posterior circulation transient ischaemic attacks (TIAs)
B. Posterior circulation strokes
C. Acephalgic migraine
D. Multiple sclerosis
E. Occipital space occupying lesion

C. Acephalgic migraine

The patient gives a strong history of positive visual symptoms such as flashing lights and dots, with no negative such as weakness or sensory loss. This would be far more suggestive of a migrainous syndrome or primary retinal pathology than cerebrovascular insufficiency, where negative symptoms would be prominent. In addition, a diagnosis of TIA or stroke should be suspicious in any patient with repeated stereotyped, similar symptoms over a long period of time. It is unlikely any patient will present with recurrent multiple TIAs without stroke over a 14 month period.

Acephalgic migraine is a frequently missed diagnosis of exclusion, where patients experience auras without a headache. Up to 38% of migraineurs experience migraine attacks without and with a headache, while 4% of migraineurs exclusively experience migraines without headaches .

Question 38 of 189

A 58-year-old female is brought into hospital by her husband with recurrent falls associated with cognitive decline noted by her husband over the past 8 weeks. The patient's husband reports a possible cough and cold about 3 months ago, during which she took 2 days off work as a personal assistant to a FTSE 100 company CEO but otherwise has no significant past medical history, is a non-smoker and drinks minimal alcohol.

On examination, she is alert and orientated to time and place but appears easily startled every time you start a sentence. You note significant bilateral finger-nose and heel-shin dysmetria, mild postural tremor and mild speech slurring. The remainder of her neurological examination was unremarkable.

Her blood tests are as follows:

Hb	124 g/l
Platelets	282
WBC	4.8
Na	143 mmol/l
K	4.7 mmol/l
Urea	6.7 mmol/l
Creatinine	86 µmol/l
CRP	3 mg/l

TSH	8.0 mu/l
Free T4	12.0 pmol/l
Anti-TPO	negative
HIV	negative
Glucose	6.5 mmol/l

A lumbar puncture was performed with results as follows:

WCC	<1 /mm³
RBC	28 /mm³
Protein	0.71 g/l
Glucose	3.4 mmol/l
Culture	no organisms grown
Viral PCR	awaited
Cytology	awaited
14-3-3	positive

An EEG demonstrated brief periodic spikes but these were not correlated with any seizure activity clinically. An MRI head demonstrated no parenchymal abnormalities except mildly increased signal in the cortical sulci.

What is the most likely diagnosis?

A. Creutzfeldt-Jakob disease
B. Viral encephalitis
C. Acute disseminated encephalomyelitis (ADEM)
D. Progressive multifocal leucoencephalopathy (PML)
E. Hashimoto's encephalopathy

A. Creutzfeldt-Jakob disease

This middle aged female demonstrates a number of worrying features suggestive of Creutzfeld Jakob disease (CJD): rapid cognitive decline, myoclonus, extrapyramidal signs (ataxia), startle response, positive 14-3-3 on CSF and periodic spiking on EEG. The MRI findings likely represent 'cortical ribboning', with high signal on the cortical sulci surfaces, which along with increased signal in putamen and caudate head, is suggestive of CJD.

She is also in the expected age group for CJD, typically presenting between 57 and 62 years old.

A number of features in the history and investigations are red herrings: it is unusual for a viral encephalitis, related to a probable viral respiratory tract infection, to be indolent for 8 weeks and continuing to progress in a non-immunosuppressed patient. The MRI findings and time course are also not suggestive of ADEM, which produces many focal areas of central demyelination within 1 to 3 weeks of a viral illness.

PML results in central demyelinating and is caused by activation of JC papovavirus in immunosuppressed patients, typically HIV positive individuals, and hence unexpected in this patient. The raised TSH likely represents subclinical hypothyroidism in this patient: while Hashimoto's encephalopathy can produce personality change, aggressive and disorientation, myoclonus and ataxia, 14-3-3 is typically negative in CSF with positive anti-TPO antibodies. Adiagnosis of CJD is thus most likely diagnosis, with the patient progressing along a typically fatal clinical course.

Question 39 of 189

A 21-year-old Caucasian female presents to eye casualty with an episode of sudden onset blurred vision in her left eye. She reports noticing it about 10 days ago and reports progressive deterioration associated with pain on eye movement until her presentation today. There is a vague history of a possible 'cough and cold' about 3 weeks ago but she has reported no other recent illnesses. She has no past medical history, is on the oral contraceptive pill and has no other medications. There is no smoking, alcohol or recreational drug history.

On examination, you note visual acuity and colour vision on Ishihara plates to be 6/6 and 17/17 plates in her right eye, 6/24 and 0/17 plates in her left eye. A left relative afferent papillary defect was demonstrated, fundoscopy was unremarkable. Examination of her other cranial nerves and limbs were unremarkable. Her blood tests were unremarkable and she has declined a lumbar puncture. An MRI head and whole spine demonstrates no abnormalities except for a swollen left optic nerve is visualised.

What is the most appropriate treatment?

A. No treatment, reassure patient vision will resolve
B. Oral prednisolone
C. Intravenous methylprednisolone
D. Intravenous immunoglobulin
E. Interferon beta

Not answered in the book

Question 40 of 189

A 32-year-old female patient presents with 48 hours of new onset vertiginous symptoms and speech slurring. She has no past medical history and is a non-smoker. On examination, you notice a left partial ptosis and miosis. Finger-nose coordination is impaired with her left arm and she also has reduced sensation to your cold tuning fork on her left face, right arm and right leg.

What is the most likely diagnosis?

A. Bilateral cerebellar infarcts
B. Right middle cerebral artery ischaemic infarct
C. Left middle cerebral artery ischaemic infarct
D. Lateral medullar brainstem infarct
E. Left basal ganglia haemorrhage

D. Lateral medullar brainstem infarct

This patient describes almost all the features of lateral medullary syndrome, classically known as Wallenberg's syndrome, consisting of ipsilateral cerebellar ataxia (lesion at the inferior cerebellar peduncle), ipsilateral loss of facial pain and temperature (ipsilateral trigeminal nucleus), vertigo and nystagmus (vestibular nucleus) and Horners syndrome (first order sympathetic chain neurones). In such a young patient without cardiovascular risk factors, vertebral artery dissection would be the most likely cause of the posterior circulation infarct, likely secondary to sudden neck twisting or extension from recent trauma, classically following a whiplash injury.

Question 41 of 189

A 16-year-old male is referred to your clinic after reporting feeling increasingly tired at school over the past 2 months. His parents are similarly concerned that their son seems to be relying on large volumes of Lucozade to keep himself alert during this stressful period of secondary school examinations. He reports no headaches. The patient was born following a normal pregnancy and development until he was 12 years old, when he underwent chemotherapy and radiotherapy treatment for an optic chiasm glioma, forcing him to miss one academic year of school. On completion of his treatment, he returned to school and has been achieving good grades. There is no other past medical or family history.

On examination, the patient is short for his age (at 2nd centile) and you note an absence of facial hair or other secondary sexual characteristics. He is thin with a BMI of 13.7 kg/m^2. Chest, cardiovascular and abdominal examinations are unremarkable. There are no skin lesions. Neurological examination including cranial nerve is unremarkable. His initial blood tests are as follows:

Hb	142 g/l
MCV	89 fl
Platelets	410 * 10 /l
WBC	7.4 * 10 /l
Na	139 mmol/l
K	4.6 mmol/l
Urea	5.1 mmol/l
Creatinine	44µmol/l
FSH	low
ACTH	low
TSH	0.13 mu/

What is the most likely diagnosis?

A. Cranial radiation injury
B. Glioma recurrence in optic chiasm
C. Klinefelter's syndrome
D. Turner's syndrome
E. Haemochromatosis

A. Cranial radiation injury

A combination of clinical features and pituitary function tests reveal panhypopituitarism. Delayed puberty does not appear to be gonadal but instead central in cause. While haemochromatosis may be a cause of panhypopituitarism, other features such as skin pigmentation, liver cirrhosis, arthralgia and type 1 diabetes mellitus would be expected. Turner's syndrome appears in females only due to an XO karyotype. Klinefelter's can cause delayed puberty secondary to a failure of Leydig cell development but would be associated typically with clinical features such as hypothyroidism, diabetes mellitus, with increased pituitary hormone release in response to gonadal dysfunction.

The location of the optic chiasm adjacent to the hypothalamic-pituitary structures and previous medical treatment should raise suspicion of cranial radiation injury, common in childhood survivors of intracranial cancers treated with radiotherapy. There is little to suggest recurrence of the tumour, which would typically present with proptosis and visual disturbance.

Question 42 of 189

An 18-year-old man presents to your follow-up clinic after the first episode of generalised tonic-clonic seizures, witnessed by his mother lasting for 4 minutes, involving all 4 limbs, before spontaneously terminating. He was initially referred to a first fit clinic and underwent an EEG and MRI, neither of which demonstrated any significant abnormalities. He has now returned to discuss his results and further treatment. The patient and his family realise that there are many ways to manage seizures and are happy to take your recommendation.

What is the most appropriate management?

A. No treatment
B. Sodium valproate
C. Lamotrigine
D. Levetiracetam
E. Carbamazepine

A. No treatment

Treatment is not usually recommended after a single seizure, as this may have been a provoked seizure instead of the first presentation of epilepsy. One prospective, but methodologically flawed, study demonstrated a 14% risk of seizure recurrent after a single, unprovoked seizure at 1 year . However, the risks significant increase after a patient has had two seizures, rising to 73% recurrent rate at 4 years . It is therefore accepted that antiepileptic treatments should only be commenced after 2 seizures, except if the risks of a further seizure is unacceptable to the patient, an underlying structural defect is proven to be the likely cause of the seizure or if the EEG demonstrated epileptiform activity.

Question 43 of 189

A 16-year-old boy is brought into the emergency department by his mother after an episode of unresponsiveness while walking, lasting transiently for seconds before fully resolving. He has no recollection of these episodes. He was diagnosed with absence seizures aged 11 and was previously prescribed anti-epileptics. These had been gradually weaned off two years ago by his neurologists following a 3-year seizure-free period.

Over the past 48 hours, he has now had 4 of his typical absences. You decide to prescribe an antiepileptic.

Which antiepileptic should be avoided?

A. Carbamazepine
B. Sodium valproate
C. Lamotrigine
D. Levetiracetam
E. No contraindications

A. Carbamazepine

Classically, carbamazepine can aggravate juvenile myoclonic epilepsy and absence seizures . In general, carbamazepine should always be avoided in patients where the type of seizure is uncertain.

It is otherwise a useful AED in the treatment of partial or secondary generalised seizures.

Question 44 of 189

A 72-year-old male is brought into the emergency department by ambulance after a third episode of limb jerking in 72 hours was witnessed by his wife. As you arrive, the patient becomes increasingly unresponsive and you witness small amplitude jerking of all four limbs. While the resus nurse obtains midazolam two minutes into his seizure, you note his eyes are closed tight and it is not possible to forcefully open them in order to check papillary reflexes. The amplitude of his limb jerking also become increasingly large. You note blood on his tongue and urinary incontinence. He does not suffer head or limb injury. His seizure spontaneously terminate before any medication is administered about 6 minutes after its onset. He becomes increasingly responsive about 2 minutes after the end of limb jerking and appears tearful. He is extremely apologetic for the fuss he has caused.

What is the most likely diagnosis?

A. Partial seizure
B. Absence seizure
C. Secondary generalised seizure
D. Pseudoseizure
E. Myoclonic seizure

D. Pseudoseizure

A number of features in this description of the seizure indicate the possibility of pseudoseizure. The patient's eyes are closed to resistance and he has a very short post-ictal state. He also appears to become alert and orientated in speech very quickly afterwards. Patients with pseudoseizures often have accompanying underlying psychiatric concerns and can be tearful around the time of the seizure. In addition, prolonged jerking of limbs, of increasing amplitude (crescendo features) should make you suspicious. A number of features should also be noted: firstly, patients of any age can present with pseudoseizures. Secondly, features such as tongue biting and urinary incontinence are not absolute features of an organic seizure, they are often present in pseudoseizures.

Question 45 of 189

You receive a call from a GP in the community. A 65-year-old female patient who was diagnosed with generalised myasthenia gravis six years ago and last reviewed in neurology outpatients 6 weeks ago reports no improvements in her neck weakness, voice weakness and fatigue. In the neurology clinic, her dose of pyridostigmine was increased from 90mg QDS to 120mg QDS. She does not appear acutely unwell but complains that her life is significantly affected by her symptoms. She has no other past medical history. On examination by her GP, she has no respiratory distress and able to swallow salivary secretions normally.

What is your advice?

A. Increase pyridostigmine to 150mg QDS
B. Start prednisolone 60mg in community, neurology to follow up in 8 weeks as outpatient
C. Start azathioprine in community, neurology to follow up in 8 weeks as outpatient
D. Admit to hospital, start oral prednisolone in hospital
E. Admit to hospital, start intravenous immunoglobulin in hospital

D. Admit to hospital, start oral prednisolone in hospital

The patient remains symptomatic despite being increased onto the maximum dose of pyridostigmine. The second decision is whether the patient is acutely, severely unwell, in which case rapid therapies such as IV Ig or plasmapheresis must be initiated, as per myasthenic crisis. In this case, she has no signs of respiratory distress or dysphagia, her symptoms are more of a case of not improved instead of rapid deterioration. Therefore, the patient does not require rapid therapy. However, she does require immunotherapy initiation. As a rule of thumb, patients who remain symptomatic despite 60mg QDS of pyridostigmine should be considered for immunotherapy.

The modality of immunotherapy must be individualised to the patient, as each drug has their own contraindications. In younger patients with no concerns regarding blood sugars, oral prednisolone is reasonable. Those with liver disease should avoid azathioprine, renal disease patients should avoid ciclosporin while those with haematological abnormalities should avoid mycophenolate and azathioprine.

However, starting of prednisolone, particularly at high doses, have been classically described to cause a paradoxical reaction in half of all patients, resulting in a transient deterioration before improvements are observed. Up to 10% of patients have been reported to have sufficiently severe respiratory failure requiring mechanical ventilation take place in a monitored hospital setting.

Question 46 of 189

A 42-year-old male presents with double vision and weakness in his fingers, which he noticed when he repeatedly dropped his pen whilst trying to write at work. His symptoms appear to have onset over the past few days. He has no past medical history other than a recent episode of diarrhoea and vomiting about two weeks ago. He reports no limb weakness and no sensory loss. He denies any back pain or palpitations. On examination, there is a 3/5 weakness in finger flexion, finger extension and wrist extension in both hands, with no fatigability. No reflexes present in the lower or upper limbs. There is no ptosis or nystagmus but reduced eye movements in all directions. His finger-nose test demonstrates reduced coordination bilaterally and the patient has too little confidence to walk.

Which investigation is most likely to be diagnostic?

A. Anti-GM1 antibody
B. Anti-GQ1b antibody
C. MRI brain and whole spine
D. Anti-MUsK (muscle specific kinase) antibody
E. Anti-acetylcholine receptor antibody

B. Anti-GQ1b antibody

The patient has presented with a classic triad of ophthalmoplegia, ataxia and areflexia, which should suggest Miller-Fisher syndrome, an acute onset demyelinating peripheral neuropathy recognised as a variant of Guillain-Barre Syndrome. Anti-GQ1b antibody is present in between 85-90% of patients with Miller-Fisher syndrome .

Key differentials of MFS include myasthenia gravis, brainstem infarcts and brainstem encephalitis. In this case, the absence of fatigability and nystagmus rule against neuromuscular junction disorders and brainstem events respectively.

Question 47 of 189

A 50-year-old Caucasian female on holiday from Australia presents to the walk-in urgent care centre with four-day history of left-sided temporal headache, which is persistent and of gradual onset. In addition, she complains of double vision as well. She is known to have migraines but is relatively well-controlled. She is normally independent with no significant family history. She takes no regular medications except the oral contraceptive pill. On examination, you note a left sided loss of the afferent papillary reflex. She also has a loss of vertical gaze and is unable to adduct her left eye. She has a reduced sensation to light touch on the left forehead and cheek, not crossing the midline.

What is the most likely diagnosis?

A. Left space-occupying lesions
B. Multiple sclerosis
C. Right MCA territory ischaemic infarct
D. Cavernous sinus thrombosis
E. Migraine with aura

D. Cavernous sinus thrombosis

The patient describes a clear history of loss of her 3rd cranial nerve, with the possible involvement of the left 4th, with V1 and V2 branches of the left trigeminal nerve. The only structure involving all these cranial nerves (and classically with the sympathetic postganglionic neuron) is the cavernous sinus. The patient has a number of risk factors for venous thrombotic disease, including recent long-haul flight and the oral contraceptive pill. The most likely causes are dehydration and VTE disease risk factors, but a carotid artery aneurysm should also be considered.

Question 48 of 189

A 78-year-old male presents to the hyperacute stroke unit with a sudden onset left sided hemiparesis and which is subsequently demonstrated to represent an acute ischaemic infarct in the right middle cerebral artery territory with no haemorrhagic transformation. He was not thrombolysed due to presentation being outside the time window. As part of his stroke investigations, echocardiogram demonstrates no mural thrombus or regional wall abnormalities and an ejection fraction of 70%. The 24 hour tape recorded no arrhythmias. Carotid Dopplers demonstrate 40% stenosis in the right internal carotid artery, 55% stenosis in the left internal carotid artery. Blood pressure measured 125/75mmHg. He takes simvastatin 40mg nocte and has no known drug allergies.

What would be the optimal treatment?

A. Refer to vascular surgery for right carotid endarectomy
B. Refer to vascular surgery for left carotid endarectomy
C. 300mg oral aspirin for 14 days, then clopidogrel 75mg
D. Subcutaneous low molecular weight heparin, then warfarin loading
E. Perindopril 4mg OD

C. 300mg oral aspirin for 14 days, then clopidogrel 75mg

Carotid endarectomy (CEA) is not indicated for either internal carotid artery in this case. The present NICE guideline recommends surgical intervention if the symptomatic side demonstrates greater than 70% stenosis and to be discussed for CEA if 50-69% stenosis . The management of asymptomatic stenosis is controversial: minimal but significant benefit is proven only for patients with greater than 60% stenosis and if the benefits outweigh the risk of stroke or death post CEA, which currently stands at 3%. NICE recommends consideration for asymptomatic CEA if stenosis is greater than 60% only. In this case, neither internal carotid stenosis fits the criteria for surgical intervention. Instead, best medical management with antiplatelet therapy is the treatment of choice. The use of anticoagulation beyond cardioembolic disease is controversial and not routinely used. The patients blood pressure is within the target range. The patient is already on a statin.

Beware when interpreting carotid stenosis measurements: two major trials of CEA for carotid endarectomy measured the degree of stenosis differently: ECST compared the stenotic diameter to the probable original diameter at the carotid bulb, the clearest benefit was for patients with greater than 80% stenosis . NASCET compared residual diameter to the lumen directly distal to the stenosis, the greatest benefit of CEA was for patients with greater than 70% stenosis . Simplistically, any patient with greater than 70% to 99% symptomatic stenosis would benefit significantly from CEA, patients with 50 to 69% stenosis would also benefit from CEA but to a lesser degree and only if performed within 2 weeks of the last episode.

Question 49 of 189

A 64-year-old gentleman presented to the neurology clinic for review. He had a history of motor neuron disease which had been progressing over the past five years. He had significant weakness in all of his limbs and was dependent on a wheelchair. He took baclofen for relief of muscle spasms, and amitriptyline to reduce salivation but was otherwise not on any medication. He mentions that in addition to his weakness continuing to progress he has been suffering from headaches in the morning. These were generalised and described as throbbing in nature. He also reported not feeling refreshed after sleep.

On examination, there is generalised muscle wasting, with fasciculations in all limbs. Reflexes were absent, other than bilateral extensor plantar responses. Eye movements and fundoscopy are normal. Palatal movements were normal, and there was no significant dysphagia on swallow test.

Which intervention is most likely to confer the greatest survival benefit in this patient?

A. Riluzole
B. Feeding via percutaneous endoscopic gastrostomy
C. Non-invasive ventilation
D. Home oxygen therapy
E. Prophylactic antibiotics

C. Non-invasive ventilation

The morning headaches and lack of feeling refreshed after sleep are suggestive of carbon dioxide retention due to respiratory impairment in patients with motor neuron disease. Non-invasive ventilation improves quality of life and confers a survival benefit in patients with respiratory impairment in motor neuron disease.

Riluzole also offers a modest survival benefit in motor neuron disease (it is the only drug known to do so), prolonging life expectancy by on average two to four months. Given there is no evidence of dysphagia feeding via a percutaneous endoscopic gastrostomy is not indicated in this patient. Home oxygen therapy and prophylactic antibiotics are not routinely used in motor neuron disease.

Question 50 of 189

A 42-year-old female presented with a 6-month history of weakness affecting her upper limbs. She found that this was worse at the end of the day, particularly if she had been doing a lot of lifting. She also reported occasional difficulty in swallowing at the end of the day, with drinks causing her to cough. She had been prescribed pyridostigmine, but she stopped taking this as she had not noticed any benefit.

On examination, there was a mild partial ptosis, and a slight facial droop bilaterally. Extra-ocular movements were normal. Power in shoulder abduction was grade 4/5 bilaterally, but was reduced to 3/5 after repeatedly abducting and adducting the shoulder 20 times. Tone and sensation were normal.

Initial investigation results are shown below:

- Nerve conduction studies: Decremental response to repetitive nerve stimulation
- Single-fibre electromyography: Increased jitter
- Anti-Jo antibodies: Negative
- Anti-Mi2 antibodies: Negative
- Anti-acetylcholine receptor antibodies: Negative

Which of the following immunological tests is most likely to contribute to the diagnosis?

A. Anti-muscle-specific tyrosine kinase(MuSK) antibodies
B. Anti-N-methyl D-aspartate (NMDA) receptor antibodies
C. Anti-glutamic acid decarboxylase (GAD) antibodies
D. Anti-acetylcholine receptor antibody
E. Anti-Hu antibodies

A. Anti-muscle-specific tyrosine kinase(MuSK) antibodies

This patient presents with weakness affecting the upper limbs, eyelids, facial muscles and pharynx, which demonstrates fatiguability. This is a characteristic description of myasthenia gravis, and this is supported by the electrophysiological tests. The majority of patients with this condition are positive for anti-acetylcholine receptor antibodies, which are present in about 85%. In the remaining patients, about 40% are positive for anti-muscle-specific tyrosine kinase antibodies. In anti-acetylcholine receptor negative cases, response to acetylcholinesterase inhibitors (such aspyridostigmine) tends to be worse.

Anti-aquaporin antibodies are associated with neuromyelitis optica, anti-N-methyl D-aspartate receptor antibodies are associated with autoimmune encephalitis, anti-glutamic acid decarboxylase antibodies are associated with stiff man syndrome, and anti-Hu antibodies are associated with a paraneoplastic sensory neuropathy and encephalitis.

Question 51 of 189

You are called to a general medical ward during the night to review 48 year female who has become acutely agitated and confused. She came into hospital two days ago with a suspected urinary tract infection and has been making uneventful progress. She has a past history of traumatic spinal injury at level C5 three years ago with resulting spastic quadraparesis. On your arrival her blood pressure is 220/105 mmHg, heart rate is 55/min, and she is flushed and diaphoretic.

Of the following, what additional feature might you expect to find?

A. Palpable bladder
B. Ejection systolic murmur in the pulmonary area
C. Flushing of the skin in the trunk and legs R
D. elative afferent pupillary defect
E. Complete heart block

A. Palpable bladder

This question is describing a case of autonomic dysreflexia. Of the options given, palpation of a distended bladder is likely and also diagnostic. Pulmonary murmurs can be a feature of the carcinoid syndrome. A relative afferent pupillary defect is seen with optic nerve pathology such as optic neuritis. Flushing of skin above the cord lesion is common due to parasympathetic feedback causing vasodilation but of course anything below the cord lesion remains vasoconstricted.

Question 52 of 189

A 53-year-old accountant presents with two weeks of a constant headache with two seizures in the last 24 hours. His family say that he has changed in character and seems more aggressive. They also say that he appears weaker, is eating less and has 2 lbs of weight over the past week.

He is known to be HIV positive and had an anterior resection for rectal carcinoma 3 years ago and a recent endoscopy shows gastric polyps. He is currently well but has suffered from multiple episodes of sinusitis and is taking a four-week course of oral antibiotics.

On examination, he has reduced power in the left upper limb across all muscular groups but preserved sensation. Reflexes are reduced on the left side. In the left lower limb, power is mildly reduced and there is an upgoing plantar with normal sensation. He has a Glasgow Coma Score of 13 and he is drowsy. Pupils are equal and reactive but there is papilloedema. His observations show a heart rate of 96 beats per minute, blood pressure 110/98 mmHg, temperature 38.0'C and respiratory rate 18 per minute with saturations of 98%.

Na	137 mmol/l
K	4.3 mmol/l
Urea	3.5 mmol/l
Creatinine	40 µmol/l
Hb	100 g/l
Platelets	378* 10 /l
WBC	12.3* 10 /l
Blood cultures	pending
CT head	requested

What is the likely diagnosis?

A. Tertiary syphilis
B. Lymphoma
C. Toxoplasmosis
D. Cerebral abscess
E. Glioma

D. Cerebral abscess

Features of raised intracranial pressure and fever points towards a cerebral abscess

There is evidence of raised intracranial pressure that is gradual in onset. Subarachnoid presents with a severe headache which has not occurred here. Tertiary syphilis is rare and there are no specific signs pointing towards this diagnosis. Toxoplasmosis is possible given he is HIV positive but there are no additional features pointing towards this. Of cerebral abscess and glioma, the presence of fever makes the former likely and the abscess is likely secondary bacterial spread from sinusitis. A glioma is possible given the weight loss and previous malignancy but would usually present over a longer period of time.

Question 53 of 189

A 23-year-old man with known Von Hippel Lindau syndrome sees his GP to routinely review his mood. He has been well previously but has known retinal haemangiomas. He is taking venlafaxine and has improved in his mood which was damaged from a recent relationship break down. He does continue to get panic attacks where he develops palpitations and feels clammy and is using mindfulness to control these.

On examination, he is well and alert. His blood pressure is 170/110mmHg. He has 6/6 visual acuity bilaterally and there are no haemorrhages or cotton wool spots on fundoscopy. His abdomen is soft and there are no palpable masses.

Na	134 mmol/l
K	4.1 mmol/l
HCO3	25mmol/l
Urea	6.7 mmol/l
Creatinine	87 µmol/l
TSH	3.2 mU/l (range 0-4)
ECG	large QRS complexes consistent with left ventricular hypertrophy

What is the likely cause of his presentation?

A. Venlafaxine
B. Phaeochromocytoma
C. Renal artery stenosis
D. Depression/anxiety
E. Liddle's syndrome

B. Phaeochromocytoma

Hypertension in Von Hippel Lindau -> phaeochromocytoma

This gentleman has presented with hypertension and episodes of sweating and palpitations. He is usually well and is on venlafaxine which can cause hypertension but not the other symptoms. Renal artery stenosis would usually present with deranged urea and electrolytes and is rare in this age group. Liddle's syndrome presents with a hypernatraemia, hypokalaemia metabolic alkalosis which is not seen here. Depression/anxiety can cause BP fluctuations but is a diagnosis of exclusion. Phaeochromocytoma would explain these symptoms and also is more common in Von Hippel Lindau so is the answer.

Question 54 of 189

A 70-year-old man with hypertension and previous myocardial infarction 3 years ago presents to his GP with a 2 day history of a painful vesicular rash over his left chest and back. It is well demarcated and confined to the T6 dermatology. His GP diagnoses shingles and prescribes pain relief. His rash resolves gradually over the next 2 weeks.

Four weeks later the man develops chest pain on the left side which is stabbing in shooting in nature. He attends the Emergency Department. On examination his blood pressure is heart rate is 50/min and blood pressure is 154/96 mmHg. His oxygen saturations on room air 98%.

His investigations results were as follows: Chest x-ray: No abnormalities.

ECG: 50/min. PR interval 230 milliseconds. QRS interval 110 milliseconds. 5 millimetre Q waves in the inferior leads. Normal T wave and ST segments.

His d-dimer and 12 hour troponin are both normal.

Which analgesic agent is contraindicated?

A. Amitriptyline
B. Duloxetine
C. Gabapentin
D. Oxycodone
E. Pregabalin

A. Amitriptyline

This gentleman has post-herpetic neuralgia causing his chest pain.

He has a history of heart attack and his ECG shows evidence of inferior myocardial infarction in the territory of the right coronary artery. This has resulted in a first degree heart block as evidenced by the long PR interval.

NICE Guidance on Neuropathic Pain (CG173) advocates a choice of amitriptyline, duloxetine, 61% 18% 5% 12% 4%gabapentin or pregabalin. According to the BNF amitriptyline is contraindicated in arrhythmias particularly heart block, as in this case. It is also contraindicated in the recovery period following myocardial infarction, though this gentleman is outside of this.

Question 55 of 189

A 25-year-old F1 driver complains of neck pain following a race. Three days later he presents with left sided facial numbness as well as numbness across the right upper and lower limb. Positive findings on examination are the loss of pain and temperature sensation on the left side of the face in all trigeminal distributed areas. There is also the loss of pain and temperature sensation in the right upper and lower limbs. The left pupil is much smaller than the right and there is a partial ptosis on the left. Eye movements are normal. Power, coordination, and reflexes are all normal.

What is the gold standard brain-imaging method used in order to establish the primary diagnosis?

A. Plain MRI brain
B. Carotid artery doppler ultrasound scan
C. Plain CT scan brain
D. CT angiogram head and neck
E. Electroencephalogram (EEG)

D. CT angiogram head and neck

This gentleman has a vertebral artery dissection following neck hyperflexion during the F1 car race. It is not uncommon for young people to get these sorts of strokes, particularly young sporting people such as in the sad case of the cricketer Phil Hughes.

The vertebral artery has a tributary (the posterior inferior cerebellar artery -PICA) to the medulla and in this case, the F1 driver has therefore developed a left sided lateral medullary syndrome (aka Wallenberg syndrome). Below are the features of this syndrome:

Cerebellar features: ipsilateral limb ataxia, vertigo, nystagmus to the side of the lesion. These are due to taking out the ipsilateral spinocerebellar tracts within the medulla.

Brain stem features:

dizziness and vomiting (taken out the vestibular and vagal nuclei) dysphagia and dysarthria (again this represents the vagal nuclei being taken out) ipsilateral Horner's syndrome (the sympathetic tract has been taken out on that side) ipsilateral facial pain and temperature sensory loss (ipsilateral trigeminal tract taken out) ipsilateral pharyngeal and laryngeal paralysis from cranial glossopharyngeal and vagus palsiesIMPORTANTLY, contralateral pain and temperature sensory loss (spinothalamic tract taken out. Remember, this crossed over well before the medulla, down at the level of the cord itself).

With all brainstem strokes, the side of the lesion is the side of the cranial nerve sign. Ie...loss of sensation on the left side of the face, for example, but with a loss of sensation of the right side of the body...still tells you that the lesion is on the left because that is the side of the cranial nerve sign. In a left-sided 'ventral pontine syndrome' (Millard Gubler), for example, you get ipsilateral facial weakness (the left facial nerve has gone -ie the cranial nerve sign) with contralateral body hemiparesis (the right corticospinal tract has been taken out).

The management of vertebral artery dissection is actually anticoagulation (once bleed excluded by scans). This is intended to prevent further thromboembolic complications (here, for example, our patient has had a subsequent brainstem stroke). Note that there are actually no randomised controlled trials to support the use of anticoagulation here, but its what people do. Antiplatelet therapy is a reasonable option to consider in patients who are suspected of suffering from a vertebral artery dissection while awaiting definitive investigations. So here, if a plain CT excluded bleed, then you clearly have a stroke and aspirin would be a reasonable choice whilst you wait for you CT angiogram. Note plain CT would not establish the diagnosis. In order to visualise the dissected vessel, you need an angiogram.

Question 56 of 189

A 29-year-old man has developed a gradual onset of bilateral leg weakness over the last 24 months such that he now needs to walk with crutches. He is also intermittently incontinent of urine. He will also often fall over in the dark because he feels his balance is worse then. He has never noticed any other symptoms prior to these. He has no significant past medical conditions. He works as an accountant. He went travelling for some years in his early 20's to the Carribean, Japan and Africa. He admits occasional intravenous drug use whilst travelling and getting a tattoo. He also has casual sexual contact with sex workers occasionally whilst travelling and does not recall using barrier contraception. On examination, you find hyperreflexia bilaterally in the legs with upgoing plantar responses. He has loss of vibration and joint position sense in the legs. Legs are 3/5 power in the knee and plantar extenders and 4/5 in the flexors. He has a stomping gait. Routine blood tests plus HIV screening come back unremarkable. MRI brain and whole spine show areas of demyelination in the lumbar spine.

Which test would you do to confirm the most likely suspected cause of his symptoms?

A. Serm JC virus levels
B. Serum and CSF HTLV-1 antibody levels
C. Syphilis serology
D. Hepatitis B serology
E. Paired serum and cerebrospinal fluid (CSF) oligoclonal band levels

B. Serum and CSF HTLV-1 antibody levels

The diagnosis is tropical spastic paraparesis (TSP).

This is otherwise called HTLV-1 Associated Myelopathy (HAM), describing how this demyelinating condition is caused by infection with HTLV-1. HTLV-I is a retrovirus endemic in southern Japan, equatorial Africa and South America. Transmission occurs through sexual or other intimate contacts, intrauterine, breastfeeding, sharing of needles by drug users, or blood transfusion from infected persons. This patient has many of these risk factors from his time travelling.

The incubation period between infection and symptomatic disease may be a few months up to decades and actually, the majority of infected individuals remain lifelong asymptomatic carriers. It is not clear what determines whether or not one becomes symptomatic but the key is suspected to be bigger viral loads resulting in progression to symptoms.

The presentation is with progressive upper motor neurone symptoms and signs particularly confined to the lower limbs (see below for differentials of such a presentation.

The key to knowing which of these differentials is the likely cause here is understanding the risk factors and ordering the correct tests (e.g. not missing out an HIV test); as the signs and symptoms are fairly similar in all of these upper motor neurone conditions.

Question 57 of 189

A 35-year-old lady with no significant past medical history presents to you with lethargy and fatigue over several years, often finding she does not sleep well at night. She complains of a sensation of discomfort in her lower extremities at rest, particularly worse when she is trying to fall asleep. She also describes an abnormal crawling and itching sensation below the knees and often walking will relieve her symptoms. There is no history of pain or nigh time snoring. Clinical examination and routine blood investigations are unremarkable. She tells you that over the years her general practitioner has ordered several tests on her that have all been normal, including brain imaging, thyroid function, and monitoring of her haemoglobin levels. She is not on any medications. She is now struggling to do her job as a teacher and is now working only part time because of the symptoms.

Considering the likely underlying diagnosis, which of the following would you use to try and alleviate her symptoms?

A. Lithium
B. Quinine
C. Pramipexole
D. Amitriptyline
E. Acetazolamide

C. Pramipexole

The diagnosis is restless leg syndrome (RLS). This is a neurologic movement disorder of the limbs that is often associated with a sleep complaint. This will often end up presenting in neurology clinics and it is important to know how to help such patients. RLS can lead to significant physical and emotional disability.

Specific DSM-5 criteria for RLS are as follows:

- an urge to move the legs that is usually accompanied by or occurs in response to uncomfortable and unpleasant sensations in the legs, characterized by all of the following: (1) the urge to move the legs begins or worsens during periods of rest or inactivity; (2) the urge is partially or totally relieved by movement; and (3) the urge to move legs is worse in the evening or at night than during the day or occurs only in the evening or at night.
- Symptoms occur at least 3 times per week and have persisted for at least 3 months.
- Symptoms cause significant distress or impairment in social, occupational, educational, academic, behavioural or other areas of functioning.
- The symptoms cannot be attributed to another mental disorder or medical condition (e.g., leg oedema, arthritis, leg cramps) or behavioural condition (e.g. positional discomfort, habitual foot tapping)
- The disturbance cannot be explained by the effects of a drug of abuse or medication

85% of patients with RLS have periodic movements of sleep, usually involving the legs (periodic leg movements of sleep [PLMS]). This is characterised by involuntary, forceful dorsiflexion of the foot lasting 0.5-5 seconds and occurring every 20-40 seconds throughout sleep. It is, therefore, worth taking a collateral history from a partner if available.

Investigations should include excluding iron deficiency (which may potentiate RLS) and you should order sleep studies to characterise the extent of sleep disturbance.

First line drug treatments are dopaminergic agents (eg, pramipexole, ropinirole, bromocriptine, levodopa-carbidopa, and rotigotine) or gabapentin/pregabalin.

Nonpharmacologic approaches include exercise, avoidance of caffeine, alcohol, and nicotine. Also important to try and stop medications that exacerbate RLS if possible, eg selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), diphenhydramine, and dopamine antagonists.

Question 58 of 189

A 75-year-old woman presents with a 24-hour history of gradual onset, severe 10/10, frontal headache associated with double vision. The history is otherwise unremarkable. On examination, she has a partial ptosis of the right eye and a pupil resting outwards and downwards with a dilated sluggishly reacting pupil. There is a failure of intorsion of the right eye. Neurological and physical examination are otherwise unremarkable. She has normal routine blood tests and a normal plain CT head.

What is the most important next investigation?

A. Lumbar puncture
B. CT angiogram cerebral vessels.
C. Carotid artery biopsy
D. Indomethacin trial
E. Single fibre EMG of the ocular muscles

B. CT angiogram cerebral vessels.

Presentation with a painful third nerve palsy is a neurosurgical emergency that normally presents to the medics as it may indicate an expanding posterior communicating artery aneurysm. Urgent CT angiogram of the cerebral vessels is required for diagnosis. Management is with surgical clipping. If this does not happen quickly, there is a risk of death from rupture or there may be permanent ptosis and eye movement deficit.

It is important to be able to differentiate between surgical causes of third nerve palsy (eg the above, or a tumour), and medical causes, eg diabetes or vasculitis. The surgical causes indicate an emergency whilst the medical causes are likely chronic conditions requiring optimisation of medical management. The parasympathetic fibres of this nerve are on the periphery of the nerve and the sympathetic fibres are in its centre. Therefore, a fixed dilated or sluggish pupil indicates that the parasympathetic fibres have been wiped out (eg by external compression from an aneurysm or tumour), leaving unopposed sympathetic tract flow within this nerve (dilating the pupil). The blood supply to the nerve is within its internal portion, meaning medical causes like diabetes or vasculitis wipe out the sympathetic portion of the nerve, leaving unopposed parasympathetic flow and consequently a constricted pupil.

The trochlear nerve sits right next to the oculomotor nerve, meaning if a structural cause is big enough, it will take the trochlear nerve out too. The trochlear nerve is responsible for intorsion of the eye (ie internal rotation in the plane of the face). So when you test for a 3rd nerve palsy, youshould also test for a 4th nerve palsy by asking the patient to follow your finger as you draw a half-circle from out to in (anti-clockwise): ie your 9'oclock to 3 o'clock. If the eye fails to follow, this is a failure of intorsion.

Question 59 of 189

A 75-year-old man presents with slowly progressive dyspnoea. There is no cough or chest pain. He is a non-smoker with a background of Parkinson's disease, rheumatoid arthritis, type 2 diabetes mellitus and atrial fibrillation. Peak flow investigations demonstrate a reduced Forced Vital Capacity (FVC), a Forced Expiratory Volume (FEV1):FVC ratio of 90%, and a low transfer factor for carbon monoxide (TLCO). High-resolution CT confirms ground-glass changes.

Which of his following medications is the most likely contributor to his lung-changes?

A. Azathioprine
B. Levodopa
C. Digoxin
D. Cabergoline
E. Exantide

D. Cabergoline

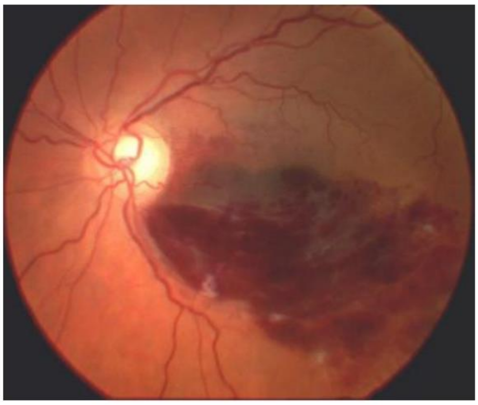
He has pulmonary fibrosis, probably related to rheumatoid arthritis and medication side-effects. Cabergoline and other ergot-derived dopamine-receptor agonists like bromocriptine and pergolide have more or less been phased out of use in Parkinson's disease now because of sideeffects including pulmonary, retroperitoneal, and pericardial fibrotic reactions. We tend to start now with the non-ergot-derived dopamine-receptor agonists including pramipexole, ropinirole, and rotigotine. Most patients eventually require levodopa. Monoamine-oxidase-B inhibitors such as rasagiline or selegiline are also used (alone or in combination with levodopa for end-of-dose fluctuations). Watch out for postural hypotension as a side effect anti-parkinsonian medication, particularly early on in the introduction of dopamine-receptor agonists. An apomorphine pump (given subcutaneously) can be very useful in the management of refractory PD, as can be deep brain stimulation (DBS).

Question 60 of 189

A 62-year-old woman presents to the emergency eye unit with a 1-day history of sudden loss of vision in her left eye. She denies pain or previous concerns with her vision. Her past medical history includes hypertension and type 2 diabetes for which she takes ramipril and metformin, respectively.

On examination, there is reduced visual acuity in her left eye and she is only able to make out hand movements. The visual acuity in her right arm is unchanged from 6/9.

Fundoscopic examination of her left eye is shown below:



What is the most likely diagnosis?

A. Diabetic retinopathy
B. Hypertensive retinopathy
C. Retinal artery occlusion
D. Retinal vein occlusion
E. Retinitis pigmentosa

D. Retinal vein occlusion

This patient has a retinal vein occlusion characterised by a sudden onset of painless loss of vision. Risk factors for retinal vein occlusion include hypertension and type 2 diabetes and are more common in the middle-aged. The fundoscopic examination shows dilated tortuous veins and intraretinal haemorrhage secondary to occlusion of the retinal vein. Other features that can be seen include cotton wool spots, dot and blot haemorrhages and macular oedema.

Hypertensive retinopathy is incorrect. Hypertensive retinopathy is typically associated with arteriolar narrowing, cotton wool spots, retinal haemorrhages and hard exudates. These are not seen in this fundoscopic examination, making the diagnosis unlikely.

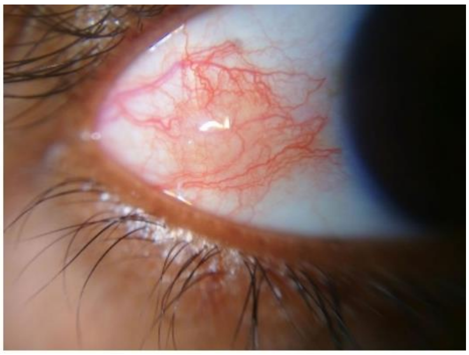
Diabetic retinopathy is incorrect. Diabetic retinopathy is a reasonable differential diagnosis given the past medical history of type 2 diabetes. However, it is unlikely to cause sudden onset visual loss. Rather, diabetic retinopathy causes gradual visual loss and can be staged from preproliferative, proliferative and maculopathy. Fundoscopic features include cotton wool spots, microaneurysms ane neovascularisation which, in turn, can lead to retinal detachment and vitreous haemorrhage.

Retinal artery occlusion is incorrect. Retinal artery occlusion is another common cause of sudden onset painless vision loss, frequently from embolic phenomenon. However, fundoscopic findings of retinal artery occlusion include a pale retina with a classic 'cherry-red spot' (the unaffected vascular choroid at the centre of the macula). Cotton wool spots may also be seen.

Retinitis pigmentosa is incorrect. Retinitis pigmentosa is an inherited disorder of the retina that is characterised by degeneration of the rod cells (responsible for night vision). In retinitis pigmentosa, there is bone-spicule deposition within the periphery of the retina. This is not seen here, nor is there a history of night blindness or reduced peripheral vision.

Question 61 of 189

A 27-year-old man presents to the general practitioner with a 1-day history of red eyes. He reports noticing them whilst brushing his teeth in the morning. He complains that his eyes are mildly sore but manageable without the need for analgesia. There is no history of itch and he otherwise feels well in himself. His past medical history includes ankylosing spondylitis.



On examination, his visual acuity is 6/6 bilaterally. His eyes are examined, as shown below:

Given the diagnosis, what is the recommended management for this patient?

A. Acetazolamide
B. Reassurance and NSAIDs
C. Topical aciclovir
D. Topical chloramphenicol
E. Topical corticosteroids

B. Reassurance and NSAIDs

This patient has a diagnosis of episcleritis. Episcleritis is the acute inflammation of the episcleral tissues and presents as an acute-onset red eye that may be mildly irritable but should not be painful or associated with vision loss. Examination reveals dilated episcleral vessels on the surface. Most cases are idiopathic, but risk factors include inflammatory bowel disease, seronegativespondyloarthropathies and vasculitides. The condition is self-limiting and no treatment is usually necessary. However, the use of NSAIDs is sometimes recommended for the active inflammation and treatment of any discomfort, and artificial tears may also be used for the relief of symptoms.

Acetazolamide is incorrect. Acetazolamide is a carbonic anhydrase inhibitor used in the treatment of acute angle closure glaucoma. Features of acute angle closure glaucoma include a unilateral painful red eye associated with photophobia, headache and vomiting. The pupil may be partially fixed and dilated with a hazy cornea. This patient's presentation is not in keeping with this diagnosis.

Topical aciclovir is incorrect. Topical aciclovir would be indicated for an acute herpetic infection of the eye. However, the mild symptoms that this patient is presenting with make an infective cause of his symptoms unlikely.

Topical chloramphenicol is incorrect. This would be the treatment of choice for a patient with bacterial conjunctivitis. Features of bacterial conjunctivitis include an itchy, watering and gritty red eye associated with blurred vision and purulent discharge with or without crusting of the eyelashes. This is not seen in this case, making conjunctivitis unlikely.

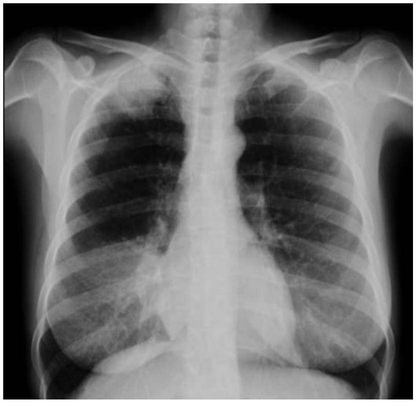
Topical corticosteroids is incorrect. This is used in the management of anterior uveitis. Patients with inflammatory bowel disease, such as this patient, are at an increased risk of anterior uveitis. However, symptoms typically include an acute red and painful eye with patients often complaining of photophobia. These symptoms are not given in this presentation. Furthermore, this patient's eye demonstrates injection of the episcleral vessels which is uncharacteristic of anterior uveitis.

Question 62 of 189

A 56-year-old woman is referred to the respiratory clinic with a 3-month history of shortness of breath and a dry cough. She was admitted to the hospital for community-acquired pneumonia 1 year ago but had recovered well with complete resolution of symptoms. Her past medical history includes hypertension and hyperlipidaemia for which she takes amlodipine, ramipril and simvastatin. She drinks 4-6 units of alcohol per week and smokes 25 cigarettes/per day.

On examination, her observations are within normal limits. There are vesicular breath sounds bilaterally.

A chest x-ray is requested, as shown below:



Given the diagnosis, what additional clinical finding is most likely to be present?

A. Erythema nodosum
B. Haematuria
C. Miosis
D. Pericardial friction rub
E. Purpura

C. Miosis

This patient has a rounded opacity in the apical region of the right lung. It appears white and has a well-circumscribed outline. This is most likely in keeping with a Pancoast tumour. The history of progressive breathlessness, cough and smoking history makes malignancy a likely diagnosis. Given the location of the tumour, it may not always be detected on auscultation. A Pancoast tumour is usually a non-small cell lung carcinoma that presents with various symptoms, including malignancy (e.g. malaise, weight loss, night sweats) and compression from the tumour (e.g. thoracic outlet syndrome, recurrent laryngeal nerve compression and Horner's syndrome). Horner's syndrome results from compression of the sympathetic ganglion and the lack of sympathetic innervation to the face giving rise to the characteristic features of ptosis, miosis and anhidrosis.

Erythema nodosum is an extra-pulmonary manifestation of sarcoidosis. Sarcoidosis presents with shortness of breath, cough and fatigue. However, chest x-ray findings differ and range from being normal to having hilar lymphadenopathy and pulmonary infiltrates which are not seen here. Erythema nodosum is also an extra-pulmonary feature of tuberculosis. The history of prolonged dyspnoea and dry cough tuberculosis. However, the patient's significant smoking history and lack of risk factors for tuberculosis make malignancy more likely.

Haematuria is a clinical feature associated with vasculitic diseases (e.g. Goodpasture's syndrome and granulomatosis with polyangiitis). Both can cause pulmonary haemorrhage that presents with dyspnoea, haemoptysis, and chest x-ray findings of pulmonary infiltrates. This is not in keeping with the current presentation.

Pericardial friction rub is occasionally heard in patients with a pericardial effusion secondary to pericarditis. Trauma, viral and bacterial infections and autoimmune diseases (e.g. rheumatoid arthritis and systemic lupus erythematosus) are all causes of pericardial effusion. However, neither of these diagnoses accounts for the apical opacity.

Similarly to haematuria, purpura is a clinical feature of vasculitic diseases or a significant infection causing septicaemia. The progressive onset of symptoms and normal observations makes septicaemia unlikely.

Question 63 of 189

A 27 year old lady with relapsing-remitting multiple sclerosis (MS) is referred to your clinic. She was diagnosed at age 18 and has been managed on interferon β 1a, with only four relapses in her total history. She has made good recovery from all four relapses and the only finding on neurological examination is of mild dysdiadochokinesis of the left arm. She scores functionally very well on an expanded disability status scale (EDSS) and has no disability as a result.

She is planning her first pregnancy and wanted ad0vice on how her MS may be affected. She has already been advised on stopping interferon β 1a in preparation for pregnancy. Aside from the impact of stopping interferon β 1a, she wants to know how pregnancy itself will affect her MS.

Which of the following is most accurate?

A. Relapse rates may decrease during pregnancy, increase at 3-6 months post-partum then return to pre-pregnancy rates.
B. There is an increased risk of developing visual disorders associated with MS.
C. There is a 30% chance that her RRMS will evolve into progressive MS.
D. There is a 15% chance that her relapse rate will decrease for the five years following pregnancy.
E. Relapse rates may increase during pregnancy, then return to pre-pregnancy rates at 9 months post-partum.

A. Relapse rates may decrease during pregnancy, increase at 3-6 months post-partum then return to pre-pregnancy rates.

A knowledge of the issues surrounding pregnancy in MS is important, since females of a childbearing age are a high risk group for developing the disease.

NICE guidance states that 'relapse rates may reduce during pregnancy and may increase 3 to 6 months after childbirth before returning to pre-pregnancy rates'. It also states that pregnancy does not increase the risk of progression of disease; the net effect of protection during pregnancy and subsequent increased relapse rate carries no increased risk of exacerbation.

With regard to Interferon β 1a in pregnancy, most neurologists would advise stopping when pregnancy is considered, due to inconsistent and conflicting data in the area. The BNF advises against use in pregnancy 'unless potential benefit outweighs risk'.

If a person with MS is thinking about pregnancy, they must have the opportunity to talk with a healthcare professional with knowledge of MS about:

- Fertility
- the risk of the child developing MS
- use of vitamin D before conception and during pregnancy medication use in pregnancy
- pain relief during delivery (including epidurals)
- care of the child
- breastfeeding.

In this scenario the use of the expanded disability status scale (EDSS) was referred to. This provides an index of clinical disability and may be used to quantify disease progression. It has widespread use in clinical trials.

Question 64 of 189

A 29-year-old man presents to the stroke ward following a right-sided middle cerebral artery territory infarct. You are reviewing him four weeks after as an outpatient. Whilst taking a history from him and his father you find out that he had a normal delivery and early development and initially performed well in school. However, from about the age of 12 he started developing focal impaired awareness seizures with secondary generalisation that were difficult to control with medications and started to struggle in school.

Since adulthood, he has suffered from frequent migraines that have again been difficult to treat with medications. He also suffers from recurrent vomiting although a thorough gastroenterological assessment including OGD with biopsies could not find any cause for the vomiting.

When aged 26 whilst out walking, he suddenly became very dizzy and unable to walk properly. These symptoms resolved in a day and he never sought medical attention. Since that incident, he has been left with a tremor that now makes his work as a painter almost impossible to do. He has also noticed that he is becoming more fatigued by walking. He goes to the gym regularly and is able to lift less and less weights as time has progressed. His mother died suddenly aged 37

Medications included: carbemazepine, clopidogrel and atorvastatin.
Examination

- Height 4ft 11inches (150 cm)
- Generalised muscle weakness with some atrophy
- Left upper limb power 3/5, right upper limb power 5/5
- Left lower limb power 5/5, right lower limb power 5/5
- Lateral nystagmus 5 beats
- Dysdiadochokinesia
- Moderate intention tremor
- MMSE 25/30

Hb	14.7 g/dl
Platelets	256
WBC	8.6
Na	140 mmol/l
K	4.5 mmol/l
Urea	4.6 mmol/l
Creatinine	54 µmol/l
Bilirubin	6 µmol/l
ALP	89 u/l
ALT	21 u/l
Total cholesterol	5.7 mmol/l
Albumin	40 g/l

CT Brain: right sided MCA territory infarct. Generalised atrophy
ABGs on air

pH	7.38
CO2	3.7 kPa
O2	15.6 kPa
Bicarb	49 mmol/l
Lactate	8.4 mmol/l

What is the most likely diagnosis?

A. Familial hypercholesterolaemia
B. MELAS syndrome
C. Carbemazepine poisoning
D. CADASIL
E. Pyruvate carboxylase deficiency

B. MELAS syndrome

The answer is B MELAS (Mitochondrial Encephalopathy with Lactic Acidosis and Stroke).

MELAS is a rare mitochondrially inherited condition characterised by short stature, recurrent migraines, vomiting, muscle weakness, seizures and then development of multiple strokes at an early age (normally before 40 for diagnosis to be considered) along with progressive dementia. There is also a raised lactic acid level in the blood and skeletal muscle biopsy will show ragged red fibres.

1% 68% 1% 28% 3%Regarding the vignette, it is possible that his mother had the same condition which is typical of mitochondrial inheritance. It also sounds like he may have had a posterior stroke that was not treated as he had sudden onset of cerebellar symptoms and is left with an intention tremor and has nystagmus. Cerebellar infarcts do not always show up on CT and MRI is the best modality for viewing the posterior fossa. Although is MMSE score is normal, for a young man a score of 25/30 is a potential worry in the clinical context.

Although CADASIL would also present with migraines and stroke at an early age, lactic acidosis is not a feature and subcortical infarct would be more typical. Although this gentleman has a high cholesterol it is not high enough for a diagnosis of familial hypercholesterolaemia and would not explain the muscle weakness, vomiting and lactic acidosis.

Carbamazepine poisoning could explain the cerebellar symptoms but not the other symptoms. Pyruvate carboxylase deficiency would cause muscle weakness, vomiting and lactic acidosis but would not explain the early onset of stroke

Question 65 of 189

A 58 year old man presents to Accident and Emergency with his wife complaining of memory loss. His first noticed a problem when he had difficulty making breakfast in the morning. When you question him, he has no memory of the events of today and patchy memory of the events of the past week although his wife informs you that he had no problem with his memory yesterday. He appears extremely anxious about his memory loss and repeatedly asks you 'Have I got dementia?'. He is able to remember his name and date of birth and recognise and name his wife. However, when using the toilet, he becomes lost and is unable to find his way back to the cubicle.

On examination his HS 1 + 2 + 0, he has corneal arcus, chest is clear. There is reduced power 4/5 to all arm movements in the right arm with normal reflexes, tone and sensation. His wife tells you that this has been present for several years following a stroke. There is no facial droop, there is no dysarthric speech or any other peripheral focal neurology and there are no cerebellar signs. Gait is normal.

He is able to count back from 20-1 and can name objects you present to him without difficulty. However he scores 0/3 on the delayed recall section of the MMSE. He is alert and fully responsive throughout the consultation. Past medical history is of previous left sided middle cerebral territory infarct and one previous TIA one year ago. Hypercholesteroalemia, hypertension. He has a 20 pack year history of smoking and used to drink 4-6 units of alcohol per day for 20 years but stopped this 25 years ago and his wife corroborates this information. His medications include Clopidogrel, Atorvastatin, Ramipril and Bendroflumethiazide.

CT Brain was performed 3 hours after waking up and is consistent with an old left sided infarct. No other abnormality detected.

What is the most appropriate treatment for this diagnosis?

A. Intravenous thiamine and Vitamin B
B. Oral thiamine and vitamin B

C. Thrombolysis
D. Donepezil
E. Supportive care only

E. Supportive care only

The answer is E. This man has a diagnosis of transient global amnesia. TGA is characterised by a sudden onset of global loss of recent memory and impaired new learning with no other cognitive defects. These patients are often very aware of their memory loss making them extremely anxious. Because of the dense anterograde amnesia, it is also characterised by repetitive questioning. This is sometimes called the broken record syndrome Loss of personal identity effectively rules out TGA Patients are alert and responsive during the episode

TGA is probably due to a transient malfunctioning of the limbo-hippocampal system which is involved in the formation of new memories and retrieval of recent memories. It normally presents in the 5th decade of life in those with pre-existing vascular risk factors, meaning there is probably a cerebro-vascular component but the cause is not known. TGA resolves spontaneously without need for treatment except for re-assurance and subsequent control of vascular risk factors.

Options A and B are inappropriate because the diagnosis is not Wernicke-Korsakoff syndrome. The presentation is too acute and too long after his heavy drinking of alcohol to be a likely diagnosis. Although there is similar defects in memory, there are normally defects in attention, concentration, frontal lobe functioning and is accompanied by symptoms such as apathy and withdrawal.

Option C is inappropriate as thrombolysis is not a treatment for TGA. In addition, thrombolysis would not usually be given to someone who has woken up with symptoms suggestive of a a stroke, even if the time window is less than 4.5 hours.

Option D is inappropriate as the diagnosis is not dementia. The onset of symptoms are too acute for this diagnosis to be considered.

Question 66 of 189

You review an 80-year old retired teacher in your clinic in your clinic. She has been complaining of numbness on her arms and difficulty walking. On examination you find she has reduced sensation lateral aspect of her arms and forearms in the anatomical position. She has no wasting on the muscles of her hands. She has reduced biceps and supinator reflexes and reduced power bilaterally.

When she gets up to go you notice she has a scissoring gait which is wide based. You ask her to close her eyes and she is unable to stand still without support.

She lives on her own and usually is independent, although recently she has been struggling to cope. She has a background of hypertension and high cholesterol.

What is the most appropriate investigation to diagnose this lady?

A. Cervical myelography
B. Cervical X-Ray
C. Nerve conduction studies
D. Nerve biopsy
E. MRI of the cervical cord

E. MRI of the cervical cord

This lady has lower motor neuron deficit and sensory loss in her upper limbs at the level of C5-C7. She has spastic paraparesis, Romberg +ve indicating loss of proprioception in her lower limbs.

This presentation is suspicious of cervical myelopathy. The main segments which are affected of the cervical cord in this condition are C5-C7, as is the case in this lady. The dermatomal distribution of her sensory loss is confined to C5-C7 therefore supporting this hypothesis.

Cervical myelopathy is caused by narrowing of the cervical spinal canal, most commonly caused by stenosis.

The aetiology includes:

- Cervical cord tumours
- ossification of the posterior longitudinal ligament
- Trauma
- Cervical degenerative changes (spondylosis)
- Cervical degenerative disc disease

The investigation of choice and one which would enable you to asses spinal and foraminal stenosis would be cervical myelography or MRI of the cervical cord. Cervical myelography entails the use of contrast and can be nephrotoxic alas MRI is the preferred modality to image and diagnose cervical spondylosis.

Question 67 of 189

A 57 year-old smoker presents to you with difficulty walking. He used to be able to mobilise unaided but recently he has required the assistance of his wife. He reports being more clumsy than usual. He drinks 3 cans of lager every month. He takes simvastatin for high cholesterol and has been taking aspirin for 10 years since his GP started it. He has lost a lot of weight in recent months, which he can't quantify.

On examination, you find that he is cachectic. He has an intention tremor and exhibits dysdiadochokinesia. His gait is broad-based. He has bilateral nystagmus on horizontal gaze. On auscultating his chest you find he has a degree of bronchial breathing on the right middle lobe. His observations are unremarkable.

His blood tests are as follows:

Hb	100 g/l
MCV	79.9 fL
Platelets	239 * 10 /l
WBC	6.6 * 10 /l
Na	134 mmol/l
K	4.3 mmol/l
Urea	6 mmol/l
Creatinine	88 µmol/l
Anti-Hu antibody	POSITIVE
Bilirubin	6 µmol/l
ALP	62 u/l
Albumin	29 g/l

CT head: No acute intracranial pathology.

What is the most appropriate investigation?

A. Chest X-ray
B. Vitamin B12 levels
C. ECG
D. Visual evoked potentials
E. Muscle biopsy

E. Muscle biopsy

This gentleman presents with signs and symptoms of the cerebellar syndrome.

He is cachectic, has a history of smoking and some signs of his chest which would raise concern given his history. Another vital clue in the question is the presence of anti-hu antibodies, which are associated with paraneoplastic cerebellar syndrome secondary to small cell lung cancer. Given the history and examination findings it is paramount to perform an X-Ray of his chest, and should that be inconclusive he will require a high-resolution CT scan.

An intracranial lesion, such as a tumour or a vascular event is also unlikely, given the normal CT head result and bilateral presentation.

Vitamin B12 deficiency is associated with subacute combined degeneration of the cord. This would present with upper and motor neuron deficits and a sensory neuropathy. It would not present with isolated cerebellar signs.

Question 68 of 189

A 40 year-old man presents to the general medical clinic with a one year history of generalised weakness. He mentions his father suffered from the same symptoms, although from a later age.

His past medical history includes type two diabetes mellitus (diet controlled) and eczema.

On examination he has male pattern balding and an expressionless face. You note a diminished left red reflex, with a normal cranial nerve examination. He has symmetrically reduced reflexes throughout, with mild reduced power distally in both upper and lower limbs.

Hb	140 g/l
Platelets	200 * 10 /l
WBC	8 * 10 /l
CK	70IU/L (reference range 60- 174 IU/L)

What is the most likely diagnosis?

A. Hyperthyroidism
B. Inclusion body myositis
C. Cushing's disease
D. Becker's muscular dystrophy
E. Myotonic dystrophy

E. Myotonic dystrophy

Myotonic dystrophy

Myotonic dystrophy is a genetic condition causing by a trinucleotide repeat expansion on chromosome 19. It demonstrates anticipation (earlier onset with successive generations).

Clinical features of the condition include:

- Frontotemporal balding Ptosis
- Distal weakness
- Depressed tendon reflexes
- Myotonic (slow relaxation of muscles)

Complications include arrhythmias, cataracts, testicular atrophy and diabetes mellitus.

Cushing's disease and hyperthyroidism cause a proximal myopathy, and the patient has no symptoms of either.

Becker's muscular dystrophy causes a proximal myopathy, but the average age of presentation and diagnosis is much younger (average is 11 years old), with several disability at 40.

Inclusion body myositis can cause both a proximal and distal myopathy. This patient's creatinine kinase is normal, which makes the diagnosis less likely and would not explain the genetic component and facial features.

Question 69 of 189

A 73 year old gentleman is admitted to the medical assessment unit with a fall. A collateral history from his wife reveals that he has been having frequent falls (nearly 2-3 times a week) for the last 4 months. This has resulted in multiple admissions where a chest infection is thought to be the main cause for his deterioration. His wife also states he is having problems swallowing, chokes on his food frequently and has not been himself recently with frequent bouts of aggression. On examination you note the patient has an expressionless face, and kyphosed posture and mild tremor bilaterally. He has cogwheeling of both upper limbs. Examination of his legs is unremarkable. On inspection of his gait, it appears parkinsonian in character, but you stop him only after a few steps as he seems unsteady. On cranial nerve examination you note he has difficulty following your finger downwards but the remainder of the cranial nerve examination is normal.

Given these features, what is the most likely underlying diagnosis?

A. Multiple system atrophy
B. Idiopathic Parkinsons disease
C. Progressive supranuclear palsy
D. Vascular Parkinsonism
E. Lewy body dementia

B. Idiopathic Parkinsons disease

There is no doubt that this patient has an element of Parkinsons disease, the clues to the underlying condition include:

- The SYMMETRICAL tremor compared with the ASYMMETRICAL tremor of idiopathic Parkinsons.
- Swallowing difficulties suggesting repeated admissions for aspiration pneumonia.
- Changes in personality.
- Truncal instability and rigidity > limbs.

- Inability of look downwards (Vertical gaze palsy).

Parkinsons Plus syndromes:

- Progressive supranuclear palsy (PSP, also known as Steele-Richardson-Olszewski syndrome) Characterised by early postural instability, frequent falls, truncal rigidity, asymmetrical onset, speech and swallowing problems, vertical gaze palsy.
- Multiple system atrophy - (MSA, also known as Shy-Drager syndrome). Autonomic features specifically postural blood pressure drop, bladder/bowel dysfunction, cerebellar and/or pyramidal signs.
- Lewy body dementia - Visual hallucinations accompanying dementia.
- Vascular parkinsons - Parkinsonism worse in the legs than the arms.
- Cortico-basal degeneration (CBD) - Asterognosis (inability to recognise objects by touch), akinetic rigidity involving one limb. Some patients may experience the 'alien limb phenomenon'.

NB: Knowledge of this differential is also vital for PACES examinations.

Question 70 of 189

A 32 year old man presented to the Emergency Department with a severe headache. The headache had started suddenly that evening while the patient was at home with his girlfriend watching television. The patient described his headache as an intense throbbing pain felt all across his head. The pain had started very quickly with the patient reporting a severity of 10 / 10 within 30 seconds. The pain had eased slightly following some morphine given by the ambulance crew. The patient denied any symptoms of neck stiffness or photophobia. There were no visual symptoms and no weakness in the patient's limbs or abnormal sensation.

The patient had no previous past medical history and did not normally suffer from headaches. He took no regular medications. The patient worked as a retail assistant and lived with his girlfriend. He rarely drank alcohol but did smoke cannabis on several occasions each month. The patient's girlfriend reported that the patient had smoked cannabis that evening prior to suffering his headache.

On examination, the patient was in visible discomfort due to his headache although had no meningitic signs. Glasgow Coma Score was 15/15 and the patient was afebrile. Cranial and peripheral nerve examination was unremarkable.

Further analgesia was given to the patient and investigations requested as detailed below.

CT brain: no evidence extra-dural or sub-dural bleeding; no intracerebral haemorrhage or subarachnoid blood; no evidence of cerebral infarction; normal ventricular system; no radiological contra-indication to lumbar puncture

Cerebrospinal fluid results:

Red cell count	1 / mm^3
White cell count	2 / mm^3
Pprotein	0.75 g / L
Glucose	60 % of serum value
Microscopy	No organisms seen
Red cell breakdown products	Negative
Opening pressure	19 cmCSF

Following initial investigation as above, the patient continued to experience severe recurrent headaches similar to that experienced at presentation and was observed to have a short,generalised seizure on the admission ward prompting further investigation. CT angiography: diffuse arterial beading identified; results otherwise as for previous CT head

What is the cause for the patient's headache?

A. Atypical migraine
B. Cervical artery dissection
C. Reversible cerebrovascular vascoconstriction syndrome
D. Posterior reversible leucoencephalopathy syndrome
E. Pituitary apoplexy

C. Reversible cerebrovascular vascoconstriction syndrome

The patient presents with a typical 'thunderclap' headache, with pain reaching a severe intensity within one minute of onset. Reversible cerebrovascular vasoconstriction syndrome (RCVS) is a cause of thunderclap headache with normal CT brain and normal or near-normal lumbar puncture results. RCVS may also be associated with focal neurological signs and seizures. Diagnosis is made by the finding of diffuse arterial beading on angiography (CT, MRI or catheter). One-half of cases occur during the postpartum period or after exposure to serotoninergic agents, adrenergic substances or cannabis. There are no evidence-based treatments for RCVS although bed-rest and nimodipine are usually prescribed. RCVS is not always benign, with one-in-four patients suffering sub-arachnoid haemorrhage or ischaemic / haemorrhagic stroke

The other answers listed in the stem are all causes of thunderclap headache with normal CT brain and lumbar puncture (i.e. sub-arachnoid haemorrhage excluded). None of these conditions area associated with diffuse arterial beading and so are less likely differential than RCVS.

Question 71 of 189

A 68-year-old man is admitted with weakness. He states that it came on at 09:45 (2 hours and 15 minutes ago). He states that his right arm and leg are weak. He also complains of word finding difficulties. He has a past medical history of hypertension and hypercholesterolaemia. On examination he has grade 4 weakness of his right arm and leg, and there is an obvious right sided facial droop. He has a right homonymous hemianopia. He can follow complex 3 stage commands, however he struggles to name simple objects.

You suspect an acute stroke and are considering suitability for thrombolysis. You perform blood tests and arrange an urgent CT scan.

What scoring system will you utilise to further assess this patient?

A. CHA,,DS,,-VASc
B. ABCD2
C. HAS-BLED

D. Total Health Risk In Vascular Events (THRIVE)
E. National Institutes of Health Stroke Scale (NIHSS)

E. National Institutes of Health Stroke Scale (NIHSS)

The NIHSS score is useful in stroke for assessing patients suitability for thrombolysis Important for me Less important

The most immediate concern is to assess the suitability for thrombolysis. Thrombolysis can result in extremely good outcomes for patients, however it is also has significant risks and it is therefore essential to balance benefits versus potential risks. The National Institutes of Health Stroke Scale (NIHSS) is an extremely useful tool for assessing the severity of the stroke. Some hospitals use an NIHSS of less than 5 (mild stroke) to exclude patients from thrombolysis. The patient in this case is likely suffering from a total anterior circulation stroke due to the presence of hemiparesis, homonymous hemianopia and higher function involvement (e.g. expressive dysphasia). He will therefore likely have a high NIHSS score.

The CHA,,DS,,-VASc score is used to predict the risk of stroke in patients with atrial fibrillation. The ABCD2 score is used in transient ischaemic attacks to predict the likelihood of a stroke in theshort term period following the TIA. The ABCD2 score ranges from 0 to 7. Recent studies have shown that the ABCD3-I scoring system is superior in the assessment of TIAs. The ABCD3-I incorporates recurrent TIA events and imaging. The minimum score is 0 and the maximum is 13. The broader range of scores allows for potentially greater refinement of risk prediction.

The HAS-BLED score is used to predict the risk of bleeding from anticoagulation in atrial fibrillation.

The Total Health Risk In Vascular Events (THRIVE) score uses NIHSS score, age, and chronic disease to predict long-term neurologic outcomes in stroke patients.

Question 72 of 189

A 54-year-old woman is seen in the neurology clinic. She initially presented to her general practitioner with paraesthesia and a burning sensation down her right side. She reports a similar episode two years ago, during which she had a four-week period of paraesthesia in the left lower limb which self resolved. In between these episodes, she experienced total resolution of her symptoms.

An MRI of the brain and spinal cord was performed and concluded as below:

MRI brain and spinal cord shows Several areas of T1 weighted hypointensities and T2 weighted hyperintensities consistent with multiple sclerosis

Which of the features in this woman represents a poor prognostic factor?

A. Female sex
B. Long interval between relapses
C. Older age of onset
D. Relapsing-remitting disease
E. Sensory symptoms only

C. Older age of onset

Older age of onset is associated with a poor prognosis in multiple sclerosis

As stated in the question, this woman has been diagnosed with multiple sclerosis (MS). Of the features listed, only older age is associated with a poor prognosis. The onset of symptoms in patients, who are in their 20s or 30s, is associated with a good prognosis.

MS is less common in males; however, when diagnosed, the prognosis is worse. Female sex is therefore associated with a better prognosis and is, therefore, an incorrect answer here.

This woman has had two years separating her two attacks which is a good prognostic indicator rather than a poor one. A long interval between relapses is, therefore, an incorrect answer.This woman exhibits a relapsing-remitting pattern of disease with distinct episodes of symptoms with improvement in between. A relapsing-remitting disease has a significantly better prognosis than a progressive disease course (continuous symptoms with gradual worsening), and therefore this is not the correct answer.

Motor symptoms are associated with a poorer prognosis. This woman has only experienced sensory symptoms, which is a good prognostic factor in this case.

Question 73 of 189

A 72-year-old male diagnosed with dementia after a one-year history of progressive cognitive decline, particularly in planning, cognitive flexibility, attention, visual memory and visuospatial manipulation on detailed neuropsychological assessments. His mini-mental state examination scores 15/30. His past medical history includes Parkinson's disease, for which he was started on Madopar 6 years ago. His son attends clinic with his father and both are very keen to start some treatment.

What is the most available treatment?

A. No treatment
B. Rivastigmine
C. Donepezil
D. Increase Madopar dose
E. Deep brain stimulation

B. Rivastigmine

The patient describes a syndrome of executive and visuospatial dysfunction on a background of PD diagnosis more than 12 months before diagnosis of cognitive impairment. This represents PD dementia (instead of Lewy Body dementia). The only licensed proven treatment for PD dementia demonstrated in a randomised clinical trial is rivastigmine. Donepezil is also useful for PD dementia but is not currently licensed in the UK. Neither DBS nor increasing PD medications improve cognitive impairment.

Question 74 of 189

A 54-year-old man presents to the emergency department with an intractable headache, worse on bending down and in the morning. It has been present for one month. He has no past medical history and does not take any regular medications.

A CT head is organised, which demonstrated a large right-sided mass lesion that appears to be causing displacement of the uncus of the temporal lobe under the tentorium cerebelli.

What is the earliest expected abnormal clinical sign to be detected given the clinical presentation?

A. Cheyne-Stokes breathing
B. Contralateral hemiparesis
C. Contralateral mydriasis
D. Ipsilateral hemiparesis
E. Ipsilateral mydriasis

E. Ipsilateral mydriasis

Uncal herniation results in pressure on the midbrain resulting in ipsilateral CN III palsy (mydriasis is the earliest sign) and contralateral hemiparesis

Ipsilateral mydriasis is correct. The CT demonstrates uncal herniation as a consequence of an intracranial mass lesion. The ipsilateral dilated pupil is caused by compression of the ipsilateral oculomotor nerve.

Contralateral mydriasis is incorrect. This is a rarer clinical sign. It may develop from contralateral oculomotor nerve compression from midline shift.

Contralateral hemiparesis is incorrect. This is an expected consequence of progressive uncal herniation but typically occurs subsequent to ipsilateral mydriasis.

Ipsilateral hemiparesis is incorrect. This is rarer than contralateral hemiparesis. However, it can occur as a consequence of the 'Kernohan phenomenon'. This is a radiological description of extensive midline shift causing mass effect. The result is denting of the contralateral cerebral crus by the tentorium cerebelli. . The corticospinal tracts are damaged and a hemiparesis contralateral to the crus cerebri results. This is ipsilateral to the mass lesion and is a false localizing sign. It is a rarer occurrence and would occur subsequent to mydriasis.

Cheyne-Stokes breathing is incorrect. This signifies impending death and is a terminal sign of progressive cerebral herniation.

Question 75 of 189

A 65-year-old female is referred to the neurology clinic with complaints of tingling and loss of sensation. Five years previously she experienced an episode of numbness and tingling affecting her right upper limb. Most recently, there has been a loss of sensation affecting her left lower limb. There has been a full recovery between episodes. She has no past medical history and does not take any regular medications.

The examination at the time of review is unremarkable. An MRI of her brain demonstrates lesions in the periventricular white matter.

Given the likely diagnosis, what clinical feature of her presentation portends the worst prognosis?

A. Age of onset
B. Complete recovery between relapses
C. Relapsing-remitting disease
D. Sensory symptoms only
E. 5 year interval between first two relapses

A. Age of onset

Older age of onset is associated with a poor prognosis in multiple sclerosis

Age of onset is correct. This patient has a diagnosis of multiple sclerosis on the basis of sensory neurological symptoms separated in time and space along with classic imaging findings of periventricular white matter lesions. Older age of onset is associated with a worse prognosis in multiple sclerosis.

Relapsing-remitting disease is incorrect. This is associated with a better prognosis than other forms of the disease e.g. primary progressive MS.

Sensory symptoms only are incorrect. This is typically associated with a good prognosis.

5-year interval between the first two relapses is incorrect. A short interval between the first relapses is associated with a worse prognosis. A 5-year interval would be associated with a betterprognosis.

Complete recovery between relapse is incorrect. If the patient did not recover fully between relapses then this would be associated with a worse prognosis.

Question 76 of 189

A 56-year-old gentleman is brought by his wife with unusual behaviour. This afternoon, she found him doing gardening in the back garden and he was repeatedly cutting at the same shrubs. He was conscious but asked her repeatedly when dinner was ready. He returned to the house where he had no recall of gardening and continued to ask the same questions repeatedly.

In the department, he seems well. He is a little confused over what has happened but is orientated in time and place. On examination, there is no ophthalmoplegia but there were two beats of nystagmus seen. He has 5/5 power in all limbs with normal tone and no myoclonus or fasciculations. His gait is normal.

His wife reports that there have been no memory problems or change in personality prior to today. He seems to be back to normal at present. He denies any excessive alcohol use and his father did have Alzheimer's disease which was diagnosed at 60 years of age.

Na	138 mmol/l
K	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	78 µmol/l
Bilirubin	27 µmol/l
ALP	105 u/l
ALT	30 u/l
Albumin	34 g/l
Hb	110 g/l
Platelets	394 * 10 /l

WBC	5.2 * 10 /l
MCV	96 fL (normal 80-100)
B12	250 pg/ml (normal 180-1000)
Folate	5 ng/ml (normal >4)
CT head	age related involutional changes, old lacunar infarcts seen on left side, no intracranial haemorrhage

What is the likely diagnosis?

A. Transient ischaemic attack
B. Creutzfeldt-Jacob Disease
C. Alzheimer's Disease
D. Wernicke's encephalopathy
E. Transient global amnesia

E. Transient global amnesia

Transient global amnesia - acute onset of anterograde amnesia, patent may keep asking the same questions, resolves within 24 hours

This gentleman presents with an acute episode of amnesia that has resolved in a number of hours. He has no neurological abnormality on examination and has returned to normal. Alzheimer's disease and Wernicke's encephalopathy would not present this acutely. Creutzfeldt-Jacob Disease has a rapidly progressive dementia and would not resolve after some hours. A TIA is possible but usually presents with stroke-like symptoms and isolated amnesia would be hard to reconcile neurologically. Transient global amnesia is a poorly understood phenomenon that may be related to migraines in pathophysiology where the individual has a profound amnesia for hours to days and is not able to form new memories. They resolve and are well following this but it can occur again.

Question 77 of 189

A 32 year old man presents to your haematology clinic with a 4 year history of fatigue, weight loss and a feeling of fullness in the stomach. He has been off sick from work for the past 3 months and has recently been divorced. He also complains of low mood and has attempted suicide in the past. He has a family history of NHL. He has been investigated in the past with CT scans, blood films and lymph node biopsies on several occasions with the most recent set of investigations occurring 6 months ago.

Despite your reassurances that he does not have a lymphoma, he is still convinced that he does and that he is dying. You suggest a referral to a psychiatrist and he becomes very angry.

What is the most likely underlying diagnosis?

A. Atypical depression
B. Specific phobia
C. Hypochondriasis
D. Conversion disorder
E. Somatoform disorder

C. Hypochondriasis

Unexplained symptoms

Somatisation = Symptoms

hypoChondria = Cancer

The answer is hypochondriasis. For a diagnosis is hypochondriasis to be made the patient needs to have a persistent belief that he or she has a serious illness which may be related to misperception of bodily symptoms. Physical causes need to have been ruled out and the patient is not reassured despite overwhelming evidence to the contrary. In addition there needs to be an impact on psychosocial functioning. In this case the patient fits all of these criteria.

Patients with hypochondriasis are likely to have concurrent depression, although depression is not the primary diagnosis here. Hypochondriasis is more common in those who have lost a close family member to a serious illness.In conversion disorder and somatoform psychological trauma is manifested as physical symptoms. In these disorders, it is a preoccupation with the symptoms which is the problem, rather than fear of a diagnosis. Whilst this patient has a fear of having lymphoma, hypochondriasis is a more appropriate diagnosis.

Question 78 of 189

A 63-year-old man presented with a three-week history of double vision and fatigue. Over this period he had noticed that when he swallowed liquids these often came back out of his nose. He reported a decreased exercise tolerance over the past six months due to fatigue and shortness of breath.

On examination he was thin. He had bilateral ptosis and diplopia on looking in multiple directions. His voice was soft and he appeared peripherally cyanosed. On auscultation his chest was clear and heart sounds were normal.

Observations:

- Heart rate: 90 beats per minute
- SaO2: 92% on room air
- Respiratory rate: 22 breaths per minute
- Temperature: 37.1 degrees Celsius
- Blood pressure: 110/68 mmHg

Arterial blood gases breathing air:

PO2	7.80 kPa (11.3 12.6)
PCO2	9.52 kPa (4.7 6.0)
pH	7.31 (7.35 7.45)
bicarbonate	32.4 mmol/L (21 29)
base excess	10 mmol/L (+/- 2)

Which urgent investigation should be performed next?

A. Chest X-ray
B. Forced vital capacity
C. Computed Tomography Pulmonary Angiogram
D. Electrocardiogram
E. Bedside echocardiogram

B. Forced vital capacity

This patient has myasthenia gravis as suggested by his fatigue, ptosis, complex ophthalmoplegia and bulbar weakness. He has an element of neuromuscular weakness which is resulting in type 2 respiratory failure. The most important step after adequately resuscitating this patient is to perform a bedside Forced Vital Capacity measurement. If this is < 1.5 then it may be necessary to involve the Intensive Treatment Unit team and consider ventilatory support.

Question 79 of 189

A 59-year-old woman is referred by her GP to neurology clinic for assessment. The patient describes intermittent episodes of pain affecting the left side of her face. She recalls the first attack vividly as a sudden onset of severe 'electric-shock' pain coming on suddenly around one year previously as she had cleaned her teeth with her electric toothbrush. The pain was felt around the cheek extending down to the jaw-line. The first attack had lasted several hours and she had ultimately attended her dentist and received a filling to a left molar tooth. While symptoms from that episode had resolved, she had then suffered from similar episodes at increasing frequency, approximately every fortnight over the last couple of months. These attacks had on occasion been unprovoked but were sometimes induced by stimulation of the affected area or cold winds. The patient was tearful as she recounted the negative impact her symptoms had had one her lifestyle. There was no history of headaches, sinus symptoms or seizures.

The patient had a fairly unremarkable past-medical history, notable only for hypothyroidism and long-standing struggles to avoid overweight. Her only regular medication was thyroxine 125 micrograms daily and the patient reported no allergies. There was no family history of neurological disease. The patient worked as a law clerk and did not smoke or drink significant alcohol.

Examination demonstrated an unremarkable cranial nerve and peripheral nerve examinations. In particular, colour vision, visual acuity and hearing where normal.

What is the correct first line management of the patients symptoms?

A. Gabapentin
B. Carbamazepine
C. Pregabalin
D. Baclofen
E. Lamotrigine

B. Carbamazepine

The patient reports a classical history of trigeminal neuralgia. Notable features are the memorable first occurrence, attacks precipitated by touch or vibration and the history of inappropriate dental treatment. Time between attacks often gradually reduces leaving patients quality of life significantly impaired.The patient has no other symptoms or neurological signs that might suggest an alternative diagnosis such as multiple sclerosis, sinusitis or a space-occupying lesion. In the presence of such features, an MRI brain is the most appropriate investigation.

Carbamazepine is the only drug licensed specifically for trigeminal neuralgia in the UK. In 70 % of patients it provides initial 100 % pain relief. However, caution must be used due to side-effects and drug interactions. Oxcarbazepine is a derivative of carbamazepine with similar efficacy but improved tolerability and side-effect profile.

In the evidence of allergy or intolerance to the above drugs then use of baclofen or lamotrigine should be considered, however the evidence base for both is thin. Gabapentin in combination with ropivacaine injections did show benefit in one randomised controlled trial but this result has not been replicated in subsequent investigations. Pregabalin had reported effectiveness in one prospective study of 53 patients.

Question 80 of 189

A 78-year-old man is admitted following being found on the floor at home. He has no recollection of how he got to floor or how long he had been there. He reports feeling generally unwell and having a cough for a number of days. There is no medical history of note and he takes no regular medications. He lives alone and appears unkempt. Examination reveals bronchial breathing throughout his left mid zone. Neurologically, he has new onset weakness of left sided shoulder abduction and adduction, alongside mild weakness in left elbow flexion. Additionally, reduced sensation in the lateral aspect of his upper arm is noted. A CT head is undertaken.

CT head report

Age related involutional change. No evidence of intracranial haemorrhage or recent ischaemic event.

What is the most likely diagnosis?

A. Stroke
B. Rotator cuff tear
C. Brachial plexus injury
D. Brown-Sequard syndrome
E. Botulism

C. Brachial plexus injury

Given the pattern of neurological signs in his left limb, this would not fit with a stroke. Global weakness and sensory loss would be expected in the affected limb.

A rotator cuff tear is possible given the likely trauma. However, sensory loss would not be expected.

Brown-Sequard syndrome is caused by damage to half of the spinal cord. It produces ipsilateral paralysis and proprioception loss, and contralateral temperature and pain loss.

Botulism classically presents with cranial nerve deficits, followed by a descending weakness and autonomic dysfunction.

A brachial plexus injury may be sustained following trauma, as in this case. The level of injury will 5% 7% 79% 5% 4%correlate with the signs. In this patient, it is at C5, causing the specific distribution of weakness and sensory loss.

Question 81 of 189

A 23 year-old student with epilepsy presents with generalised tonic-clonic status epilepticus. He is already taking phenytoin. Despite intravenous administration of diazepam and then phenobarbital, he is still fitting after 30 minutes.

What is the best course of action?

A. Check phenytoin levels and reload if necessary
B. Send urine for toxicology
C. Organise brain imaging
D. Obtain an electroencephalogram (EEG)
E. Induction of general anaesthesia with thiopentone

E. Induction of general anaesthesia with thiopentone

The correct answer in this scenario is the induction of general anaesthesia with thiopentone. In a case of refractory status epilepticus, where seizures have not responded to first and second-line treatments such as benzodiazepines (e.g., diazepam) and anti-epileptic drugs (e.g., phenobarbital), it is important to escalate treatment rapidly. Induction of general anaesthesia with thiopentone can help achieve rapid control of seizures, prevent further neuronal injury, and reduce the risk of long-term complications.

Regarding the other options:

Check phenytoin levels and reload if necessary: While checking phenytoin levels may be useful in determining whether the patient's ongoing seizures are due to subtherapeutic drug levels, it would not be appropriate to delay more definitive treatment in this case. The urgency of treating status epilepticus outweighs waiting for lab results, which could take hours.

Send urine for toxicology: Although identifying an underlying cause for the seizure is important, sending urine for toxicology would not provide immediate information needed to manage this acute situation. Management should prioritize stopping the seizure activity first before investigating potential causes.

Organise brain imaging: Brain imaging can provide valuable information about structural abnormalities that may be contributing to the patient's seizures; however, it is not an immediatepriority during an ongoing status epilepticus episode. Once seizure activity has been controlled and stabilised, brain imaging may be considered as part of a comprehensive evaluation.

Obtain an electroencephalogram (EEG): An EEG can help confirm the diagnosis of status epilepticus and monitor response to treatment. However, obtaining an EEG should not delay urgent interventions like induction of general anaesthesia with thiopentone. Ideally, continuous EEG monitoring should be initiated after initiating anaesthesia to assess seizure control and guide further management.

Question 82 of 189

A 28 year-old woman presents with a two month history of double vision, which is worse at the end of each day. On examination, there is bilateral ptosis which is fatiguable. There is a complex ophthalmoplegia which does not conform to the pattern of one or more cranial nerves. Examination of the limbs is unremarkable.

Which of the following would be most suggestive of a diagnosis of myasthenia gravis?

A. Weakness confined to extraocular muscles
B. A decremental response to repetitive nerve stimulation
C. An incremental response to repetitive nerve stimulation
D. Thymic enlargement seen on chest imaging
E. Internuclear ophthalmoplegia

B. A decremental response to repetitive nerve stimulation

In myasthenia gravis affected muscles show a decremental response to repetitive nerve stimulation (there is a progressive decline in the amplitude of the compound muscle action potential with repeated stimulation).

An incremental response to repetitive nerve stimulation is seen in the Lambert-Eaton myasthenic syndrome.

Weakness confined to extraocular muscles is certainly compatible with myasthenia gravis but is not diagnostic, and may be seen in thyroid eye disease, brainstem syndromes, and mitochondrial diseases. Ocular myasthenia is the mode of presentation of around half of patients with myasthenia gravis. A proportion may go on to develop generalised disease.

Thymic hyperplasia and thymoma are commonly seen in association with myasthenia gravis, as well as other autoimmune disease. Thymectomy is indicated in all patients with thymoma, due to the risk of malignant transformation. Thymectomy in the case of thymic hyperplasia is more controversial, and is generally reserved for younger patients with generalised disease and antiAChR antibodies.

True internuclear ophthalmoplegia occurs in lesions of the medial longitudinal fasciculus in the brainstem, and as such is not a feature of neuromuscular junction disorders such as myasthenia gravis. However, the involvement of extraocular muscles (one or both medial recti) may on occasion mimic internuclear ophthalmoplegia.

Question 83 of 189

As the medical registrar on-call you are fast-bleeped to see a patient in the resuscitation room of the Emergency Department.

A 27 year-old lady presented with severe breathing difficulties and hypoxia, and had become increasingly drowsy whilst in the department. Arterial blood gases performed by the emergency physicians showed:

- pH 7.142
- pCO_2 12.5 kPa
- pO_2 9.19 kPa
- HCO_3 25.3 mmol/l

Due to the rapidity of her decline, the emergency physicians tell you that only a very brief history was possible before she required intubation. She described a productive cough over the last few days, and mentioned that she was taking tablets for a neurological condition.

On examination, she is intubated and maintained on sedation with propofol. You notice a wellhealed midline sternotomy scar. On auscultation of the chest there are coarse crackles audible in the left mid and lower zones.

She is transferred to the Intensive Care Unit for continued mechanical ventilation and is commenced on empirical broad-spectrum antibiotics.

Which one of the following additional interventions will most hasten her recovery?

A. Botulinum anti-toxin
B. Edrophonium
C. Plasma exchange
D. 3,4-diaminopyridine
E. Steroids

C. Plasma exchange

This lady has myasthenia gravis and is taking pyridostigmine tablets for symptomatic relief. Shehas had a thymectomy in the past.

The acute presentation is of myasthenic crisis, with dramatically deteriorating weakness progressing to respiratory failure. Crisis is typically precipitated by infection (in this case pneumonia), or non-compliance with medication.

The initial priority is ventilatory support. Falling oxygen saturations and PaO2 are late indicators of ventilatory compromise. A rising PaCO2 is a more sensitive marker. Although inappropriate in this case, forced vital capacity should be measured and generally if below 1.5L ventilatory support should be considered.

In considering antibiotic cover, gentamicin should be avoided as it may interfere with neuromuscular transmission. Similarly, the anaesthetists should be warned that the patient will be extremely sensitive to small doses of non-depolarising muscle relaxants such as atracurium and vecuronium, which are commonly used for rapid sequence induction in the emergency setting.

Plasmapheresis and intravenous immunoglobulin are used to provide a rapid disease-modifying effect in myasthenic crisis. In plasma exchange, circulating anti-acetylcholine receptor antibodies are removed, relieving neuromuscular blockade and improving weakness. The major side effects are worsening of sepsis, due to removal of protective antibodies, and coagulopathy due to removal of clotting factors and destruction of platelets.

Botulinum anti-toxin is a specific treatment for botulism.

Edrophonium (Tensilon) is a short-acting acetylcholinesterase inhibitor which is used in the diagnosis of myasthenia gravis.

3,4-diaminopyridine is a specific treatment for the Lambert-Eaton myasthenic syndrome.

Steroids and other immunopressive agents may be used for the treatment of myasthenia gravis but in this case plasma exchange is preferred as a rapid response is required.

Question 84 of 189

A 46 year-old man is admitted to hospital after he is found wandering the streets, unable to remember who he his or how he got there. After a collateral history is obtained, he is referred to the neurologists for further investigation.

Over the last two months he has become increasingly forgetful and clumsy, and his behaviour has become progressively more bizarre. His speech has become confused, and he struggles with daily tasks. Others have commented that he has become very 'twitchy', and he sometimes drops things out of his hands without meaning to.

He was previously fit and well and the main carer for his father who suffers from motor neuron disease. His sister who previously helped him care for their father was recently killed in a car accident.

His only past medical history is that at age 22 he underwent extensive surgical resection of a large parafalcine meningioma which was discovered after investigation of chronic headache. Since the operation he has been free of headache.

On examination he is completely disoriented in time, place, and person. His gait is broad-based and uncoordinated, and during the examination you notice several shock-like jerks of his arms. Tone, power, reflexes, and sensation are otherwise normal, and cranial nerve examination is unremarkable.

What is the most likely diagnosis?

A. Viral encephalitis
B. Creutzfeld-Jakob disease
C. Frontotemporal dementia
D. Alzheimer's disease
E. Dissociative fugue

B. Creutzfeld-Jakob disease

The history of rapidly progressive dementia, ataxia, and myoclonus is highly suggestive of Creutzfeld-Jakob disease (CJD). The previous neurosurgery may have required the use of a dural graft and if so this is the likely method of transmission of the prion protein (iatrogenic CJD).Viral encephalitis is unlikely over a two month period.

Frontotemporal dementia causes a dementia with prominent personality change and behavioural disturbance, which may progress rapidly over months to years. There is an association with motor neuron disease.

Alzheimers disease would not typically occur at such an early age, or cause such a rapid deterioration. Ataxia would be unusual, and although myoclonus can occur in advanced dementia, this would not be typical early in the disease.

Dissociative fugue is a psychiatric condition characterised by disintegration of personality and memory, typically precipitated by a stressful event, and accompanied by wandering.

Question 85 of 189

A 35-year-old female presents to the Emergency Department with three days of increasing weakness in the left arm and reduced visual acuity in the left eye. She was diagnosed with relapsing-remitting multiple sclerosis two years earlier. She takes fingolimod as maintenance therapy and denies any compliance issues.

On examination, she has weakness in wrist extension and finger abduction in the left hand and visual acuity in the left eye was measured at 6/24 with an associated reduction in colour saturation.

Her blood tests were unremarkable and in particular, her white cell count was normal. Her MRI scan does show two new enhancing lesions in the right pericallosal region.

How should this be managed acutely?

A. Commence high dose oral prednisone and wean over a month
B. Commence intravenous dexamethasone
C. Commence natalizumab infusion
D. Commence high dose methylprednisolone for 3-5 days
E. Biopsy the enhancing lesions

D. Commence high dose methylprednisolone for 3-5 days

Given that this patient has relapsed on maintenance therapy, and that she has multi-focal signs affecting vision and motor function, she should be admitted to hospital and commenced on highdose intravenous methylprednisolone.

Acute relapses can be treated with either high dose oral prednisolone or intravenous therapy. The choice depends on multiple factors including the severity of symptoms, the requirement for hospital admission for monitoring, and co-morbidities such as diabetes and depression.

After this patient has recovered from this acute relapse a review of her maintenance therapy should occur, and this may be escalated through her neurologist based on a number of criteria.

Question 86 of 189

A 67-year-old male presents to the hospital with 2 hours of acute onset right sided weakness and speech difficulties.

A CT cerebral angiogram shows proximal left middle cerebral artery (LMCA) thrombosis.

Seven days prior to this presentation he underwent a laparotomy for bowel obstruction secondary to an incarcerated umbilical hernia.

In the absence of IV thrombolysis which of the following emergency therapies may benefit the patient?

A. Intra-arterial clot retrieval
B. Prasugrel
C. Mannitol
D. Intravenous heparin infusion
E. Rosuvastatin

A. Intra-arterial clot retrieval

Patient's presenting with a confirmed acute proximal MCA or distal internal carotid artery or basilar artery occlusion may benefit from intra-arterial clot retrieval. Ideally, patients should undergo the procedure within 6 hours of symptom onset.

Recent abdominal surgery is an exclusion criterion for intravenous thrombolysis which is why the patient in this question may benefit from intra-arterial clot retrieval.

Three recently published randomised trials established the safety and efficacy of intra-arterial clot retrieval in addition to intravenous thrombolysis for eligible patients presenting with acute stroke. Patients who are ineligible for IV thrombolysis who present within the appropriate time-frame with large vessel occlusion may also benefit from intra-arterial clot retrieval.

All other answers have not been proven to benefit the patient in the emergency setting.

A statin based therapy should however be initiated in all ischaemic stroke patients as part of their secondary prevention regimen.

Question 87 of 189

A 75-year-old man is being reviewed after transient expressive dysphasia and clumsiness in the right hand. His symptoms completely resolved after 20 minutes.

He does not have a background diagnosis of ischaemic heart disease or diabetes but is an exsmoker with a 50 pack year history. His blood pressure was 160/70 mmHg and he was in sinus rhythm. He had no detectable neurological signs on examination.

His MRI brain scan showed a very small area of restricted diffusion in the left frontotemporal region consistent with ischaemia.

He has a total fasting cholesterol of 4 mmol/L (normal) with an LDL level of 2.5 mmol/L (normal).

With regards to cholesterol, in addition to dietary advice and exercise what else may benefit this patient?

A. Commence on a fibrate
B. Commence a statin
C. Commence a fibrate and a statin
D. Commence fish oil tablets
E. Assess for diabetes and only if present commence a statin

B. Commence a statin

In addition to diet and exercise modifications, all patients who are diagnosed with stroke or TIA should be commenced on statin therapy irrespective of the cholesterol level.

Question 88 of 189

A 63-year-old man presents to the emergency department with a 5-minute episode of slurred speech earlier in the day. His wife noticed that his face was drooping to one side as well. He had no arm weakness and is now completely back to normal. He is normally well and on no regular medication and is not allergic to any medication. He works as a plumber and smokes 10 cigarettes per day for the last 40 years and drinks alcohol socially. On further questioning he mentions that he had a similar episode also lasting 5 minutes four days ago whilst at work. On examination, his blood pressure is 135/70 mmHg and his heart rate is 58/min. He has no focal neurology and his cardiovascular and respiratory examinations are unremarkable. He has been given 300mg of Aspirin by the paramedics.

His blood tests are as follows:

Hb	138 g/l
Platelets	283 * 10 /l
WBC	8.1 * 10 /l
INR	1.1
PT	13 seconds
Na	142 mmol/l
K	4.4 mmol/l
Urea	6.4 mmol/l
Creatinine	89 µmol/l
CRP	5 mg/l
Total cholesterol	3.8 mmol/l
HDL	1.3 mmol/

His ECG shows normal sinus rhythm and rate of 65/min.

What is the most appropriate management for this patient?

A. Outpatient TIA clinic appointment
B. Outpatient CT head and carotid dopplers within the next week
C. Admit for urgent (< 24 hours) CT head & carotid dopplers
D. Thrombolysis
E. Long term clopidogrel

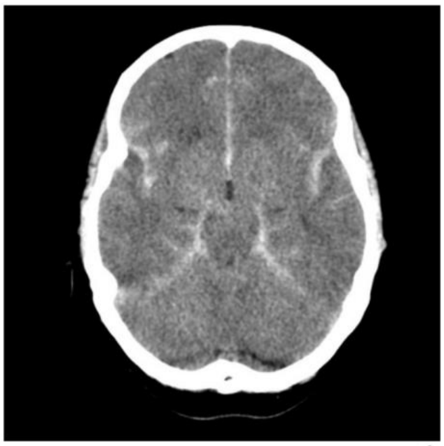
C. Admit for urgent (< 24 hours) CT head & carotid dopplers

This gentleman has had crescendo TIAs (2 in a 7 day period). This necessitates treatment as high risk i.e. admission and urgent (<24 hours) CT head and carotid dopplers. His ABCD score is 3 (1 for age and 2 for symptoms). This would normally put him in the low-risk category (see below) but the presence of crescendo episodes the ABCD score is irrelevant. Thrombolysis is not appropriate as the neurology has resolved. OP TIA clinic and imaging and dopplers within the week are not appropriate given the crescendo episodes.

Question 89 of 189

A 79-year-old woman is admitted to the Emergency Department via an ambulance after being found in an unresponsive, drowsy state. Her daughter phoned her earlier in the day routinely. At this point she complained of a headache. Upon arriving at her mother's house she found her confused and lying on the floor.

On examination her GCS is 9/15 (M4V3E2), pulse 96/min and blood pressure 140/78 mmHg. A CT head is arranged:



© Image used on license from Radiopaedia

What is the most likely diagnosis?

A. Epidural haematoma
B. Subdural haematoma
C. Subarachnoid haemorrhage
D. Sagittal sinus thrombosis
E. Cavernous sinus thrombosis

C. Subarachnoid haemorrhage

The CT shows diffuse subarachnoid haemorrhage in all basal cisterns, bilateral sylvian fissures and the inter-hemispheric fissure. This case demonstrates the typical distribution that takes the blood into the subarachnoid space in a subarachnoid hemorrhage.

Question 90 of 189

An 83-year-old female presents to the emergency department. The patient describes a vague history of arm and leg weakness and loss of vision though is unsure of a particular limb or visual field distribution. She states that these symptoms seemed to last around 6 hours. There are no abnormalities noted in the upper and lower neurological examination nor cranial nerve examination in the emergency department. The patient has a history of regular migraine of around 2 a week for the last 20 years, type two diabetes mellitus treated with metformin and hypertension which was diagnosed 8 years ago currently treated with amlodipine.

Her observations are.

- Blood pressure - 145/90 mmHg
- Heart rate - 83 beats per minute
- Temperature - 37.5C
- Respiratory rate – 15
- Oxygen saturation - 98% on air

You suspect the patient may have had a transient ischaemic attack.

Which radiological investigation is the most appropriate to aid diagnosis at this stage?

A. MRI head with fluid attenuation inversion recovery (FLAIR)
B. CT head with contrast
C. Carotid dopplers
D. MRI head
E. MRI head with diffusion weighted imaging

E. MRI head with diffusion weighted imaging

This patient is an example of someone who has had a suspected transient ischaemic attack (TIA) who requires urgent brain imaging.The national institute of clinical excellence (NICE) state that patients with a suspected TIA who are at a high risk of stroke (ABCD2 score of 4 or above) where the pathology or vascular territory is uncertain require urgent brain imaging, preferably diffusion weighted MRI.

The patient in this question has an ABCD2 score of at least 5, the vague clinical history also make the vascular territory uncertain. Therefore diffusion weighted MRI is most suitable. She may require a Doppler ultrasound of her carotid arteries in the future, though this would preferably happen after the MRI.

Question 91 of 189

A 72-year-old lady was admitted with a cough productive of green phlegm, shortness of breath and a low-grade fever. Past medical history included Parkinson's disease for which she was on cocareldopa and hypertension. Chest x-ray showed a right basal consolidation and she was treated for pneumonia with oral antibiotics. As a result of the pneumonia she had a poor appetite and the patient had been refusing to take her medication.

She was given intravenous fluids and encouraged to take her oral antibiotics. Over the next 1-2 days, the nurses noted that she had started to have fever spikes of greater than 38ºC, had developed a tremor and was becoming increasingly rigid, agitated and confused. Her blood pressure had also been extremely variable.

What test would help you confirm the diagnosis?

A. Repeat chest x-ray
B. Creatine kinase
C. Blood cultures
D. CT head
E. Urine sample

B. Creatine kinase

This patient has developed neuroleptic malignant syndrome (NMS) as a result of not taking her Parkinson's medication. NMS is a life-threatening neurological disorder most often caused by an adverse reaction to antipsychotic drugs (e.g. olanzapine, risperidone, aripiprazole, amisulpride, quetiapine, chlorpromazine, haloperidol and clozapine). However, a wide range of drugs can also cause NMS. These include dopaminergic medication i.e. levodopa and this often occurs when these medications are stopped abruptly, anti-dopaminergic medication such as metoclopramide and even drugs without anti-dopaminergic effects such as lithium can also cause NMS. NMS is caused by a sudden, reduction in dopamine activity, either from blockade of dopamine receptors or withdrawal of dopaminergic agents.

NMS should be suspected if a patient has muscle rigidity, muscle cramps, fever, autonomic instability and alterations in their mental status (confusion, agitation, coma). Symptoms can last anywhere from eight hours to forty days. These features are coupled with an elevated plasma creatine kinase (CK). A raised white cell count may occur and patients can develop rhabdomyolysis.Metabolic acidosis and hypertensive crisis have also been reported.

Treatment is needed urgently as death can occur if untreated. Culprit medication should be stopped. Hyperthermia can be treated with fan therapy, cold blankets and ice packs. Dantrolene is the treatment of choice, however, amantadine and bromocriptine are also used. Patients may require supportive care in an intensive care unit to help support capable of ventilation and circulation.

Question 92 of 189

A 56-year-old female was admitted to the Emergency Department with a 90-minute history of new onset weakness in her left arm and leg. She stated that she was out shopping when the weakness suddenly came on. Since the onset of the weakness she has noticed some regained strength but still felt definite weakness. She had a past medical history comprising new atrial fibrillation for which she was undergoing investigation, hypertension, hypercholesterolaemia and asthma. She also had a perforated gastric ulcer 16 years ago. She was prescribed amlodipine 5mg OD, bisoprolol 2.5mg OD, atorvastatin 20mg OD, Clenil modulite 200mcg BD and aspirin 75mg OD. She declined formal anticoagulation regarding her atrial fibrillation. When questioned specifically, she denied the presence of any visual loss, headache, vomiting, loss of consciousness or cardiac symptoms. She smoked 20 cigarettes per day and did not consume alcohol.

On examination she was alert and walking with a hemiplegic gait. Her blood pressure was 168/74 mmHg, heart rate 78bpm, respiratory rate of 18/min, temperature of 37.2 C and oxygen saturations of 99% on air. Other than an irregularly irregular pulse, examination of the cardiovascular, respiratory and gastrointestinal systems were unremarkable.

Examination of the central neurological system revealed normal cranial nerves 2-12, with equal and reactive pupils, normal fundoscopy and a GCS of 15. Examination of the peripheral nervous system revealed the presence of power 3/5 in all muscles of the left upper and lower limbs, with decreased tone and absent deep reflexes. Power was otherwise 5/5 in all other muscle groups, with downgoing plantar reflexes. Sensation and coordination testing was unremarkable.

Initial investigations revealed the following results:

Hb	179 g/l
MCV	99 fl
Platelets	452 * 10 /l
WBC	12.2 * 10 /l

ECG: atrial fibrillation 74 bpm no acute changes

CT head scan: no evidence of intracranial haemorrhage, mass shift or space occupying lesions

What is the next best management step?

A. Commence intravenous heparin
B. Commence thrombolysis therapy
C. Arrange urgent haematology consult
D. Commence aspirin 300mg and admit to stroke unit
E. Commence immediate amlodipine 5mg OD

B. Commence thrombolysis therapy

This lady has suffered an ischaemic stroke and fulfils the criteria for urgent thrombolysis. There are no absolute contraindications to thrombolysis and this will maximize the probability of regaining full function of the affected limbs. The other management options may serve a role but in the hyperacute setting of the above options initiating thrombolysis is the most appropriate management option.

Question 93 of 189

A 69-year-old retired accountant was seen in the neurology clinic having been referred by his GP. He presented with a three-month history of malaise and weakness. The weakness initially affected his legs, and at times he felt that his legs would not support him standing up. Over the course of the last month, however, he also noticed weakness in his hands, especially his left hand. This was particularly noticeable when he rode his motorbike when he felt that his fingers were not strong enough to apply the brakes. In addition, his wife remarked that his speech had changed in tone though he did not have any difficulties with understanding or expressing speech. His past medical history comprised hypertension, hypercholesterolaemia, depression and hypothyroidism. His medication regimen included amlodipine 5mg OD, atorvastatin 20mg ON, citalopram 20mg OD and levothyroxine 125mcg OD. He also remarked that he had been referred by his GP to the fast track gastroscopy clinic and was pending an appointment for new-onset difficulty in swallowing food over the last month. He did not smoke and did not consume alcohol. Upon a systems review, he denied the presence of other symptoms though he did admit to losing 3kg of weight since the onset of his symptoms.

On examination, he appeared cachectic with obvious dysarthria. His blood pressure was 128/78 mmHg and his heart rate was 78bpm. Examination of his cranial nerves revealed the presence of tongue fasciculations with tremulous lips and an absent jaw jerk reflex but was otherwise unremarkable. Examination of his peripheral nervous system revealed small muscle intrinsic wasting of both hands, as well as wasting of his thigh muscles. The tone was reduced in his lower limbs but increased in his upper limbs. He had obvious weakness of all muscle groups, with a grade 4/5 weakness in his lower limbs and proximal upper limb and a grade 3/5 weakness in his distal upper limbs. Fasciculations were present in his thighs and forearms. Both upper and lower limb reflexes were brisk with downgoing plantars. Examination of sensation was normal. Examination of the cardiovascular, respiratory and gastrointestinal systems was unremarkable.

Investigations conducted by the GP prior to referral are as follows:

Hb	111 g/l
Platelets	99 * 10 /l
WBC	12.2 * 10 /l
ESR	18 mm/hr
CRP	6 mg/l
ANA	positive
Rheumatoid factor	negative

Which one of the following interventions is most likely to be of benefit?

A. Mitoxantrone
B. Riluzole
C. Rivastigmine
D. Methotrexate
E. Azathioprine

B. Riluzole

This patient has motor neurone disease (MND), with clinical evidence of amyotrophic lateral sclerosis and bulbar palsy. Of the above options only riluzole, an anti-glutamate, has been shown to be of any benefit and is suitable for the amyotrophic lateral sclerosis variant of MND. The presence of ANA antibodies is a red herring; it is thought to be present in up to 15% of healthy individuals and is not associated with MND.

Question 94 of 189

A 60-year-old male with a history of hypercholesterolaemia is brought to the emergency department with a 3-hour history of right sided body weakness and an inability to talk. The weakness was gradual in onset and has been progressing thereafter.

The patient has a history of peptic ulcer disease secondary to H.Pylori infection. He was treated with omeprazole, clarithromycin and amoxicillin-clavulanic acid. A recent upper GI endoscopy done 2 months ago was normal.

His medication includes omeprazole 20mg daily, atorvastatin 40mg daily and he takes paracetamol occasionally for joint pains.

On examination, he has a blood pressure of 140/80mmHg. He is aphasic, the tone on the right side is increased with the muscle power being 2/5 in the right upper limb proximally and distally while it is 1/5 in the lower limb both proximally and distally. There is no evidence of meningeal irritation and his pupils are normal.

Lab investigations reveal

Hb	150 g/l
Platelets	450 * 10 /l
WBC	13.0 * 10 /l
Na	138 mmol/l
K	4.4 mmol/l
Urea	6.9 mmol/l
Creatinine	118 µmol/l

ECG: Sinus tachycardia with occasional ventricular ectopics

CT scan brain: no evidence of cerebral haemorrhage, suspected left middle cerebral artery infarction.

What is the most appropriate management option for this patient?

A. Aspirin, clopidogrel, IV fluids and bowel and bladder care
B. Thrombolysis with alteplase
C. Modified release dipyridamole
D. Anticoagulation with LMWH
E. Anticoagulation with apixaban

B. Thrombolysis with alteplase

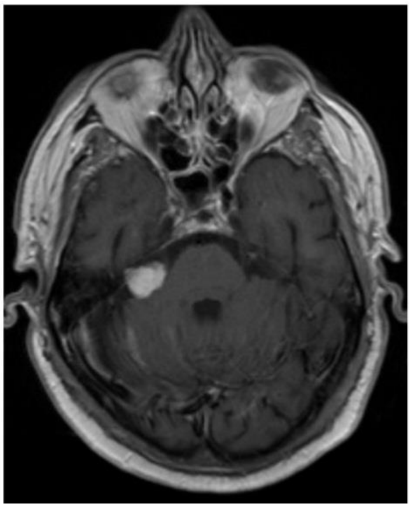
The patient has developed an ischaemic stroke and the question assesses the most appropriate management options. Evidence supports the role of thrombolysis in patients with a proven ischaemic stroke of less than 4.5 hours duration.

Question 95 of 189

A 75-year-old woman presents to the clinic with a six-month history of lower limb weakness and difficulty rising from a chair. The weakness is more pronounced in the morning and shows temporary improvement after exercise. She has been diagnosed with ovarian carcinoma for which she is receiving palliative care. On examination, her deep tendon reflexes are absent, but it is observed that they reappear after brief periods of exercise following her admission to an inpatient facility.

Which antibodies are most likely to be positive in this patient?

A. Anti Hu
B. Aquaporin 4
C. NMDA receptors
D. Voltage-gated calcium channels
E. Voltage-gated sodium channels



D. Voltage-gated calcium channels

Lambert-Eaton syndrome - antibodies against the voltage-gated Ca2+ channels

Voltage-gated calcium channels is the correct answer. The clinical presentation of this patient suggests Lambert-Eaton myasthenic syndrome (LEMS), which is often associated with malignancies, most commonly small cell lung cancer and, in very rare instances, ovarian cancer as highlighted by a case report. The pathogenesis of LEMS involves autoantibody production against presynaptic voltage-gated calcium channels within the peripheral nervous system. This autoimmune response leads to reduced acetylcholine release and subsequent muscle weakness. A characteristic feature of LEMS is post-tetanic facilitation, an improvement in reflexes following exercise, which serves as a strong diagnostic indicator for the syndrome. The antibodies in question specifically target voltage-gated calcium channels, thereby disrupting normal calcium influx and diminishing acetylcholine secretion at nerve terminals.

The role of voltage-gated sodium channels is not relevant in this scenario since it is the calcium channels that are targeted by autoantibodies in cases of LEMS.

Although the patient's history of ovarian cancer might raise suspicion for anti-NMDA receptorencephalitis, this condition usually presents with acute psychiatric symptoms and behavioural changes that are inconsistent with the clinical presentation observed here; therefore, NMDA receptors are an incorrect choice. Moreover, post-exercise facilitation of deep tendon reflexes is not a feature of NMDA encephalitis.

Anti-Hu antibodies serve as markers for various paraneoplastic neurological syndromes such as limbic encephalopathy and sensory neuronopathy. These conditions do not correspond with the clinical findings discussed here. Anti-Hu antibodies are predominantly linked to small-cell lung cancer, with approximately 85% of positive cases being associated with this type of malignancy.

Lastly, neuromyelitis optica (NMO) is characterised by aquaporin 4 antibodies; however, there are no clinical signs or symptoms indicative of NMO present in this patient's case. Therefore, selecting aquaporin 4 as an answer would be incorrect.

Question 96 of 189

A 60-year-old schoolteacher is referred to the neurology clinic by his General Practitioner to assess his symptoms further. He has an MRI brain before review in the neurology clinic. The MRI brain showed

What is the most likely diagnosis?

A. Cavernous hemangioma
B. Facial nerve schwannoma
C. Infratentorial meningioma
D. Trigeminal schwannoma
E. Vestibular schwannoma

E. Vestibular schwannoma

The MRI brain shows an intracanalicular solid nodular mass with an intense contrast enhancement in the left internal auditory meatus (IAM) suggestive of vestibular schwannoma. Occasionally, cystic degeneration or haemorrhagic areas may also be seen, but calcification is typically not present.

Vestibular schwannoma is the correct answer. Vestibular schwannomas, or acoustic neuromas, are relatively common tumours arising from the vestibulocochlear nerve (CN VIII) and represent ~80% of cerebellopontine angle (CPA) masses. The classical presentation for vestibular schwannoma includes tinnitus, sensorineural hearing loss, vertigo and absent corneal reflex. Cranial nerves V and VII may also be affected.

Cavernous hemangiomas, also commonly known as cerebral cavernous venous malformations or cavernomas, are common cerebral vascular malformations, usually with characteristic appearances on MRI. MRI often demonstrates a characteristic 'popcorn' or 'berry' appearance with a rim of signal loss due to hemosiderin. The patients usually remain asymptomatic but may present with headaches and focal neurological deficits from intracranial haemorrhage.

Facial nerve schwannoma, or facial nerve neuroma, is a rare schwannoma that arises from the facial nerve. They are generally uncommon and make up less than 1% of all temporal bone tumours when involving the temporal bone.

Infratentorial meningiomas are rare even though meningiomas, in general, are the second most common cause of a cerebellopontine mass. They typically appear as extra-axial masses with a broad dural base and are usually homogeneous and well-circumscribed. Patients often present with headaches, paresis and changes in mental status.

Trigeminal schwannomas are uncommon slow-growing encapsulated tumours of Schwann cells. They are the second most common intracranial schwannoma, far less common than vestibular schwannoma, and have a predominantly benign growth.

Question 97 of 189

A 74-year-old patient with known Parkinson's disease presents for review in the geriatric clinic. He has been suffering from sudden onsets of attacks where he is barely able to move. This has been a problem for the last few months. His symptoms are normally well controlled and attacks occur suddenly, lasting for 30 minutes and then resolving without any intervention. He takes levodopa and carbidopa for his Parkinson's disease which has been on a stable dose for the last three years. On examination, he has a mild unilateral tremor and slight bradykinesia which is worse on the right side. His eye movements are normal and he has no postural symptoms when standing.

What is the likely explanation of his symptoms?

A. Dyskinesia
B. Vascular Parkinsonism
C. Multi-system atrophy
D. Progressive supranuclear palsy
E. On-off effect

E. On-off effect

The correct answer is on-off effect. Over time, levodopa becomes less effective. Patients can experience after a few years of treatment that their symptoms are well-controlled parts of the day and other times their mobility is heavily affected. This is the most likely explanation given the fact that these symptoms started over two years after treatment and the medication regime will need to be adjusted. A Parkinson-plus syndrome is unlikely as these would not have originally responded to levodopa, and would be associated with other features. For example, progressive supranuclear palsy is associated with gaze palsy whilst multi-system atrophy is associated with postural hypotension. Dyskinesia is continuous writhing movements which occur as a side effect of levodopa.

Question 98 of 189

A 35-year-old man is brought into the Emergency Department after 3 successive tonic-clonic seizures. He was given 10mg of rectal diazepam and has since stabilised.

A brief history from his girlfriend states that he was usually fit and well apparent from recurrent sinusitis. Over the past month, however, he had been complaining of increasing headaches and had received a course of antibiotics from his GP.

He takes no regular medication but his partner states that they do occasionally take ecstasy whilst on nights out.

On examination, he is drowsy with a Glasgow Coma Scale (GCS) of 12. His temperature is 38.8 degrees Celsius, his pulse is 57 bpm and regular, blood pressure 150/90 mmHg, oxygen saturations 97% on 15L oxygen via a non-rebreathe mask.

Cardiovascular examination reveals normal heart sounds, capillary refill time of 3 seconds. His calves were soft and non-tender. His chest was clear with no signs of consolidation. Abdominal examination was unremarkable.

Neurological examination was difficult in view of the patients low GCS but no focal abnormality could be detected. On attempt to passively flex his neck he became agitated and obviously uncomfortable. Pupils were equal and reactive to light. Fundoscopy demonstrated bilateral oedematous optic discs.

Bloods were as follows:

Na+	130 mmol/L
K+	3.9 mmol/L
Urea	5 mmol/L
Creatinine	80 µmol/L
Hb	160 g/L
WBC	25.0x10^9/L
Neutrophils	91%
LFTs	Normal
CRP	90 mg/L

Based on the findings above, what is the most likely diagnosis?

A. Intracerebral abscess
B. Sepsis secondary to sinusitis
C. Ecstasy overdose
D. Meningitis
E. Cerebral lymphoma

A. Intracerebral abscess

This is a 30-year-old man who presented with a history of headaches, seizures and a fever. The history of headaches and a course of antibiotics could suggest partially treated sinusitis. This has likely extended posteriorly resulting in an intracranial abscess as indicated by the inflammatory markers, signs of raised intracranial pressure and seizures.

Meningitis can sometimes present with seizures if this has progressed to meningoencephalitis but the history of recurrent sinusitis and headaches with raised intracranial pressure are more suggestive of a space occupying abscess.

Although ecstasy overdose can cause pyrexia and seizures, it is not in keeping with the chronic progression of this patient's symptoms.

Seizures have been associated with severe sepsis but it is not in keeping with all of the signs and symptoms demonstrated here.

Question 99 of 189

A 79-year-old is brought into hospital with muscle cramps, fevers and passing dark urine. He is known to have previously had Parkinson's disease and takes Sinemet 125 five times a day. His daughter, who normally picks up his medicine for him from the pharmacy has been called away on business for the past 5 days. As a result, the patient's supplies ran out and he has not taken his PD meds for 3 days. His blood pressure is fluctuant, from 77/52 mmHg to 150/88mm Hg. On examination, his temperature is 39.2 degrees, his heart sounds are quiet but present and chest auscultation is unremarkable. You note rigid muscles in four all limbs, no obvious superficial evidence of head injury and new confusion, with abbreviated mental test 0/10. You start intravenous fluids, intravenous broad spectrum antibiotics, catheterise the patient and insert a nasogastric tube to administer his regular medications.

What is the underlying diagnosis?

A. Urosepsis
B. Restrictive pericarditis
C. Idiopathic Parkinson's disease progression
D. L-dopa dyskinesia
E. Neuroleptic malignant syndrome

E. Neuroleptic malignant syndrome

The history gives a clear history of lack of access to regular Parkinsonian medications associated with pyrexia and muscle cramps. This would point towards a diagnosis of Parkinsonismhyperpyrexia syndrome, a form of neuroleptic malignant syndrome observed when PD medications are withdrawn or changed. A key feature to be noted here is the labile blood pressure, suggesting autonomic instability, suggesting the need for careful intensive care monitoring and supportive therapy. Treatment is by replacing the original dose of withdrawn medication, either orally or via a nasogastric tube. If this is not possible intravenous L-dopa is possible while dopamine agonists can be given parenterally: rotigotine can be applied as a transdermal patch while apomorphine is available as an intravenous or subcutaneous infusion.

Question 100 of 189

A 58-year-old female with known myasthenia gravis complains of increasing tiredness and reducing exercise tolerance over the past 3 days. During your examination, she has a weak voice is unable to finish her sentences and appears slightly slumped in the chair she is sitting in.

What is the most important investigation at this acute stage?

A. Forced vital capacity (FVC)
B. 12 lead ECG
C. Forced expiratory volume in 1 second (FEV1)
D. Blood tests including full blood count, U+Es, LFTs, CRP
E. Chest x-ray

A. Forced vital capacity (FVC)

The patient is approaching a myasthenic crisis. One of the most acute dangers to be aware of is impending respiratory distress, caused by a failure of respiratory muscles. Other symptoms can include dysphonia, dysphagia and generalised weakness. Forced vital capacity is the most accurate assessment of inspiratory and expiratory mechanisms. FEV1 is better at demonstrating an obstructive than respiratory muscle strength. Although blood tests and chest radiography may be useful in identifying an underlying infective cause for the deterioration, the acute issue remains the patients possible progressive respiratory deterioration, which may warrant elective intubation.

Question 101 of 189

A 22-year-old male is referred to clinic by his GP. His initial complaint had been that his friends have been increasingly remarking on how his eyelids look increasing 'droopy' over the past 9 months. He denies any diplopia or muscle weakness. He has no past medical history, is a nonsmoker and non-drinker. On examination, you note bilateral inability to abduct or adduct his eyes. Vertical gaze is also inconsistently impaired. His upper and lower limb neurological investigation was unremarkable except very mild finger-nose dysmetria, his bloods tests show no abnormalities. His ECG demonstrates sinus rhythm with a PR interval of 260ms. Fundoscopy reveals a pigmented retina.

What is the diagnosis?

A. Myasthenia gravis
B. Thyroid eye disease
C. Oculopharyngeal musculodystrophy
D. Extraocular muscle fibrosis
E. Kearns-Sayre syndrome

E. Kearns-Sayre syndrome

This young patient demonstrates a combination of retinitis pigmentosa, chronic progressive external ophthalmoplegia, bilateral ptosis, mild cerebellar signs and a cardiac conductive defect (first degree heart block). These features are consistent with a mitochondrial disorder, in particular Kearns-Sayre syndrome. Some patient may also display proximal myopathy, cognitive impairment or short stature. The underlying cause is a genetic mitochondrial disorder. Patients rarely live beyond their 40s and there are no therapeutics currently available.

Question 102 of 189

A 23-year-old male presents with a 5-day history of increasing shortness of breath, exertional dyspnoea and bilateral ankle swelling. He has no previous past medical history and was previous a keen sportsman. On examination, his heart sounds I + II are present with a pansystolic murmur and a displaced apex. Auscultation of his chest demonstrates bibasal crackles. His ECG demonstrates a PR interval of 190 ms but sinus rhythm. Further neurological examination demonstrates bilateral partial ptosis noted associated with bilateral foot drop. You also note slow release of finger flexion.

What is the underlying diagnosis?

A. Myotonic dystrophy
B. Myasthenia gravis
C. Inflammatory myositis
D. Facioscapulohumeral dystrophy (FSD)
E. Guillain Barre syndrome

A. Myotonic dystrophy

The patient has presented with clinical heart failure on a background of systemic disease, involving structural heart disease, conductive heart block, bilateral ptosis bilateral foot drop and slow finger flexion release suggestive of myotonia. It would not be possible to distinguish at this stage between DM1 or DM2 myotonic dystrophy, the latter being less severe than DM1. The diagnosis would be clinched with genetic testing for an expanded CTG repeat in the DMPK gene: normally, 5-34 CTG repeats are found. Greater than 50 alleles is strongly diagnostic of disease manifestations.

Question 103 of 189

An 84-year-old male presents as a blue light ambulance call with a twelve hour history of sudden onset inability to move his right side. On examination, you note an expressive and receptive dysphasia associated with a dense right sensori-motor syndrome. Cardiovascular examination was unremarkable except for an irregular heartbeat at 80 per minute. A hyperacute CT head demonstrated a large area of ischaemia in a the left middle cerebral artery vascular territory. The patient was outside the window for thrombolysis and started on 300mg aspirin. Subsequent echocardiogram demonstrated 60% ejection fraction with no mural thrombus, 40% left and 35% right stenosis on carotid Doppler while a 24hr tape demonstrated new atrial fibrillation.

How can the risk of subsequent strokes be reduced?

A. Subcutaneous low molecular heparin at 48 hours after stroke
B. Warfarinisation at 48 hours after stroke
C. Warfarinisation at 14 days after stroke
D. Referral to vascular surgery for left carotid endarectomy
E. Insertion of permanent pacemaker

C. Warfarinisation at 14 days after stroke

This patient demonstrates an ischaemic infarct secondary to likely new atrial fibrillation, for which the optimum treatment is anticoagulation. The degree of carotid stenosis is not sufficiently significant to justify carotid endarectomy. The patient has no indications for a pacemaker. The treatment of choice for atrial fibrillation in such a high-risk patient for further strokes is anticoagulation.

In the absence of intracerebral haemorrhages or haemorrhagic transformation of infarcts, NICE guidelines recommend starting anticoagulation at 14 days after the onset of stroke . Due to the risk of haemorrhage as the infarcted brain matures, which is increased with the size of the initial infarct, early anticoagulation is not recommended. A recent meta-analysis collated the results of seven trials studying early anticoagulation in acute ischaemic strokes. Although the risk of further ischaemic strokes between days 7 and 14 is significantly reduced from 4.9 to 3%, the risk of symptomatic intracerebral haemorrhage was also significantly increased fro 0.7% to 2.5% . As a result, early anticoagulation before 14 days is not indicated by NICE or the American Heart and Stroke Associations .

Question 104 of 189

A 55-year-old female presents with 3 weeks of bilateral tingling sensation in her medial one and half digits at night. She has noted a clawing of her 4th and 5th digits and she is particularly concerned by the cosmetic elements. She also complains of a left sided foot drop present over the past 8 months. Her past medical history includes type 2 diabetes mellitus, for which she take metformin 850mg TDS and she admits to occasional poor compliance. Her last HbA1c was 53 mmol/mol. She has also had multiple admissions for surgery to her feet at childhood but she is unaware of further details. She was adopted and is unaware of her birth family history. On examination, she clinically has a left common peroneal palsy with bilateral thin calves, and loss of sensation in bilateral ulnar nerve territories.

What is the unifying diagnosis for her presenting paraesthesia and foot drop?

A. Hereditary neuropathy with liability to pressure palsies
B. Diabetic neuropathy
C. Chronic inflammation demyelinating polyneuropathy (CIDP)
D. Systemic lupus erythematosus (SLE)
E. Sarcoidosis

A. Hereditary neuropathy with liability to pressure palsies

The patient has thin calves and previous foot deformities requiring surgery, suggestive of CharcotMarie-Tooth disease or hereditary motor sensory neuropathy (HSMN), a disorder caused by deletion in the PMP22 gene, the same gene mutation responsible for hereditary neuropathy with liability to pressure palsies. Common peroneal nerve is the most commonly affected nerve (36%) followed by the ulnar nerve (28%). Diagnosis is confirmed by genetic testing.

Question 105 of 189

A 32-year-old female presents with four episodes of loss of consciousness within the past 4 weeks. She denies palpitations or chest pain but reports sudden onset binocular black dots in visual fields, occasional flashing lights, dysarthria and hearing loss, all of which resolves after about 60 minutes. She is unsure about the relevance of an occipital headache, onset with frequency of about three times per week for the past year. She denies any limb weakness, altered sensation or facial droop. She has no past medical history or family history of epilepsy. Your neurological examination, including fundoscopy is unremarkable. An EEG is unremarkable.

What is the likely diagnosis?

A. Cluster headache
B. Transient ischaemic attacks
C. Basilar migraine
D. Bilateral retinal detachment
E. Guillain-Barre syndrome

C. Basilar migraine

The symptoms are most likely to represent a rare migraine subtype with aura known as basilar migraine. A large Danish study identified up to 10% of all non-hemiplegic migraineurs as basilar migraines, most of whom report a brainstem-associated range of symptoms lasting for around one hour . 61% of patients report vertigo and over half dysarthria. One in four report episodes of loss of consciousness. Investigations include 24 hour tape and echocardiogram to exclude cardiac syncope and MRI to exclude posterior fossa space occupying lesion. An EEG may not exclude posterior epileptiform activity. Prevention can be offered with verapamil or topiramate.

Question 106 of 189

A 76-year-old male is referred by the GP to your Parkinson's disease clinic. The patient and his wife described an increasing frequency of falls, the most frightening of which occurred when he fell 4 steps down a flight of stairs last week, luckily with no lasting damage. On

examination, you note a slow pill rolling tremor equally on both hands and bilateral cog-wheeling. His cranial nerves are unremarkable except a poverty of upwards gaze. His speech appears distinct and nasal in character.

What is the most likely diagnosis?

A. Idiopathic Parkinson's disease
B. Vascular parkinsonism
C. Progressive supranuclear palsy (PSP)
D. Multi-system atrophy (MSA)
E. Corticobasal degeneration (CBD)

C. Progressive supranuclear palsy (PSP)

PSP is most likely in this scenario. A number of features should alert you to a Parkinson's-plus syndrome instead of idiopathic Parkinson's disease: bilateral, symmetrical symptoms are uncommon, particularly in early PD. In addition, eye signs are very unusual. PSP patients classically present with increasing falls near the stairs due to an impaired vertical gaze and a nasal 'DonaldDuck' voice secondary to pseudobulbar palsy. MSA patients classically present with significant cerebellar or autonomic symptoms. CBD present with higher order dysfunction such as apraxia and aphasia, but classically with 'alien hand syndrome', thought to be as prevalent as 60% of CBD patients, when the patient has no control over their own hand movements.

Question 107 of 189

A 32-year-old male presents with a sudden onset left sided weakness with new onset expressive dysphasia and dress apraxia. He has a seven year history of progressive cognitive impairment and seizures, lives in sheltered accommodation and was brought in after his relatives, who visit him on a weekly basis, noted a change from his baseline. The patient is a poor historian and could not remember the duration of symptoms. He reports a recent history of burning sensation when passing urine associated with increased frequency and reduced oral intake for the past four days. An MRI head demonstrates multiple areas of ischaemia within left and right cortex inconsistent with one single vascular territory. A urine dip is positive for leucocytes and nitrites, negative for ketones. A venous blood gas is taken:

pH	7.15
PaCO	2.4 kPa
Bicarbonate	6 mmol/l
Lactate	18 mmol/l
Anion gap	16 mmol/

What is the unifying diagnosis?

A. MELAS
B. Diabetic ketoacidosis
C. Ingestion of antifreeze
D. Severe dehydration secondary to urosepsis
E. Metformin induced lactic acidosis

A. MELAS

Young patients with significant cognitive impairment should raise suspicion. This patient presents with a significant lactic acidosis, with low bicarbonate likely secondary to chronic neutralisation in the presence of systemic acidosis. Multiple ischaemic infarcts inconsistent with vascular territories are suspicious of a metabolic disorder within the brain parenchyma. In this case, a mitochondrial genetic condition, mitochondrial encephalopathy with lactic acidosis and stroke like episodes (MELAS), is most likely. Focal and generalised seizures are common for MELAS patients, as is early onset dementia, focal weakness and cortical blindness from multiple ischaemic stroke episodes.Symptoms normally present at late childhood and early adulthood, with patients develop normally until then. Diagnosis is made through lactic acidosis, a progressive neurological and dementing clinical course and muscle biopsy for ragged red fibres. The majority of patients have been linked to an underlying mutation in transfer RNA .

In this case, the UTI is a red herring. While the patient may have a UTI, it does not produce a unifying diagnosis of cerebral and metabolic abnormalities. A normal anion gap rules out ingestion of inorganic acids or DKA. The patient is negative for urinary ketones. There is no suggestion he takes metformin.

Question 108 of 189

An 18-year-old man presents to the emergency department with pleuritic chest pain. He has no past medical history.

The examination is unremarkable.

A chest x-ray reveals a visible pleural edge with a distance of approximately 1.1cm from the pleural edge to the lung margin at the level of the hilum.

Given the likely diagnosis, what advice should he be given about flying?

A. He can fly 1 week post treatment with a chest x-ray demonstrating resolution
B. He can fly 6 weeks post treatment with a chest x-ray demonstrating resolution
C. He can fly immediately upon clinical improvement
D. Indefinite ban on flying
E. There is no contraindication to flying at any point

A. He can fly 1 week post treatment with a chest x-ray demonstrating resolution

Pneumothorax -> can fly 1 week after treatment if chest x-ray shows resolution

He can fly 1-week post-treatment with a chest x-ray demonstrating resolution is the correct answer. The patient has a small PTX < 2cm without any lung disease history. He is likely to be suitable for discharge and outpatient review. He can be advised that he can fly one week post any required treatment if a chest x-ray demonstrates resolution.

He can fly 6 weeks post-treatment with a chest x-ray demonstrating resolution is incorrect. This was previous BTS advice but has now been replaced by the above advice.

He can fly immediately upon clinical improvement is incorrect. We need to see chest x-ray evidence of resolution prior to flying. This would be more suitable advice if he had a pneumonia.

Indefinite ban on flying is not correct. A prior history of resolved PTX is not a contraindication to flying.There is no contraindication to flying at any point is incorrect. An active, unresolved PTX is an absolute contraindication to air travel.

Question 109 of 189

A 45 year old male presented with right shoulder pain and weakness. Three weeks ago he had been brought to the emergency department (ER) with the same complaint. The pain was so severe that it awoke him from sleep. At that time he took two paracetamol tablets but that gave him no relief. Eventually the ER team had been forced to give him morphine to relieve his agony having tried less potent analgesia. On further questioning he described the pain as sharp, exacerbated by movement of the shoulder, with numbness at the shoulder tip.

On examination, he was holding his right arm with his left one in adduction and internal rotation. Wasting of the deltoid muscle had been noted. The biceps tendon jerk was absent. Sensations were intact except in a small region over deltoid muscle. Lower limb examination was normal. One month ago he had a flu. The past medical history was otherwise of no significance.

He admitted to drinking alcohol at least four times a week. He has a ten year old son who is an insulin dependent diabetic.

The following investigations were ordered:

Hb	14 g/dl
Platelets	180 * 10^9/l
WBC	6 * 10^9/l
MCV	85 fl
MCH	0.6 fmol/cell
MCHC	21 mmol/l
Na+	135 mmol/l
K+	4 mmol/l
Creatinine	85 µmol/l
Urea	3.2 mmol/l
ESR	4 mm/hr
ANA	negative

What is the most likely diagnosis?

A. Syringomyelia
B. Brachial neuritis
C. Adhesive capsulitis
D. Polymyalgia rheumatica
E. Cervical radiculopathy

B. Brachial neuritis

Adhesive capsulitis usually presents with shoulder pain and restrictions of movement. It would not cause wasting nor neither lower motor neurological signs. Adhesive capsulitis is usually associated with diabetes and thyroid disorders.

Question 110 of 189

A 58 year old man progressively develops hand clumsiness, gait difficulty and dysphagia over several months. His voice has also become high pitched and nasal. Sensory examination has remained normal throughout. Plantars are up-going, with absent ankle reflexes bilaterally and wasting of the distal leg musculature.

Which treatment has been shown to lengthen survival for the underlying condition?

A. Intravenous immunoglobulin
B. Donepezil
C. Pyridostigmine
D. Non-invasive ventilation (NIV)
E. Steroid

D. Non-invasive ventilation (NIV)

The answer here is motor neurone disease (specifically Amyotrophic Lateral Sclerosis (ALS) in this case). There is mixture of diffuse upper motor neurone features (the up-going planters and pseudo-bulbar 'Donald duck' speech) along with lower motor neurone features (wasting and areflexia) . The giveaway that it is not other causes of mixed upper and lower motor neurone features e.g. cervical spine pathology/syringomyelia/conus medullaris lesion is the bulbar involvement.

NB: Always look for the presence of tongue fasciculations if you pick up a mixed upper and lower motor neurone picture. If they are evident, think ALS rather than these other causes as they are too low down anatomically to involve the tongue (and bulbar muscles).

Management of ALS involves an multidisciplinary team (MDT) approach. Don't forget to organised Speech and Language Team (SALT) assessment: poor swallow and aspiration pneumonia can kill. Additionally, NIV should be considered to treat respiratory insufficiency in ALS, both to lengthen survival and to slow the rate of Forced Vital Capacity (FVC) decline. It has been shown to increase survival by around 205 days. Riluzole has been shown to slow disease progression in patients with ALS by around 2-3 months.

Question 111 of 189

A 41 year old lady with a background of vitiligo and pernicious anaemia presents with weakness largely affecting her shoulders and hip muscles. The problem is variable throughout the day dependent on how much activity she has done. She does feel that symptoms are at their worst at the end of the day, when indeed her family also say her voice becomes quieter. Clinical examination demonstrates proximal muscle weakness after repeated testing. Electromyography demonstrates a decline in the amplitude of successive potentials (decremental response). Antibodies to the acetylcholine receptor (AChR) are negative on serum testing. Her CT thorax is normal.

Which of the following is likely to be most helpful in establishing a diagnosis?

A. Anti-smooth muscle antibodies
B. Anti-muscle specific kinase (MuSK) antibodies
C. Anti-striated muscle antibody
D. Anticardiolipin antibodies
E. Anti-transglutaminase antibodies

B. Anti-muscle specific kinase (MuSK) antibodies

The diagnosis here is Myasthenia Gravis (MG). Most (but not all) patients with MG are seropositive for the acetylcholine receptor (AChR) antibody. Antibodies to muscle-specific receptor tyrosine kinase (MuSK), a surface membrane component essential in the development of the neuromuscular junction, have recently been identified and are found in up to 50% of MG patients who are seronegative for AChR antibodies. Emerging data suggests that the patterns of weakness and response to certain treatments may be different from those with AChR positive MG. Antistriated muscle antibody usually positive in MG patients that have a thymoma.

Don't forget to recognise the autoimmune past medical history in this patient. It often gives useful diagnostic clues that the underlying condition is also an autoimmune one.

Question 112 of 189

A 36-year-old lady on natalizumab for relapsing-remitting multiple sclerosis develops left leg weakness. Over 3 weeks this progresses to left hemiparesis and visual impairment. She also notices poor memory and struggles to process numbers at work as an accountant. Examination reveals left-sided 4/5 power, right homonymous hemianopia, and an abbreviated mini-mental state score of 21/30. Routine blood tests are unremarkable. MRI brain shows new multiple confluent lesions in the parietooccipital and right motor white matter areas as well as the left occipital area, with no mass effect or enhancement.

Which of the following tests is likely to be most helpful in establishing a diagnosis?

A. Serum glucose
B. HIV serology
C. JC Virus serology
D. Cerebral angiogram
E. Full blood count (FBC)

B. HIV serology

The diagnosis here is progressive multifocal leukoencephalopathy (PML). This is a demyelinating disease of the CNS characterised by widespread lesions due to brain infection of oligodendrocytes by the JC Virus (JCV). These are visible on an MRI and have a characteristic appearance. The signs correspond to the areas occupied by the lesions. PML occurs almost exclusively in immunocompromised patients such as those with HIV or on immunotherapy. You should consider PML in your differential in such patients when they present with new odd neurology and an abnormal MRI scan.

This question's other aim is to introduce to you one of the newer therapies in multiple sclerosis (MS) called nataluzumab. It is actually very frequently used in MS and indeed now approved for the treatment of relapsing-remitting MS (RRMS) in more than 50 countries. It is a monoclonal antibody that inhibits the migration of leucocytes into the central nervous system, hence reducing inflammation and demyelination. It is given as an IV infusion once a month. It is indicated in patients getting relapses despite treatment with interferon-beta or patients who just have rapidly evolving severe RRMS. It has been shown to decrease the risk of progression of disability by 4254% and the annualised rate of relapse by 68%. The two principle side-effects are hepatotoxicity and increased PML risk, and we monitor patients for these with monthly liver function tests (LFTs) and 6-monthly JCV serology. It would not be unreasonable of them to expect you to know something about nataluzumab in the exam (especially to recognise PML as a side-effect) given that the drug is now in such common use.

Question 113 of 189

A 32 year old female is referred for a neurological opinion. She describes two separate occasions within the last six months of unilateral blurred visual loss. Her symptoms developed over a few days, comprising blurring of the vision and pain, particularly on eye movement. On both occasions this peaked within three days then gradually resolved over two weeks. Lumbar puncture reveals elevated protein level and CSF pleocytosis. Serum Aquaporin-4 is positive.

What is the most likely diagnosis?

A. Multiple sclerosis
B. Neuromyelitis optica
C. Leptomeningeal gliomatosis
D. Myasthenia gravis
E. Idiopathic intracranial hypertension

B. Neuromyelitis optica

Her symptoms are highly suggestive of Neuromyelitis optica (NMO, also known as Devic disease). NMO causes demyelination of the optic nerves or spinal cord due to autoimmune inflammation. Aquaporin-4 (AQP-4) is a water channel protein located in the astrocytic foot processes; NMO-IgG antibody attacks AQP-4 causing demyelination.

NMO typically presents with episodes of optic neuritis or transverse myelitis. The optic neuritis can be clinically indistinguishable from that seen in multiple sclerosis (MS), whereas the transverse myelitis is commonly more of a complete picture than that of MS. This is a result of the fact that the resulting spinal cord demyelination seen in NMO is longer and more extensive.

Question 114 of 189

A 25 year old man presents to A+E in a comatose state. He was found by his university flatmate collapsed on the floor. His flatmate states that the man had been behaving bizarrely in the last 24 hours and had been quite agitated and aggressive at times. When you examine him he has a GCS of 8 (E 2 V 1 M 5). He has a temp of 39.4ºC, heart rate 120/min, blood pressure 178/89 mmHg, sats 98% on room air and respiratory rate 20/min. Chest clear abdomen soft and non-tender, bowel sounds present. Globally greatly increased tone in all 4 limbs.

When looking at his previous electronic notes the only information that you can find is a recent admission to a psychiatric hospital where a diagnosis of paranoid schizophrenia was established.

CT Brain: normal

Hb	15.4 g/dl
Platelets	232
WBC	11.5
Na	143
K	4.1
Urea	8.1
Creatinine	101
Bilirubin	14
ALP	63 u/l
ALT	28 u/l
Calcium	2.64 mmol/l
Albumin	41 g/l
Creatine kinase	21,000 iu/l
Serum glucose	6.4 mmol/l

Lumbar Puncture:

Glucose	4.9 mmol/l
Protein	0.3g/l
Culture	nil organisms found
Opening pressure	21 mmHg

What is the most likely diagnosis?

A. Viral meningitis
B. Serotonin syndrome
C. Neuroleptic malignant syndrome
D. Bacterial meningitis
E. Malignant hyperthermia

C. Neuroleptic malignant syndrome

The answer is neuroleptic malignant syndrome. NMS is characterised by a triad of altered conscious state, hyperpyrexia and raised CK in a person on neuroleptic medications. Young males recently started on a high dose of a high potency antipsychotic are most at risk from this potentially fatal complication. Autonomic instability is also a feature.

Serotonin syndrome shares many clinical features with NMS but normally you would expect to see GI features and cerebellar symptoms in addition and rigidity and hyperthermia are usually more mild. In addition serotonin syndrome is associated with antidepressant medication. This is therefore a less likely diagnosis in an individual recently diagnosed with schizophrenia.

Malignant hyperthermia also shares many clinical features with NMS but this is a genetic disorder provoked by the use of anaesethic agents and there is nothing in the history to suggest this. A normal Lumbar Puncture MC+S essentially rules out bacterial meningitis and viral meningitis is unlikely to cause such severe symptoms.

Question 115 of 189

A 68-year-old female is admitted into the acute medical unit after suffering from a prolonged tonic-clonic seizure. She was diagnosed with status epilepticus which was terminated with lorazepam and a phenytoin infusion. Two days into the admission you are asked to review her due to ongoing confusion. She has a past medical history of depression which is currently treated with fluoxetine.

On examination of her cardiorespiratory system there is nothing of note. Her abdomen is soft and non tender. You note rapid blinking, which the nursing staff confirmed has been on-going over the past 24 hours.

Investigation results are as follows:

Hb	135	Na	137	Bilirubin	14 µmol/l
CRP	<4	Lactate	1.2	Albumin	32 g/l
Platelets	385	K	4.2	ALP	88 u/l
WBC	6.6 *	Urea	4.4	ALT	44 u/l
Neuts	4.2 *	Creatinine	75	γGT	68 u/l
Lymphs	2.2				
Eosin	0.2				

What is the most likely diagnosis?

A. Non-Convulsive status epilepticus
B. Psychogenic seizure
C. Tardive dyskinesia
D. Convulsive status epilepticus
E. Delirium

A. Non-Convulsive status epilepticus

Non-convulsive status epilepticus can present with subtle signs, such as twitching or blinking and/or fluctuating mental statusImportant for me Less important

Non-convulsive status epilepticus (NCSE) is defined as a prolonged (>30 mins) electrographic seizure activity with non-convulsive signs such as twitching or blinking. It can be a challenging diagnosis to make which often relies on EEG confirmation. It requires a high index of suspicion in individuals with risk factors and suggestive clinical features. Early recognition and treatment are essential to optimize response to treatment and to prevent neurological and systemic sequelae.

NCSE is very common in patients who have suffered convulsive status epilepticus, comatosed patients and in the general ICU population.

In this case, the prolonged post-ictal confusion and subtle motor signs are very suggestive of NCSE, and an urgent EEG should be arranged.

There is nothing on examination to suggest infection, and this is reassured with the normal inflammatory markers.

Given the history of depression, a reasonable differential includes a psychogenic seizure, however NCSE would be more likely and more important to rule out.

Tardive dyskinesia can cause blepharospasm however it is rarely caused by SSRIs.

Question 116 of 189

A 34-year-old female attends for review. She has a background of schizophrenia which is currently managed with quetiapine having failed treatment with olanzapine and risperidone in the past. She informs that she has on-going derogatory third person auditory hallucinations. You elect to start her on clozapine.

You perform a baseline blood tests which are as follows:

Hb	145 g/l
Platelets	320 * 10 /l
WBC	6.8 * 10 /l
Neutrophils	3.8 * 10 /

What other investigation is important to perform before starting clozapine?

A. Abdominal x-ray
B. Cardiac echo
C. Liver function tests
D. ECG
E. Urea and electrolytes

D. ECG

Clozapine can cause myocarditis. A baseline ECG should be performed before initiating treatment

Clozapine can cause myocarditis. Therefore, a baseline ECG should be performed before initiating treatment.

Clozapine requires differential white blood cell monitoring weekly for 18 weeks, then fortnightly for up to one year, and then monthly as part of the clozapine patient monitoring service.Prolactin, lipids, glucose, and body weight should also be regularly monitored.

It is important to be aware that clozapine can cause impairment of intestinal peristalsis, potentially resulting in constipation, intestinal obstruction, faecal impaction, and paralytic ileus. However there is no need to perform an abdominal x-ray as a baseline if not clinically indicated.

Question 117 of 189

A 64-year-old woman presents with a painful right eye which came on this evening. On examination, she is notably photophobic with a semi-dilated right pupil. Her visual acuity is 6/6 on the left and 6/12 on the right. Her past medical history includes urinary incontinence for which she takes solifenacin.

What is the definitive treatment for this condition?

A. Acetazolamide
B. Laser peripheral iridotomy
C. Laser trabeculoplasty
D. Pilocarpine
E. Steroid and cyclopentolate eye drops

B. Laser peripheral iridotomy

Laser peripheral iridotomy is the definitive treatment for acute angle-closure glaucoma Important for me Less important

Laser peripheral iridotomy is correct. The clinical features are highly suggestive of acute angle closure glaucoma (AACG). The patient takes an anti-muscarinic (solifenacin) drug which can precipitate AACG. Definitive management of this condition is with laser peripheral iridotomy.

Acetazolamide is incorrect. This drug can be used in the emergency setting to lower intra-ocular pressures, however, the definitive treatment is with laser peripheral iridotomy.

Laser trabeculoplasty is incorrect. Laser trabeculoplasty is performed as an additional measure to lower the intraocular pressure in patients with open-angle glaucoma. It can also be performed in a closed-angle glaucoma patient with a patent iridotomy (e.g. following a laser peripheral iridotomy).

Pilocarpine is incorrect. This drug can be used in the emergency setting to lower intra-ocular pressures, however, the definitive treatment is with laser peripheral iridotomy.Steroid eye drops and cyclopentolate is incorrect. This combination of medications can be used to treat anterior uveitis. Although this condition also presents with an acutely painful red eye, the presence of a semi-dilated pupil favours the diagnosis of AACG. In anterior uveitis, the pupil is classically oval and non-reactive.

Question 118 of 189

A 55-year-old woman is referred to the neurology outpatient department with a 3-month history of headaches. The headaches are localized to her right temporal region. They are sharp and stabbing in nature and occur approximately 15 times a day, lasting for 20 minutes on each occasion. She notices a runny nose and tearing of her eyes when they occur. This has occurred daily for the time period with no period of remission. She has no past medical history and is not on any regular medications.

The examination is unremarkable at the time of review.

What is the likely diagnosis?

A. Chronic paroxysmal hemicrania
B. Cluster headaches
C. Giant cell arteritis
D. Hemicrania continua
E. Migraine

A. Chronic paroxysmal hemicrania

Chronic paroxysmal hemicrania is characterised by multiple (5+) short (5-30 min) headaches centered around the eye. CPH headaches are shorter and more frequent than cluster headaches

Chronic paroxysmal hemicrania is the correct answer. This headache disorder is characterized by multiple (5+) short (5-30 minutes) headaches localized to the orbital, supraorbital or temporal region that are associated with ipsilateral autonomic features (rhinorrhoea, lacrimation).

Giant cell arteritis is incorrect. This typically causes a persistent rather than intermittent headache and is associated with scalp tenderness and other clinical features such as jaw claudication and visual obscuration.

Migraine is incorrect. Migraines usually last from 4-72 hours and occur with less frequency than chronic paroxysmal hemicrania. There may be an aura that precedes the headaches.Cluster headaches is incorrect. While this can also cause unilateral headaches with ipsilateral autonomic features, the headaches are typically longer (usually 1-3 hours) and less frequent (usually twice a day and rarely more than eight a day).

Hemicrania continua is incorrect. This is a continuous unilateral headache characterized by fluctuation in severity. There is no episodes of being headache free like in chronic paroxysmal hemicrania. It is also associated with ipsilateral autonomic features.

Question 119 of 189

A 45-year-old man is brought to the hospital via ambulance with a tonic-clonic seizure. He has a past medical history of epilepsy, gastro-oesophageal reflux and latent TB. His medications include sodium valproate, omeprazole, isoniazid and he commenced carbamazepine as a consequence of poor seizure control 4 weeks previously. He is known to drink moderate-large quantities of grapefruit juice.

At the time of review, he has recovered and his Glasgow coma scale is 15/15. A CT head is unremarkable.

The ingestion of which substance has caused his seizures?

A. Carbamazepine
B. Grapefruit juice
C. Isoniazid
D. Omeprazole
E. Sodium valproate

A. Carbamazepine

Carbamazepine is known to exhibit autoinduction. hence when patients start carbamazepine they may see a return of seizures after 3-4 weeks of treatment

Carbamazepine is correct. This medication exhibits autoinduction, which means that it may become less effective as a consequence. Due to this loss of response, patients may see a return of seizures 3-4 weeks after commencing treatment.

Grapefruit juice is incorrect. This is a cytochrome P450 enzyme inhibitor and therefore would increase rather than decrease the concentration of another drug.

Isoniazid is incorrect. This is a cytochrome P450 enzyme inhibitor and therefore would increaserather than decrease the concentration of another drug.

Omeprazole is incorrect. This is a cytochrome P450 enzyme inhibitor and therefore would increase rather than decrease the concentration of another drug.

Sodium valproate is incorrect. This is a cytochrome P450 enzyme inhibitor and therefore would increase rather than decrease the concentration of another drug.

Question 120 of 189

You are asked for advice from a GP regarding a 52-year-old woman with a diagnosis of Generalised Anxiety Disorder. She is having symptoms of free-floating anxiety for the past 5 years and this is causing work and relationship difficulties. The GP tells you that 5 years ago she was admitted to hospital with epigastric pain and anaemia and required a therapeutic endoscopy. A repeat endoscopy showed a small ulcer at D2 with a small amount of ooze which was treated with adrenaline. She still suffers from occasional heartburn.

She also has a history of alcohol dependency. She drank 20 units of alcohol per day for 20 years but has now cut down to 1-2 units per day. An ultrasound scan of the abdomen showed mild portal hypertension, hepatomegaly and no gastric varices. There is no history of deliberate selfharm or overdoses. She takes Vitamin B Co strong and thiamine 100mg PO OD and omeprazole 20mg PO OD and is compliant with medication currently but has a history of non-compliance with medication.

Which would be the safest therapy for treatment of her generalised anxiety disorder?

A. Clonazepam
B. Diazepam
C. Sertraline
D. Citalopram
E. Imipramine

E. Imipramine

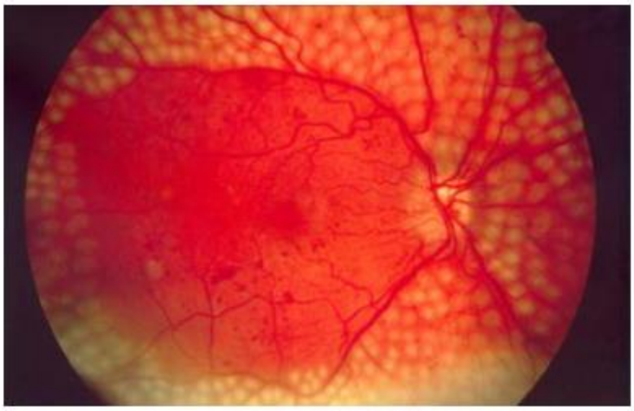
Clonazepam and Diazepam are benzodiazepines. They are not recommended in the treatment of generalised anxiety disorder due to the chronic course of the illness and the dangers of developing tolerance and dependence upon the drug. The risk is even higher in this lady, who has a history of alcohol dependence. In addition, benzodiazepines potentiate the effect of alcohol as they both act on the GABA receptor making it an unsafe medication in someone with a history of alcohol dependency who is still consuming alcohol.

Sertraline and Citalopram are SSRIs. SSRIs inhibit platelet aggregation and are known to increase the risk of upper GI bleeds. This individual has a history of UGI haemorrhage, with recent bleeding duodenal ulcer and continuing symptoms. She also has portal hypertension and continues to drinkalcohol putting him at risk of varices in the future. Whilst being on omeprazole will reduce this risk, there is a history of non-compliance with medication.

Imipramine is a TCA. TCAs are recommended when SSRIs are contraindicated in the treatment of generalised anxiety disorder. There is no increased risk of GI bleeds when on TCAs. It is potentially dangerous in overdose. However, there is no documented history of overdose with this individual

Question 121 of 189

A 67-year-old man with diabetes is attending the outpatient clinic complaining of a headache that has been bothering him for the last week. He reports he experienced some problems with the vision of his left eye two years ago, for which he was treated. Fundoscopic examination of his left eye appears as follows:



What treatment has this man taken for his previous visual problems?

A. Intravitreal ranibizumab
B. Intravitreal voriconazole
C. Laser photocoagulation
D. Oral voriconazole
E. Vitrectomy

C. Laser photocoagulation

Laser photocoagulation is the correct answer. In this fundus picture are dot and blot haemorrhages and neovascularisation of the disc and retina, suggesting background proliferative diabetic retinopathy. There are laser scars in the peripheral retina, which are seen after laser photocoagulation. The pathophysiology, classification and management of diabetic retinopathy are explained in the notes linked below.

Intravitreal ranibizumab is incorrect. Ranibizumab is a VEGF inhibitor, and anti-VEGF agents are used widely to treat some forms of diabetic retinopathy. Indications of anti-VEGF agents in diabetic retinopathy include diabetic macular oedema with visual impairment and proliferativediabetic retinopathy. The patient in this scenario could have had intravitreal ranibizumab administered during his treatment. However, findings in the fundus picture should be considered critical to the solution, making laser photocoagulation the correct answer.

Intravitreal voriconazole is incorrect. This is administered in cases of fungal endophthalmitis involving the vitreous. Fundus examination in cases of fungal endophthalmitis reveals fluffy chorioretinal infiltrates with irregular margins. Diabetic patients have a higher predisposition to develop fungal infections. However, the fundus picture in this case is more suggestive of laser photocoagulation.

Oral voriconazole is incorrect. This is prescribed for conditions such as fungal keratitis. The fundus would not show any specific findings in a case of keratitis, making this an unlikely answer.

Vitrectomy is wrong. Vitrectomy is a procedure employed for treating complications of proliferative diabetic retinopathy like vitreous haemorrhage. Other indications for performing vitrectomy include tractional retinal detachment and progressive neovascularization that does not respond to photocoagulation. The fundus picture shows laser scars, which makes vitrectomy unlikely.

Question 122 of 189

A 26-year-old female presents with a 4-month history of continuous left sided facial pain and frontotemporal headache. She reports it to be constantly present and throbbing in nature, with exacerbations of worsened severity every 3 days. She reports exacerbations to typically be associated with injected left eye and left nasal congestion, with occasional teariness in her left eye.

She has no past medical history or drug history except the oral contraceptive pill. Her routine blood tests are unremarkable. A MRI head organised by her GP also demonstrated no intracranial pathology. A trial indomethacin you have organised is positive.

What is the most likely diagnosis?

A. Short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing (SUNCT)
B. Hemicrania continua
C. Cluster headaches
D. Paroxysmal hemicrania
E. Migraines

B. Hemicrania continua

The patient has a constant headache with exacerbations in the distribution of the left ophthalmic distribution of the fifth cranial nerve associated with autonomic symptoms: this represents one of the trigeminal autonomic cephalgias (TACs). TACs is a class of disorders differentiated by the frequency and duration of attacks, and their response to indomethacin.

SUNCT, paroxysmal hemicrania and cluster headaches present with attacks of approximate duration seconds, minutes to 30 minutes, up to 180 minutes respectively. Symptoms are not present in between attacks. Cluster headaches appear more commonly in men while young women are more predisposed to paroxysmal hemicrania. Hemicrania continua produces pain that is always present with exacerbations in severity. Crucially for diagnosis, only hemicrania continua and paroxysmal hemicrania are responsive to indomethacin, making it a useful diagnostic and therapeutic prophylactic drug.

Question 123 of 189

A 23-year-old investment banking intern presents to the urgent care centre complaining of progressive unsteadiness on walking over the past 6 months. He has no past medical history except type 2 diabetes, which is diet controlled, diagnosed one year ago. He has no family history of any diseases. He has been working very long hours for the past 2 years and reports high levels of stress at work, coupled a culture of 'binge-drinking' to team bond after work. Over the past 3 months, he has noticed a lack of articulation with his speech, which he assumed was secondary to alcohol. He estimates he drinks up to 30 units of alcohol a week. On examination, his cardiovascular, respiratory and abdominal systems are unremarkable. His finger-nose test is impaired bilaterally and is unable to tandem walk. He denies any neck stiffness or headache. He has a full range of eye movements. He has absent reflexes in his lower limbs and upgoing plantars bilaterally.

Which investigation will provide the definitive diagnosis?

A. MRI head with gadolinium contrast
B. CT angiography including posterior vessels
C. Lumbar puncture
D. Serum genetic testing
E. Muscle biopsy

D. Serum genetic testing

The patient describes cerebellar signs of dysarthria, poor coordination and ataxia, in addition to absent ankle jerks and upgoing plantars, presenting at an early age with progressive symptoms. Friedrich's ataxia and other spinocerebellar ataxias must be considered. A diagnosis of type 2 diabetes is odd in such a young patient. However, up to 1/3 of patients with Friedrich's ataxia experience impaired glucose tolerance or diabetes mellitus. These patients often present with cardiomyopathy as well, causing arrhythmias and heart failures.

This patient presents slightly late, most patients have symptoms by childhood. Up to 90% present by 25 years old . It is often assumed that spinocerebellar ataxias, in this case an autosomal recessive one, must be accompanied by a family history. In 40% of Friedrich's ataxia, there is no positive family history at all .

Diagnosis is by serum genetic testing of the GAA trinucleotide repeat. Treatment is limited but involves a multidisciplinary team of neurologists, cardiologists and endocrinologists. There are theories that iron chelation is important in Friedrich's ataxia but these are yet to be proven in large-scale studies2.

Question 124 of 189

A 58-year-old man presents with severe dyspnoea at rest. He has a past medical history of motor neurone disease which was diagnosed 9 months ago. On examination his chest sounds clear. His respiratory rate is 20 breaths per minute with a shallow depth.

You perform an arterial blood gas which is as follows:

PaO2	7.1 kPa
PCO2	6.3 kPa
pH	7.32
HCO3	38 mmol/l

How will you manage this patient?

A. BiPAP
B. CPAP
C. LTOT
D. Palliation of breathlessness with morphine
E. Intubation and ventilation

A. BiPAP

Non-invasive ventilation (NIV) should be the treatment of choice for patients with chest wall or neuromuscular disease causing type 2 respiratory failure. Additional LTOT may be required in case of hypoxaemia not corrected with NIV

The patient has developed type 2 respiratory failure as demonstrated by a PaO2 < 8 kPa and a respiratory acidosis. This is likely due to diaphragmatic weakness secondary to motor neurone disease. Non-invasive ventilation (NIV), in particular BiPAP, should be the treatment of choice for patients with chest wall or neuromuscular disease causing type 2 respiratory failure. Additional LTOT may be required in case of hypoxaemia not corrected with NIV.

Question 125 of 189

A 22-year-old woman presents with a worsening headache. She states that it is worse in the morning and exacerbated by straining. On examination, you note bilateral papilloedema with enlarged blind spots. Visual acuity is 6/6 in both eyes.

Blood results are as follows:

Hb	122 g/L	Male: (135-180) Female: (115 - 160)
Platelets	162 * 10 /L	(150 - 400)
WBC	9.6 * 10 /L	(4.0 - 11.0)
Na	140 mmol/L	(135 - 145)
K	3.9 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	64 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)
Glucose	5.8 mmol/L	(4-7)

A CT head is organised:

CT head	Papilloedema with flattening of the posterior sclera; bilateral venous sinus stenosis predominantly of the lateral segments of the transverse sinuses

A diagnostic lumbar puncture is organised:

Opening pressure	52 cm H2O	(7-18)
WBC count	3 cells/µL	(0-5)
Glucose	5.4 mmol/L	(> 0.7 x serum glucose)
Protein	22 mg/dL	(<45)

What treatment is indicated?

A. Acetazolamide
B. Optic nerve sheath decompression and fenestration
C. Serial lumbar punctures
D. Topiramate
E. Ventriculoperitoneal shunt

A. Acetazolamide

Acetazolamide is a carbonic anhydrase inhibitor that is used to treat idiopathic intracranial hypertension

The radiological and lumbar puncture results support a diagnosis of idiopathic intracranial hypertension (IIH).

The main principles of management of IIH are: to treat the underlying disease to protect the vision to minimise the headache morbidity

Acetazolamide is correct. The patient does not have an imminent threat to vision and should therefore be commenced on acetazolamide, and advised to lose weight if appropriate.

Optic nerve sheath decompression and fenestration is incorrect. There is evidence that many of the surgical procedures, such as CSF diversion and optic nerve sheath fenestration (ONSF), work well in the short term. However since the patient in this case does not have an imminent threat to vision, then medical management should be implemented in the first instance.

Serial lumbar punctures is incorrect. The relief from a lumbar puncture is typically short-lived as CSF is secreted from the choroid plexus at a rate of 25€‰mL/hour and consequently, the volume removed in a so-called therapeutic tap is rapidly replaced. Therefore, Serial lumbar punctures are not recommended for the management of IIH.

Topiramate is incorrect. Topiramate has carbonic anhydrase activity and can suppress appetite. There is growing evidence suggestive of the efficacy of this drug in treating IIH, however, it currently remains a second-line agent.

Ventriculoperitoneal shun is incorrect. Ventriculoperitoneal (VP) is the preferred CSF diversion procedure for visual deterioration in IIH, due to lower reported revisions per patient.

Question 126 of 189

An 80-year-old man has presented with his son who is concerned he is starting to become more confused and forgetful over the last few months. His son also reports that his previously independent father has required more help with activities of daily living, has lost his appetite and is having frequent falls. He has never drunk alcohol or smoked.

MMSE is 20/30. Upon neurological examination of the lower limbs, there is bilaterally increased tone, 3 out of 5 (MRC scale) global weakness, lack of sensation to light touch and vibration up to the knees, brisk knee-jerks and loss of ankle jerk reflexes and extensor plantar reflexes.

Hb	110 g/L	Male: (135-180)
MCV	110 fL	(80-100)

Nerve conduction studies demonstrate a normal conduction velocity but reduced amplitude.

What is the most likely diagnosis?

A. Hypothyroidism
B. Lead poisoning
C. Multiple sclerosis
D. Pernicious anaemia
E. Tabes dorsalis

D. Pernicious anaemia

When interpreting NCS, a reduced amplitude but normal conduction velocity is indicative of axonal pathology

Pernicious anaemia is the correct option due to being the most common cause of macrocytic anaemia in this age group (due to B12 deficiency). Subacute dementia and the subacute degeneration of the spinal cord (affecting the dorsal columns and peripheral nerves to present with the bilateral loss of sensation) with the classic triad of the brisk knee, absent ankle andextensor plantar reflexes can be explained by the B12 deficiency. This deficiency is a result of a chronic lack of intrinsic factors to metabolise dietary B12 to its active form. The lack of B12 has led to the axonal degeneration pattern seen with the reduced amplitude in the nerve conduction studies.

Hypothyroidism is incorrect. Untreated hypothyroidism would cause macrocytic anaemia and axonal neuropathy, however, would not explain the associated cord signs and symptoms described in this case.

Lead poisoning is incorrect, although it is another possible cause for an axonal pattern of nerve degeneration. However, in this case, the lead poisoning would not account for subacute dementia or cord signs.

Multiple sclerosis is incorrect as this does not usually result in cognitive impairment and would usually affect the corticospinal tracts also. Furthermore, it would not cause the axonal pattern in nerve conduction studies. The B12 deficiency is more likely in this case given the signs and symptoms.

Tabes dorsalis is incorrect. This is a result of tertiary syphilis and would explain the neurological signs seen here as it also affects the dorsal columns predominantly, however it would not explain the cause of the macrocytic anaemia.

Question 127 of 189

A 26-year-old woman presents with recurrent slurring of her speech that worsens as she continues to talk. She has double vision that worsens while watching TV and subsequently improves with rest, as well as intermittent weakness of the limbs.

On examination, she has visible ptosis - she explains this also improves with rest. Proximal muscle weakness is evident, with no wasting.

As well as the suspected neurological diagnosis, she demonstrates pyrexia and concurrent infection is suspected. The source is investigated.

Which antibiotic should be avoided, given the likely underlying neurological diagnosis?

A. Co-amoxiclav
B. Gentamicin
C. Meropenem
D. Nitrofurantoin
E. Vancomycin

B. Gentamicin

Aminoglycoside antibiotics are contraindicated in patients with myasthenia gravis due to the risk of fatal myasthenic crisis and respiratory failure

The history described above is highly suggestive of myasthenia gravis, given the history and signs found on examination. In a patient with this condition, a number of drugs may cause significant exacerbations and increase the risk of myasthenic crises. A number of antibiotics are contraindicated, including aminoglycosides such as gentamicin. Other classes generally avoided include macrolides, quinolones and tetracyclines.

Co-amoxiclav is generally considered safe to use in myasthenia gravis, as are other penicillinbased antibiotics.Meropenem is a beta-lactam antibiotic used in many situations where broad-spectrum treatment is needed. It is also considered safe to use in myasthenia gravis.

Nitrofurantoin is commonly used for the treatment of urinary tract infections. It is considered safe in patients with myasthenia gravis.

Vancomycin is a glycopeptide antibiotic, often used for complex or resistant infections. It is thought to be safe to use in myasthenia gravis.

Question 128 of 189

A 27-year-old man attends ambulatory care with a one day history of facial droop. He is a mountain bike instructor and is extremely anxious that this may be related to a fall last month. He hasn't been riding for the last month because he has felt unwell with aches and pains and some odd bruising up his leg.

On examination he has a bilateral VII nerve weakness but no other cranial nerve lesions detected. The arms and legs show no focal neurology.

Skin is intact with no skin lesions seen. There is no evidence of any joint effusions and all joints appear to have a full range of motion

Investigations:

Haemoglobin	127 g/L (130-180)
White cell count	10.0 Ã— 109/L (4.0-11.0)

Chest X-ray	Normal

What is the most likely diagnosis?

A. Sarcoidosis
B. Lyme disease
C. Syphilis
D. Bells palsy
E. Subdural haemorrhage

B. Lyme disease

This patient has bilateral seventh nerve palsy. The most likely diagnosis is Lyme disease. Lyme disease is caused by Borrelia burgdorferi bacteria that affects human from ticks that also feed on rodents.

Infected tick bites are common especially in the New Forest area of the UK. 70-80% of persons infected develop a rash (erythema migrans - target rash). Weeks after the initial bite thespirochetes spread via the bloodstream to joints, heart and nervous system.

Syphilis is on the rise but the more likely cause of the bilateral seventh nerve palsy is Lyme disease especially given the rash.

Subdural haemorrhage can occur after trauma - such as bike fall. Symptoms are likely to occur within days rather than having a first presentation one month after the accident.

Question 129 of 189

A 25-year-old lady attends her first neurologist appointment after moving areas. She has been referred by her GP with possible migraines for which she was receiving acetazolamide.

She attends reporting that the headaches are severe. They are typically up to 10/10 and are worse at the start of the day and improves as her day progresses. She finds sitting in a chair helpful and can sometimes vomit with them. Coughing and chewing hard food makes the headaches worse.

On examination, she has normal eye movements. Her optic discs appear a little blurred and there are no visual field defects. She refuses to lie flat and is non tender over her temporal scalp. She has normal observations and is afebrile. Her most recent tests are transferred to you

Na	132 mmol/l
K	3.1 mmol/l
Urea	4.2 mmol/l
Creatinine	76 µmol/l
HCO3	18mmol/l
MRI head	No mass lesion seen, increased subarachnoid space around the optic nerves

What is the most appropriate management?

A. Endovascular clipping
B. Lumbar puncture
C. Nifedipine
D. Sumatriptan
E. Refer to neurosurgery

B. Lumbar puncture

Idiopathic intracranial hypertension -> lumbar puncture is 2nd line treatment

The key to headaches is the history. This is not sudden and so is not a subarachnoid haemorrhage and nifedipine and endovascular clipping would therefore be inappropriate. Likewise, it does not sound entirely migrainous and sumatriptan would probably not help. There are no features that warrant a referral to neurosurgery. The enlarged subarachnoid space and postural headache suggest this is idiopathic intracranial hypertension. The first line is medicines like carbonic anhydrase inhibitors and if these fail then therapeutic lumbar puncture should be provided.

Question 130 of 189

A 50-year-old man is seen in the Emergency Department with fevers. He has been feeling generally unwell for the last 3 days and has just returned from a 2 week stay with his sister who lives on the other side of the U.K. He has had a mild non-productive cough and shortness of breath. He has had no vomitting, diarrhoea, dysuria or abdominal pain.

He has a past medical history of epilepsy, schizophrenia, hypertension and diet-controlled type 2 diabetes.

On examination he has a temperature of 38.3 ºC and is saturating at 94% on room air. His heart rate is 111 beats per minute and blood pressure is 118/75 mmHg. He looks clammy and pale but systems examination is otherwise unremarkable.

His chest x-ray shows clear lung fields. His blood tests are as follows:

Hb	140 g/l	Na	141 mmol/l
Platelets	443 * 10 /l	K	3.7 mmol/l
WBC	1.5 * 10 /l	Urea	7 mmol/l
Neuts	0.6 * 10 /l	Creatinine	98 µmol/l
Lymphs	0.5 * 10 /l	CRP	170 mg/l

He is started on broad spectrum antibiotics and fluids.

Which drug is most likely to have precipitated this condition?

A. Clobazam
B. Clozapine
C. Phenytoin
D. Sodium valproate
E. Venlafaxine

B. Clozapine

Agranulocytosis/neutropenia is a life-threatening side effect of clozapine - monitor FBC

This gentleman has neutropenic sepsis. The antipsychotic clozapine is well documented to cause agranulocytosis, neutropenia and lymphopenia. Patients on clozapine must be registered with the monitoring service specific to their brand of the drug and have regular drug levels and full blood counts. This gentleman has been travelling and has likely missed his monitoring appointment.

Clobazam side effects include drowsiness and confusion.

Phenytoin can cause leucopenia but this is unlikely in the absence of its other extensive side effect profile which includes drowsiness, tremor, gum hypertrophy, acne and hirsutism.

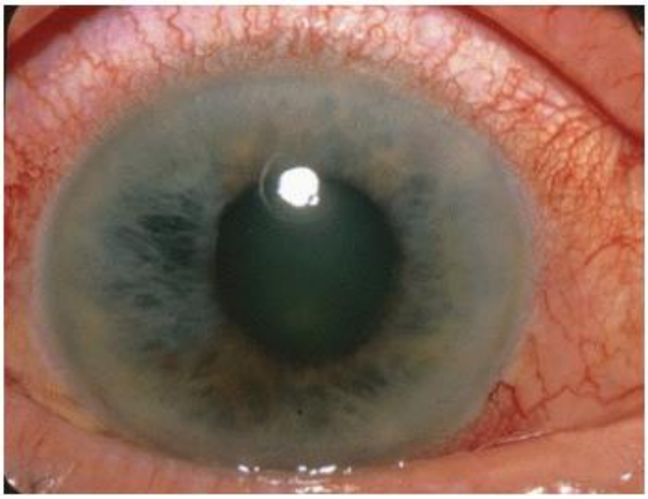
Sodium valproate also has a broad side effect profile which includes nausea, diarrhoea, weight gain, extra-pyramidal symptoms and hair loss. Again leucopenia is a documented side effect but rare.

Venlafaxine is associated with changes to serum cholesterol, hypertension, micturition disturbance and vasodilatation.

Question 131 of 189

A 50-year-old man presents to the emergency department with a painful right eye. The pain started approximately 4 hours ago whilst watching a movie. He also reports that his vision is blurry in the same eye. His past medical history includes type 2 diabetes and rheumatoid arthritis.

His eye is examined, as shown below:



What is the most appropriate management for this patient?

A. Reassurance and discharge
B. Topical aciclovir
C. Topical chloramphenicol
D. Topical corticosteroids
E. Topical timolol

E. Topical timolol

Topical timolol is correct. This patient's right eye is erythematous with a semi-dilated pupil. Combined with the clinical history and examination findings of reduced visual acuity, the patient has a likely diagnosis of acute angle-closure glaucoma. Hypermetropia (long-sightedness) is also a risk factor for acute angle-closure glaucoma. The management consists of reducing the intraocular pressure with a combination of medications to reduce aqueous humour production and increase uveoscleral outflow. Timolol is a beta-blocker eye drop that decreases aqueous humourproduction. Of note, acute angle-closure glaucoma is an ophthalmological emergency and requires urgent referral to ophthalmology. A combination of drugs is required in addition to timolol including, a muscarinic agonist eye drop (e.g. pilocarpine) and intravenous acetazolamide.

Reassurance and discharge is incorrect. Acute angle-closure glaucoma is an ophthalmological emergency and discharging home without intervention can result in blindness in the affected eye.

Topical aciclovir is incorrect. This is used in the management of viral ocular infections (e.g. herpes simplex virus). This usually presents with eye pain, watering and irritation. The eye may be erythematous and there are occasionally ulcers or vesicles seen along the eyelid margins. Examination of the eye with blue light after fluorescein administration may reveal the presence of a dendritic ulcer.

Topical chloramphenicol is incorrect. This is used in the management of bacterial conjunctivitis and keratitis. Keratitis is a potential differential diagnosis for this patient given the history of contact lens use. Symptoms of keratitis include erythema, photophobia, pain and lacrimation that are similar to this patient. However, it does not cause pupil dilatation making acute angle-closure glaucoma more likely.

Topical corticosteroids is incorrect. This is used in the management of anterior uveitis that presents as ocular pain, erythema and reduced visual acuity. Anterior uveitis is often associated with inflammatory conditions (e.g. ankylosing spondylitis). However, a change in pupil size is not a feature of anterior uveitis making it less likely to be the underlying diagnosis.

Question 132 of 189

A 80 year old woman is referred to neurology clinic after experiencing increasing diplopia, typically worsening during the course of the day. The patient reported no speech or swallowing problems and no limb weakness.

Past medical history included chronic obstructive pulmonary disease and ischaemic heart disease. The patient was able to mobilise around her flat with a frame but was required to use a wheelchair outside the home due to exertional breathlessness. Regular medications were inhaled salbutamol and tiotropium, aspirin, simvastatin, bisoprolol and ramipril. The patient lived with her husband and had once daily carers to assist with activities of daily living.

Examination in clinic was significant for the development of ptosis on prolonged upwards gaze. There was no significant weakness of facial muscles, palate or tongue. There was no evidence of fatiguable weakness in the arms or legs.

A summary of the patients investigations is given below.

Serum acetylcholine receptor antibodies	negative
Serum muscle specific tyrosine kinase	positive

Neurophysiology: no evidence of repetitive nerve stimulation

CT thorax: retro-sternal soft-tissue density mass equal in attenuation to muscle; mass demonstrates heterogeneous enhancement following contrast injection

What is the appropriate management of the retro-sternal mass?

A. Proceed to thymectomy
B. Proceed to thymectomy if patient does not respond to first line treatment
C. Surgical biopsy
D. No action required
E. Trans-bronchial biopsy

D. No action required

Thymectomy is a well recognised treatment for myasthenia gravis and should also be consideredin non-thymomatous generalised myasthenia in patients with antibodies to acetylcholine receptor who are aged under 50. Biopsy is not generally required prior to surgery.

However, thymectomy is not generally carried out in myasthenia gravis when patients have antibodies to MUSK, late onset disease or purely ocular disease as in this case. The patient's poor performance status would also argue against surgical intervention.

Repetitive nerve stimulation is a specific test for myasthenia gravis but has a relatively low sensitivity, especially in ocular only disease.

Question 133 of 189

A 24-year-old man presents with lower limb weakness. His past medical history is largely unremarkable, however, he does admit to intravenous drug use with heroin. He last injected heroin three weeks ago.

On examination, you note weakness of ankle plantar flexion (MRC grade 3), ankle dorsiflexion (MRC grade 3), knee flexion (MRC grade 4) and knee extension (MRC grade 4). The ankle jerk and knee jerk are only present on reinforcement. There is a loss of sensation to the mid-calves. A neurological examination was otherwise unremarkable.

What treatment is indicated?

A. Botulism antitoxin
B. Intravenous immunoglobulin (IVIG)
C. Plasma exchange
D. Steroids
E. Tetanus immunoglobulin

B. Intravenous immunoglobulin (IVIG)

IVIG is generally used first-line for Guillain-Barre syndrome

Intravenous immunoglobulin (IVIG) is correct. The most likely diagnosis is Guillain-Barre syndrome. IVIG is generally used as first-line management for Guillain-Barre syndrome.

Botulism antitoxin is incorrect. Botulism is characterised by a descending, flaccid paralysis, in contrast to Guillain-Barre syndrome which presents with an ascending paralysis. It is important to note that the patient is an intravenous drug user which is a risk factor for botulism.

Plasma exchange is incorrect. Although plasma exchange is just as effective as IVIG, it has more risks associated with it and is much more labour-intensive. For these reasons, IVIG is usually used first-line.Steroids is incorrect. Several trials have shown no benefit of steroids or immunosuppressants in Guillain-Barre syndrome.

Tetanus immunoglobulin is incorrect. Tetanus is a life-threatening disease characterised by a descending spastic paralysis. Although the causative bacteria Clostridium tetani has been found in contaminated heroin, the clinical features of an ascending paralysis are more suggestive of Guillain-Barre syndrome.

Question 134 of 189

A 23-year-old university student presented with a year long history of occipital headache. This was worse on coughing, sneezing and straining and partially relieved by lying flat. On one occasion the headache had been associated with vomiting. She had previously consulted her family doctor who was treating her for migraine. Over the past two months she had noticed pain in her both arms and felt unsteady on her feet.

On examination touching her arms caused pain and there was reduced appreciation of pinprick and temperature sensation throughout both arms. Tone, power and reflexes in the upper limbs were normal. On testing upper limb co-ordination there was some past-pointing and a very mild intention tremor. On inspection of the feet there was pes cavus and Rombergs test was positive. Again tone, power and reflexes were normal in the lower limbs and plantars were downgoing. Proprioception was impaired with absent joint position sense until the level of the knee. Vibration sensation was impaired in both feet.

Given the clinical findings outlined above which of the following is the most likely diagnosis?

A. Syringomyelia
B. Friedrichs ataxia
C. Brown-Sequard syndrome
D. Charcot-Marie-
E. Tooth disease Multiple sclerosis

A. Syringomyelia

Syringomyelia results from the formation of a fluid filled cavitation (called a syrinx) within the central canal of the spinal cord. The most common cause of a syrinx is obstruction to the flow of cerebrospinal fluid (CSF) by an Arnold Chiari malformation. An Arnold Chiari malformation is a developmental abnormality in which the cerebellar tonsils project through the foramen magnum and sit in a position which is normally occupied by the cervical spinal cord.

In this case the patient has features suggestive of an underlying Arnold Chiari malformation: occipital headache exacerbated by valsalva manoeuvre (coughing, sneezing and straining), pes cavus and cerebellar signs (past pointing and intention tremor in the upper limbs).

She also has features of an associated syringomyelia. The spinothalamic tracts are involved early inthe process due to their decussation within the cord. This means that there is loss of pain and temperature sensation corresponding to the level of the syrinx. This often occurs in a shawl-like distribution. Hyperalgesia and allodynia are also seen in the upper limbs in some cases.

As the syrinx enlarges the dorsal columns are affected resulting in loss of proprioception and vibration sensation in the lower limbs. This explains the positive Rombergs test which indicates that there is a proprioceptive problem.

If the syrinx expands further the anterior horn cells can be affected resulting in wasting and weakness in the hands.

Friedrichs ataxia is an autosomal recessive inherited condition in which there is progressive ataxia, dysarthria, loss of proprioceptive and vibration sensation and weakness.

Brown-Sequard syndrome results from a lateral hemisection of the spinal cord. It presents with a loss of pain and temperature sensation on the side of the body contralateral to the lesion and a hemiplegia and loss of vibration sensation and proprioception on the ipsilateral side to the lesion.

Charcot-Marie-Tooth (also known as Hereditary Sensory and Motor neuropathy) encompasses a group of inherited conditions which present in mid-adult life with peripheral neuropathy. Patients commonly have pes cavus and often present with foot drop.

Multiple sclerosis (MS) can present in a variety of ways with cerebellar features, optic neuritis, paraesthesiae and tranverse myelitis all being reported. Although in theory many of the clinical features in this question could be explained by an underlying diagnosis of MS, the clinical presentation here is typical of syringomyelia secondary to an underlying Arnold Chiari malformation.

Question 135 of 189

A 34-year-old man presents with insidious onset right hand weakness over the last week. He is right hand dominant and struggling to perform basic tasks such as opening a door with a key.

On examination he has marked weakness of thumb flexion at the interphalangeal joint and weakness of flexion of the index and middle finger. There is no detectable sensory deficit.

What is the likely diagnosis?

A. C8 nerve root radiculopathy
B. Motor neurone disease
C. Median nerve palsy
D. Carpal tunnel syndrome
E. Anterior interosseous syndrome

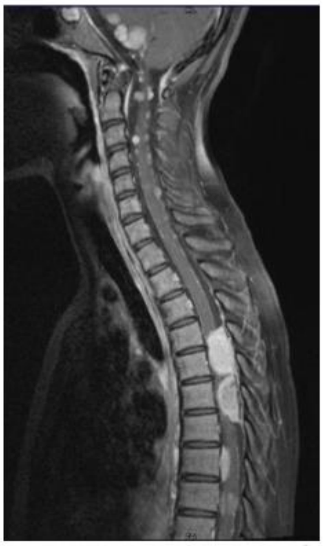
Question 136 of 189

A 24-year-old woman is referred urgently to neurology for lower limb weakness. This has been getting gradually worse over the past 4 weeks and she is now experiencing problems walking.

She also complains of bilateral tinnitus which has been present for the past 3 months. This is associated with episodes of vertigo.

On examination, both lower limbs have reduced power (3/5), with increased tone and hyperreflexia. The patient has one 1cm tan lesion on her torso but no other skin lesions are noted.

An MRI of her spine is requested:



What is the most likely diagnosis?

A. Multiple sclerosis
B. Neurofibromatosis
C. Von Hippel-Lindau disease
D. Tuberous sclerosis
E. Ataxia telangiectasia

B. Neurofibromatosis

This patient had neurofibromatosis type 2 (NF2). The MRI shows multiple tumours of the spinal cord in the context of the syndrome of multiple intracranial schwannomas, mengiomas and ependymomas.

Patients with NF2, in contrast to type 1, often have few skin changes. This patient had tinnitus due to the presence of bilateral acoustic neuromas.

The diagnostic criteria for NF2 are:

- Bilateral vestibular schwannomas
- A first degree relative with NF2 AND
    - Unilateral vestibular schwannoma OR
    - Any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

Unilateral vestibular schwannoma AND

- Any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

Multiple meningiomas AND

- Unilateral vestibular schwannoma OR
- Any two of: schwannoma, glioma, neurofibroma, cataract

Question 137 of 189

A 65-year-old male presents to the neurology outpatient department with a history of recurrent bouts of unsteadiness and vomiting over the last 10 years, with partial resolution. He has also had episodes of visual problems, which he describes as the sudden loss of vision in the right eye, with an almost complete recovery of vision over the course of the next few weeks. He has a history of type 2 diabetes and is hypertensive and is generally non-compliant with his treatment. He is also a smoker with a 50 pack year history.

His medication includes glimepiride 2mg daily and metformin 500mg TDS. He also takes telmisartan 40mg daily.

On examination, he has nystagmus in the right eye with the fast component towards the right. His gait is ataxic and he has evidence of spasticity in both lower limbs with exaggerated reflexes and bilateral ankle clonus. Fundoscopic examination revealed a pale optic disc.

MRI brain shows diffuse lesions in multiple sites. The report queried demyelinating plaques vs multiple infarcts.

Which of the following would be the most appropriate next investigation?

A. MRI spinal cord
B. CSF examination for oligoclonal bands
C. MR angiography of the verterbrobasilar system
D. Titres of anti-Hu antibodies
E. Visual evoked potentials

A. MRI spinal cord

The diagnosis, in this case, is that of multiple sclerosis and the question aims to assess the candidate's ability to plan further investigations if the MRI of the brain is inconclusive.

An MRI of the brain is a sensitive imaging modality for the detection of plaques in patients with MS, but it lacks specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination. The presence of spinal cord lesions, however, is quite specific for inflammatory disorders such as MS rather than ischaemic lesions. Thus cord imaging is useful when there is diagnostic difficulty.

Oligoclonal bands are found in the CSF in >90% of cases of MS but are not specific for MS. They are also found in

- Lyme disease
- Systemic lupus erythematosus
- Neurosarcoidosis
- Subacute sclerosing panencephalitis
- Subarachnoid hemorrhage
- Syphilis
- Primary central nervous system lymphoma
- Sjogren's syndrome
- Guillain-Barre syndrome
- Meningeal carcinomatosis
- Neuromyelitis optica

Question 138 of 189

A 55-year-old cachectic male is brought into hospital after having been found on the floor by his sister, who visits him once a week. She reports a long history of depression and his appetite to have been poor for a number of years. He denies any loss of consciousness episodes, palpitations, chest pain, dysphagia or presyncopal symptoms. When asked how he ended up on the floor, he vaguely reports to have slowly fallen from being generally weak and denies head injury. He does report a recent sore throat and dry cough. He is alert and orientated. On examination, he scores 3 and 4 out of 5 power in all movements. Lower limb reflexes could not be elicited with a tendon hammer but bilateral upgoing plantars are noted.

Which treatment might reverse the underlying condition most rapidly?

A. IV methylprednisolone
B. IV immunoglobulin infusion
C. Plasmapheresis
D. IV thrombolysis
E. IM vitamin B12 + IV pabrinex

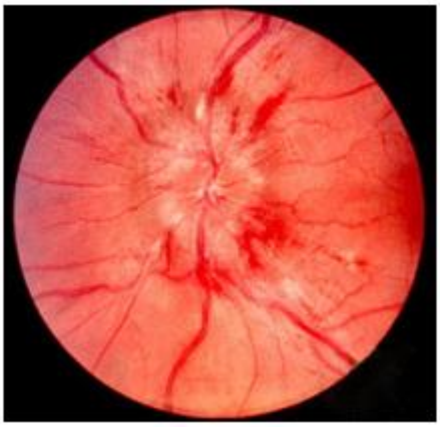
E. IM vitamin B12 + IV pabrinex

The patient presents with upgoing plantars and absent ankle jerks. This should alert all MRCP candidates to 5 classic diagnoses: subacute combined degeneration of the cord (SCDC), motor neurone disease, Friedrich's ataxia, tabes dorsalis (syphilis) and dual peripheral with central pathology. In the context of cachexia and poor oral intake should alert a vitamin B12 deficiency, leading to a combination of peripheral and dorsal column degeneration, known as subacute combined degeneration of the cord. Vitamin B12 can in some cases reverse the neurology very rapidly.

Question 139 of 189

A 44-year-old woman presents to the emergency department with a 2-week history of worsening headaches. She also complains of occasional bouts of dizziness and double vision. Her past medical history includes borderline type 2 diabetes and her regular medications include metformin and the combined contraceptive pill.

On examination, her observations are within normal limits. Her BMI is 32 kg/m². There is no focal neurology to find on examination. Fundoscopy is carried out (as shown below):



Given the finding from this patient's fundoscopy, what is the next step in the management of this patient?

A. CT head
B. Reassurance and routine ophthalmology follow up in 2 weeks
C. Topical corticosteroids
D. Urgent lumbar puncture
E. Urgent referral to ophthalmology

A. CT head

This patient has papilloedema on fundoscopic examination, as seen with the enlarged optic disc with blurred margins and venous congestion. Papilloedema arises secondary to raised intracranial pressure (e.g. inflammation, infection, malignancy or idiopathic intracranial hypertension). Given this finding on examination, in addition to the symptoms of headache, dizziness and blurredvision, it is most important to complete a CT head to rule out any space-occupying lesion that may be causing raised intracranial pressure.

Reassurance and routine ophthalmology follow-up in 2 weeks is incorrect. It is not appropriate to discharge with follow-up at this stage as a combination of papilloedema and headaches can be suggestive of serious underlying pathology such as an intracranial tumour. Therefore, a CT head must be requested.

Topical corticosteroids are incorrect. Topical corticosteroids are used for the treatment of anterior uveitis, a condition that causes a painful red eye with photophobia and blurred vision. Patients also require an urgent review by ophthalmology. However, topical corticosteroids have no role in the treatment of papilloedema.

Urgent lumbar puncture is incorrect. A lumbar puncture is a reasonable investigation to request given the possibility of this patient having idiopathic intracranial hypertension (given the presence of an obese woman taking oral contraceptives) or an infectious cause of her headache. However, a lumbar puncture must not be completed until after a CT head is performed to rule out a spaceoccupying lesion that may be responsible for raised intracranial pressure.

Urgent referral to ophthalmology is incorrect. Although papilloedema is a worrying feature to find on examination, it does not require an urgent referral to ophthalmology. Rather, it requires neuroimaging to rule out intracranial pathology.

Question 140 of 189

A 24-year-old woman is admitted with a fever and headache. She reports this began acutely and worsened over the last 24 hours, now being associated with difficulty looking at lights.

She is febrile and photophobic with neck stiffness present. Her other observations are normal. GCS is 15 and no seizure activity is reported. There are no focal neurological deficits and no rash is observed.

She is commenced on IV ceftriaxone and dexamethasone for presumed bacterial meningitis. A lumbar puncture is performed which yields the following results.

Opening pressure	14cm H2O (6-15)
WBC	127 cells/mm³ (<5)
WBC Differential	85% lymphocytes, 15 % polymorphs
CSF Protein	0.7g/L (0.2-0.4)
CSF Glucose	4.9mmol/L (>2/3 serum)
Serum glucose	5.6mmol/L (3.3 - 5.8)
Culture	No organisms isolated
Bacterial PCR	Negative for *Neisseria meningitidis*, *Streptococcus pneumoniae* and *Haemophilus influenzae*
Viral PCR	Positive for Herpes simplex virus type 2

What is the most appropriate course of action?

A. Add IV aciclovir
B. Continue dexamethasone for 4 days and ceftriaxone for 10 days
C. Stop ceftriaxone and dexamethasone, start IV aciclovir for 14 days then repeat LP
D. Stop ceftriaxone and dexamethasone, start oral valaciclovir
E. Stop ceftriaxone and dexamethasone, supportive treatment only

E. Stop ceftriaxone and dexamethasone, supportive treatment only

Herpes simplex meningitis does not require treatment. This is in contrast to herpes simplex encephalitis which requires 14-21 days of intravenous aciclovirImportant for me Less important

The correct answer is stop ceftriaxone and dexamethasone, supportive treatment only. This patient's clinical presentation is consistent with a meningitic process which presents with fever, headache, neck stiffness, and photophobia. Viral meningitis, in stark contrast to viral encephalitis or bacterial meningitis, generally does not require treatment. Antibiotics should be discontinued and with supportive treatment, the condition generally resolves in 2-5 days. Enteroviruses are the most common cause, but HSV type 2 is recognised and associated with a condition now called recurrent benign lymphocytic meningitis.

Add IV aciclovir is incorrect. IV aciclovir is the treatment of choice for viral encephalitis caused by herpes simplex virus type 1. This condition involves inflammation of the brain parenchyma rather than the meninges. It results in an altered conscious level, agitation, seizures, and/or focal neurological deficits. None of these are described in this case. There would also be no rationale for continuing ceftriaxone and dexamethasone with negative cultures and a CSF examination consistent with a viral infection.

Continue dexamethasone for 4 days and ceftriaxone for 10 days is incorrect. This is the treatment recommendation for pneumococcal meningitis. This more commonly affects older adults, with bacterial meningitis in younger adults more commonly meningococcal. CSF in pneumococcal meningitis generally shows a predominance of polymorphs with raised protein and low glucose. Cultures may be negative where antibiotics have been given before lumbar puncture, but the negative bacterial PCR is reassuring.

Stop ceftriaxone and dexamethasone, start IV aciclovir for 14 days then repeat LP is incorrect. This would be the treatment of choice for HSV encephalitis, usually caused by HSV type 1. As discussed above, this presents with an altered conscious level, agitation, seizures, and/or focal neurological deficit. If the repeat LP at 14 days remains PCR positive, treatment is extended for a further 7 days.

Stop ceftriaxone and dexamethasone, start oral valaciclovir is incorrect. Valaciclovir is an alternative agent to oral aciclovir which can help with compliance, as it is administered twice daily rather than 5 times daily. However, its use is in oral or genital HSV infection rather than CNS infection. Also, as discussed above, there is no need for treatment in the case described.

Question 141 of 189

A 65-year-old woman presents to her general practitioner with a two-month history of a severe, 'all-over' throbbing headache, which varies in intensity over the course of the day. She has a past medical history of obesity and a traumatic fracture of the knee three months previously. She takes codeine regularly. She smokes 10 cigarettes per day.

The examination is unremarkable and the fundoscopy is normal. Her body mass index is 42 kg/m². A CT of her brain shows no abnormality.

Blood tests: CRP 3mg/L (<5)

Given the likely diagnosis, what is the appropriate management?

A. Acetazolamide
B. Prednisolone
C. Therapeutic lumbar puncture
D. Withdraw codeine gradually
E. Withdraw codeine now

D. Withdraw codeine gradually

Medication overuse headache

simple analgesia + triptans: stop abruptly

opioid analgesia: withdraw gradually

Withdraw codeine gradually is the correct answer. The patient presents with a new daily headache. As she has had a recent fracture, it is likely that codeine treatment was started at the same time. This new headache occurring after commencing opioid analgesia is likely reflective of a medication overuse headache. It varies over the course of the day as the dose of codeine wears off before the next dose is taken. Management of a codeine-associated medication overuse headache is to withdraw the medication gradually.Acetazolamide is incorrect. She is overweight and this would put her at risk of developing idiopathic intracranial hypertension (IIH). However, fundoscopy has excluded papilloedema and so this makes this diagnosis unlikely. Furthermore, headaches associated with raised intracranial pressure are typically specifically worse in the morning rather than varying over the course of the day.

Therapeutic lumbar puncture is incorrect. This is an option for the treatment of IIH if confirmed. However, that diagnosis is unlikely in the setting of a normal fundoscopic examination.

Prednisolone is incorrect. Any new headache in someone > 50 should prompt consideration of giant cell arteritis (GCA). However, the headache of GCA is typically unilateral and associated with scalp tenderness. Additionally, it is extremely unlikely to have this condition and a normal CRP (now felt to be a more accurate marker of systemic inflammation than ESR in this condition).

Withdraw codeine now is incorrect. Withdrawal of opioids in medication overuse headache should be gradual rather than abrupt to avoid withdrawal and a worsening of the clinical situation.

Question 142 of 189

A 19-year-old lady comes to her clinic appointment and is distraught. She has had severe headaches for the past year and this has led to her dropping out of her university degree. These often stop her doing anything else. She has vomits most days of the week when the pain is at its worse and her vision feels blurry. She has been managed by her GP who has tried sumatriptan, NSAIDs, paracetamol and relaxation techniques all without much benefit. She is currently taking sertraline for depression and she does not smoke.

Her headache are a constant severe frontal headache with radiation around the eyes. She can vomit at times and this is commonly before with her breakfast. She has rarely found relief from these but does note that her symptoms are better in the evenings.

On examination, she has normal visual fields. All her limbs have equal strength and normal tone. There is no sensory loss. Her fundi show no bleeds or exudate but the disc is blurred. She has a raised body mass index of 26kg/m² and afebrile. She has no sinus tenderness and not inflammation of the upper respiratory tract mucosa can be seen.

Na	138 mmol/l
K	4.3 mmol/l
Urea	5.1 mmol/l

Creatinine	87 µmol/l
CT head	no intracranial haemorrhage, mass effect or lesions seen
MRI head	flattening of the sclera of the eye, partially empty sella turcica, enlarged subarachnoid space around the oculomotor and optic nerves

What is the likely diagnosis?

A. Ependymoma
B. Idiopathic intracranial hypertension
C. Venous sinus thrombosis
D. Myopia
E. Chronic sinusitis

Postural headache but normal imaging -> idiopathic intracranial hypertension

This is a chronic postural headache suggested by its improvement as the day progresses. Myopia and chronic sinusitis would not cause a postural headache. Ependymoma and a venous sinus thrombosis would both be seen on imaging. Therefore, by exclusion, this headache is idiopathic intracranial hypertension.

Question 143 of 189

A 23-year-old man presents to you in General Practice with symptoms of low mood, anhedonia, irritability and disturbed sleep. He denies feelings of self-harm or suicidal ideation.

His PHQ-9 score is 10 indicating moderate depression. You refer him for cognitive behavioural therapy (CBT) and decide to commence him on fluoxetine.

What is the most appropriate next step in follow-up for this patient?

A. Follow up review in the community within 2 weeks
B. Follow up review in the community within 7 days
C. Follow up review in the community within 72 hours
D. No routine follow up required - patient to represent if needed
E. Referral to mental health services

B. Follow up review in the community within 7 days

Patients ≤ 25 years who have been started on an SSRI should be reviewed after 1 week

This patient has moderate depression as indicated by their PHQ-9 score. Patients under the age of 25 who are started on an SSRI should be followed up within 1 week due to the increased risk of suicide within this age group and therefore option 2 - follow-up review in the community within 7 days is the correct answer. Patients over the age of 25 who are started on antidepressant therapy should be followed up in the community within 2 weeks.

Follow-up in the community within 2 weeks and follow up in the community within 72 hours are incorrect as they are not the recommended time scales for follow-up.

No routine follow-up required - patient to represent if needed is incorrect as all patients who are initiated on antidepressant therapy should have planned follow-up due to the risk of worsening symptoms when initiating treatment.Referral to mental health services is incorrect as there is no indication for referral to mental health services at this stage.

Question 144 of 189

A 60 yr old woman went swimming with her family, and after finishing her swim and having a shower, her daughter noted that she became confused suddenly, repetitively asking if they had gone for a swim today. She could not remember events that occurred in the past 24 hours, and when told the answers to her questions, would ask the same question 5 minutes later. There was no change in her personality, no change in her speech, nor any muscle weakness. She is able to recall her address, the names of her daughters and husband, and her date of birth. Her daughter said her mother did not suffer any trauma during the swim, and did not lose consciousness anytime throughout the day. The patient's past medical history includes hypertension and depression, and she takes ramipril 2.5mg once daily, and citalopram 20mg once daily.

On examination the patient was alert, but constantly asked where she was and why was she in hospital. She was afebrile, heart rate 80 bpm, blood pressure 138/68 mmHg, respiratory rate of 18 breaths per minute, and oxygen saturation of 99% on air. Neurological examination was unremarkable, but her abbreviated mental test score was 6/10.

Her investigation results were as follow:

C Reactive protein	4 mg/l
Haemoglobin	14.8 g/dl
White cell count	5.6 x 10^9/L
Na+	142 mmol/l
K+	4.3 mmol/l
Urea	4.2 mmol/l
Creatinine	68 µmol/l
Corrected calcium	2.32 mmol/l
Plasma glucose	5.8 mmol/

Computer Tomography (CT) head scan No acute intracranial pathology. Over the next 12 hours, her memory improves and she is discharged from the observation ward.

What is the best advice for the patient with regards to driving in the future?

A. She can drive 4 weeks after the event if the cause has been identified and treated
B. DVLA need not be notified, no driving restrictions
C. She must be symptom free for 1 year before being eligible to drive
D. DVLA must be informed, and her licence will be revoked for 6 months
E. She must cease driving until there is satisfactory control of her symptoms

This lady has suffered an episode of transient global amnesia, a neurological condition characterised by acute short term memory loss, lasting no more than 24 hours. Patients often developed perseveration, with repetitive questioning as they are unable to keep short term memory, but are able to recall long term memories. The aetiology of this condition is unknown.

DVLA guidelines for transient global amnesia are that as long as epilepsy, any sequelae from head injury and other causes of altered awareness have been excluded, there are no restrictions on driving and the DVLA need not be informed.

Question 145 of 189

A 43-year-old right-handed female legal secretary has presented into your general medical clinic in an extremely distressed state. Over the past 2 weeks, she has been 'unable to write'. When questioned further, she reports that she 'wants to write but my hand just stops as soon as I pick up the pen.' She has no past medical history, lives with her husband and is a non-smoker and nondrinker. On examination, her neurological examination is unremarkable. You ask her to write. Her hand and fingers suddenly flex, resulting in illegible handwriting.

What is the most likely diagnosis?

A. Psychogenic functional neurology
B. Focal dystonia
C. Dominant parietal lobe space occupying lesion
D. Right median nerve palsy
E. Brachial plexopathy

B. Focal dystonia

The patient describes a history suggestive of writers cramp, a focal dystonia characterised by flexion, extension or rotation of the muscles of the hand. The underlying pathophysiology is unclear but is thought to relate to a change in the plasticity of cortical networks.

Question 146 of 189

A 68-year-old female presents via blue light ambulance to the emergency department with a first seizure, witnessed by her husband. He describes a sudden onset limb jerking lasting for around 6 minutes, associated with urinary incontinence and tongue biting, with a period of confusion and drowsiness immediately after. He is not aware of her having had any previous seizures, she has no other past medical history and does not take drugs on a medical history. He, however, does describe her to be 'not quite herself' over the past four weeks when she appears to have been extremely agitated and occasionally extremely paranoid. He had thought it to be linked to her not feeling very well, during a period when she had complained of a 'flu-like' headache, generalised muscle ache and a non-productive cough.

You examine her, finding significant gait and limb ataxia with no truncal ataxia. Her blood tests are unremarkable except for positive anti-NMDA antibodies. Her MRI scan demonstrates swelling in bilateral limbic cortices and other no other intracranial abnormalities. She has declined a lumbar puncture and is thought to retain capacity.

Which investigation would most likely provide the underlying diagnosis?

A. CT abdomen/pelvis with contrast
B. Lumbar puncture
C. Nerve conduction studies and EMG
D. MRI spine
E. Muscle biopsy

A. CT abdomen/pelvis with contrast

This middle-aged woman has presented with seizures on a background of personality change, agitation, paranoia and cerebellar ataxia. The diagnostic test is her positive anti-NMDA antibody, with MRI confirm limbic encephalitis as a result of a paraneoplastic syndrome. The underlying diagnosis is classically an ovarian teratoma, presenting antigens to the body's immune system similar to the brain limbic areas, driving an immune-related encephalitis. Treatment requires immunosuppression with intravenous steroids, immunoglobulin's or plasma exchange, in addition to removal of the underlying tumour by surgery.

Question 147 of 189

A 44-year-old male presents to your headache clinic with a 6-month history of left-sided daily headaches located in the frontal and retroorbital area. He denies any pain-free periods. The headaches are of moderate 5/10 severity with unpredictable exacerbations of severe pain going up to 9/10 severity. He describes to you what sounds to you like left-sided conjunctival injection and lacrimation often occurring alongside the headaches.

Which of the following is most likely to aid you in making a diagnosis?

A. a trial of high flow 100% oxygen
B. Lumbar puncture
C. a trial of indomethacin
D. CT brain
E. MRI brain

C. a trial of indomethacin

A headache with absolutely no pain-free periods otherwise described like this (i.e. like a trigeminal autonomic cephalalgia (TAC)) is hemicrania continua.

The trigeminal autonomic cephalalgias should be side-locked (i.e. one side only) and typically but not exclusively in the retroorbital/temporal region. They should include some autonomic parasympathetic feature such as eye-watering, red eye, running nose, a sensation of fullness in the ear, or miosis. These should be ipsilateral to the pain. They are a spectrum and most conveniently differentiated by how long the headache lasts for and how frequent the attacks happen per day. Some features are quite noticeable in TAC, e.g in a cluster headache (aka 'suicide headaches') people are usually very animated and pace about/hold their head in pain/want to smash their head against the wall (contrast this to migraine: which is not a TAC and usually involves sitting still in a dark room and not making any noise).

It is worth looking up the International Classification of Headache Disorders diagnostic criteria for TACs. Here are some important features:

- Cluster headaches: attacks have a frequency between one every other day and 8 per day and last 15-180 minutes.
- Paroxysmal hemicrania: attacks have a frequency above five per day and last 2-30 min. The condition responds absolutely to indomethacin
- Hemicrania continua: a constant form of paroxysmal hemicrania (no headache-free periods). Also responds absolutely to indomethacin.

- Short-lasting unilateral neuralgiform headache attacks: could get 20 attacks in a day, each last around 1600 seconds.

Notice the differences between how long each lasts and how many attacks there can be per day. The rest of the features are quite similar to each other between the headaches, so learn the general features of a TAC then memorise how long each should last and its frequency to help you differentiate them.

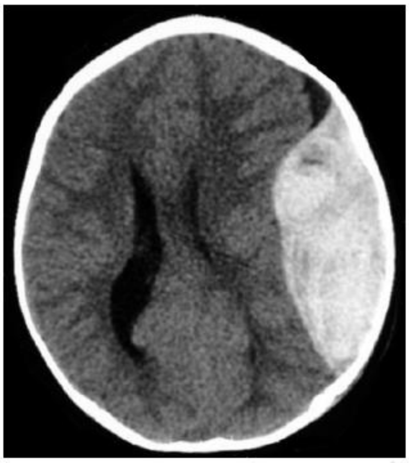
Returning to the question: hemicrania continua and paroxysmal hemicrania clearly are the two that completely resolve with indomethacin. The history, therefore, helps differentiate which is which. Practically speaking, you bring these patients in, on two separate days, for a trial injection of indomethacin or placebo (water) where patient (and nurse if possible) is blinded to which is which and we see which one of the two days was associated with resolution of headaches at a later date in clinic (give the patient a headache diary to take home with). Note the 100% oxygen trial would be used for cluster headaches, which tends to respond to this.

Question 148 of 189

You are asked to review a 32-year-old man who was brought in by ambulance after an assault. A witness states that he lost consciousness before waking up fully. He has subsequently become more drowsy. His current GCS is 9/15 (E2 V3 M4).

Neurological examination is difficult due to GCS. Of note, pupils are symmetrical and there is an extensor right plantar.

A cross-section of his CT brain is shown below.



Which of the following parts of the history is associated with a poorer prognosis?

A. Extensor plantar response
B. Low GCS at presentation
C. Lucid period
D. Symmetrical pupils
E. Young age

B. Low GCS at presentation

The above history describes a reduced level of consciousness following an assault. The CT brain shows a biconvex hyperdensity in the left temporal region which is in keeping with an extradural haematoma. There is evidence of mass effect with midline shift and effacement of the left lateral ventricle which, combined with a reducing conscious level, is concerning for raised intracranial pressure (ICP).

A low GCS at presentation is correct. Low GCS is likely associated with raised ICP and/or traumatic brain injury and therefore carries a poorer prognosis.

Extensor plantar response eludes to an upper motor neuron lesion, in this case, an epidural haematoma, and would be an expected finding but does not denote a poorer prognosis.

Poorer prognosis is associated with patients that do not experience a lucid period. Asymmetrical pupils are associated with a poor prognosis and are a sign of raised ICP. Young age is a protective factor compared to old age which carries a worse prognosis.

Question 149 of 189

A 52-year-old woman presents to your clinic with a history of vertigo.

She describes short-lived episodes of true vertigo which often occur whilst lying down in bed, turning over or sitting up.

The episodes last between ten to twenty seconds and then quickly dissipate.

You perform the Dix-Hallpike test in the clinic which gives a positive result and you make a diagnosis of BPPV.

Whilst consenting the patient to perform an Epley manoeuvre to treat her BPPV the patient asks how successful this is at treating her condition.

In what percentage of cases is this successful?

A. 25%
B. 50%
C. 60%
D. 80%
E. 99%

D. 80%

The Epley manoeuvre is successful in treating around 80% of cases of BPPV

The Epley manoeuvre is successful in treating around 80% of cases of BPPV. Repeated treatments with the Epley manoeuvre can be helpful if it fails at the first attempt. Patients can also be shown how to do 'home Epley' manoeuvres to complete by themselves.

Question 150 of 189

A 76-year-old man was brought into the emergency department by his wife. She was concerned because she had noticed that he had been slurring his words at breakfast that morning at 07:00. She had also noticed he was suffering from left-sided weakness. These symptoms persisted and he was struggling to feed himself when they ate lunch at 13:30.

He had a past medical history of hypertension for which he takes amlodipine. He did not smoke and was independent in his activities of daily living.

On examination, he was dysarthric and had hemisensory loss of his left side. Power was 2/5 in his left leg and left arm. He had normal sensation and power on the right side of his body. His pulse was irregular.

Observations were as follows:

- oxygen saturations 98% on room air
- respiratory rate 14/min
- heart rate 67bpm
- blood pressure 135/78mmHg
- temperature 37.1ºC.

A CT angiogram was performed with perfusion imaging which revealed the presence of a thrombus in the right middle cerebral artery. There was a small area of infarct present and a large area of surrounding ischaemic penumbra.

What is the most appropriate management of this patient?

A. Load with aspirin and admit to the stroke ward
B. Thrombectomy
C. IV thrombolysis with alteplase
D. IV heparin infusion
E. Decompressive hemicraniectomy

B. Thrombectomy

For thrombectomy in acute ischaemic stroke, an extended target time of 6-24 hours may be considered if there is the potential to salvage brain tissue, as shown by imaging such as CT perfusion or diffusion-weighted MRI sequences showing limited infarct core volume

This patient has had an ischaemic stroke, likely as a result of inadequate anticoagulation in the context of atrial fibrillation. As the symptoms were first noticed during breakfast, this patient is outside the 4.5 hour time window in which thrombolysis can be attempted.

Despite this, his CT perfusion scan shows only a small area of infarct, surrounded by a large area of potentially salvageable ischaemic tissue (the penumbra). NICE guidelines suggest that thrombectomy should be offered as soon as possible to patients who have suffered an ischaemic stroke (as demonstrated by CTA) within 6 to 24 hours (including wake-up strokes) if there is the potential to salvage brain tissue (as shown on CT perfusion imaging or diffusion-weighted MRI).

Patients who have a pre-existing disability (e.g. frailty, poor functional baseline) often have poor outcomes even if thrombectomy is successful, so NICE recommends that thrombectomy is reserved for those with a pre-stroke Modified Rankin score of <3. This patient meets these inclusion criteria given his good baseline function.

Patients who are outside the time window or otherwise do not meet the criteria for thrombolysis/thrombectomy should be managed on a stroke ward with antiplatelet agents and control of risk factors (e.g. blood pressure control, anticoagulation for atrial fibrillation commenced 2 weeks after the stroke).

IV heparin infusions are not used to treat ischaemic strokes. Unfractionated heparin is used for rapid anticoagulation (in the treatment of thromboembolic disease for example) in patients who are at high risk of bleeding (the anticoagulant effect can be terminated rapidly by stopping the infusion).

A decompressive hemicraniectomy is reserved for malignant middle cerebral artery syndrome

Question 151 of 189

A 25-year-old man presents with a four-day history of anorexia, feverishness and vertigo. He has had intermittent difficulty balancing and staying upright when walking and has had episodes of mild vertigo lasting 10-20 minutes at a time. His hearing is unimpaired. On examination, he has some cervical lymphadenopathy. The examination is otherwise unremarkable.

What is the likely diagnosis?

A. Meniere's disease
B. Benign Paroxysmal Positional Vertigo
C. Otitis media
D. Vestibular neuronitis
E. Multiple sclerosis

D. Vestibular neuronitis

Vestibular neuritis stereotypical history: recovering from an upper respiratory tract infections presents with recurrent attacks of vertigo associated with nausea and vomiting. There is no hearing loss or tinnitus

Vestibular neuronitis may be preceded by viral symptoms. Vestibular neuronitis is associated with spontaneous onset vertigo and imbalance often associated with nausea and vomiting. Unlike labyrinthitis, it does not cause tinnitus or hearing loss.

Urgent referral should be considered with any of the following red flags: Neurological symptoms or signs, acute deafness, a new type or new onset headache, vertical nystagmus.

Question 152 of 189

A 55-year-old male presents with a 3-week history of speech slurring, dysphagia and droopiness of his eyelids. His only past medical history includes type 2 diabetes mellitus and hypertension, both of which are well controlled. On examination, you note bilateral ptosis with a full range of eye movements. When asked to count upwards from his speech begins to slur at 15. In addition, he spits out upper airway secretions three times during you examination but is able to swallow half a glass of water. Neurological

examination of the rest of his cranial nerves, upper and lower limbs are unremarkable. FVC is 85% of predicted.

What is the most appropriate treatment?

A. Intravenous immunoglobulins
B. Plasmapheresis
C. Oral pyridostigmine
D. Oral prednisolone
E. Oral azathioprine

C. Oral pyridostigmine

Pyridostigmine is a long-acting acetylcholinesterase inhibitor that reduces the breakdown of acetylcholine in the neuromuscular junction, temporarily improving symptoms of myasthenia gravis

The patient describes a clear history of bulbar and ocular myasthenia gravis. The key distinction is that this patient is not in crisis when respiratory function is compromised or complete dysphagia is noted. During a crisis, IVIg and plasmapheresis are indicated but not in a new diagnosis setting. The appropriate treatment is pyridostigmine, an acetylcholinesterase inhibitor. An immunomodulating agent is added only if the patient remains symptomatic with pyridostigmine. Steroids such as prednisolone or azathioprine, ciclosporin or mycophenolate mofetil are reasonable choices. Neither would immediately be required in a new diagnosis

Question 153 of 189

Which of the following patients fits a diagnosis of neurofibromatosis type 1 according to the National Institute of Health (NIH) criteria?

A. A 9-year old male with 2 lisch nodules and 6 cafe au lait macules larger than 5mm diameter
B. A 15-year old female with a dysplastic naevus and a 1st-degree relative with neurofibromatosis
C. A 22-year old male with a shagreen patch and 10 cafe au lait macules larger than 20mm diameter
D. A 25-year old female with axillary freckling and 10 cafe au lait macules larger than 10mm diameter
E. A 30-year old male with an acoustic neuroma an a cutaneous neurofibroma

A. A 9-year old male with 2 lisch nodules and 6 cafe au lait macules larger than 5mm diameter

The NIH consensus development group published some criteria to aid diagnosis of neurofibromatosis type 1 in 1988, as neurocutaneous disorders can be difficult to distinguish. It is important to note that these criteria focus on cafe au lait macule size in adults and children. A child with 6 or more cafe au lait macules larger than 0.5 cm would fit one of the criteria but they would need to be 1.5 cm or larger in an adult. Other criteria include axillary freckling, 2 or more cutaneous/subcutaneous neurofibromas or one plexiform neurofibroma, optic pathway glioma, bony dysplasia, 2 or more Lisch nodules or a 1st-degree relative with neurofibromatosis type 1. At least two of these criteria are required to reach clinical diagnosis.

Acoustic neuromas are associated with neurofibromatosis type 2.

Question 154 of 189

A 32-year-old lady develops a progressive loss of central vision in both eyes over two days. Her eyes are also painful to move. 24 hours later she develops additional paraesthesia in both arms with an associated weakness of both arms. On examination, she has central scotoma of both eyes. She also has a 3/5 global weakness of both arms with hyperreflexia and patchy sensory loss. In the following days, this progresses to paraesthesia and weakness in both lower limbs plus extensor plantar responses.

Raised serum levels of which of the following would be most helpful in establishing the suspected underlying diagnosis? helpful in establishing the suspected diagnosis?

A. Anti-Hu antibodies
B. Antinuclear antibodies
C. N-methyl-d-aspartate (NMDA) receptor antibodies
D. Anti-Aquaporin-4 antibodies
E. Voltage gated potassium channel antibodies

D. Anti-Aquaporin-4 antibodies

Neuromyelitis optica is associated with aquaporin 4 positive serum antibody

The diagnosis is neuromyelitis optica (NMO). It's features are best remembered by what they describe: the co-occurrence of optic neuritis and myelitis. Myelitis describes swelling of the spinal cord and in NMO it characteristically extends over three or more vertebral segments, and the limb features correspond to the level affected. The optic neuritis in NMO is bilateral.

The clinical course of NMO is variable. It may occur as a monophasic illness that is either fulminant and fatal or associated with varying degrees of recovery. Polyphasic courses characterised by relapses and remissions also occur.

A curative treatment for NMO does not exist to date and management, like in MS, focuses on remission and prevention of relapse.

Treatment of an acute attack is with steroids: 5 days of IV methylprednisolone at a dose of 1g, followed by an oral steroid taper. Maintenance therapy is normally with azathioprine, rituximab, or mycophenolate mofetil.

Question 155 of 189

A 45-year-old man presents to the emergency department with the worst headache he has ever head. He reports he was sitting with his wife when he felt sudden onset pain at the back of his head. The pain reached 10/10 intensity rapidly. He also feels nauseous but has not vomited yet.

His past medical history includes adult dominant polycystic kidney disease and hypertension for which he takes ramipril. On examination, his Glasgow coma scale is 15/15 and there is no focal neurology.

You are concerned regarding an intracranial bleed and request a non-contrast CT head, which demonstrates hyperdensity in the subarachnoid space and ventricles.

Given the diagnosis, what is the most appropriate definitive intervention?

A. Thrombectomy
B. External ventricular drain
C. Haematoma evacuation
D. Aneurysm clipping
E. Aneurysm coiling

E. Aneurysm coiling

Following a subarachnoid haemorrhage, most intracranial aneurysms are now treated with a coil by an interventional neuroradiologist

The description given is of a thunderclap headache which is synonymous with a subarachnoid haemorrhage. Further evidence to support this is the CT findings of fresh blood in the subarachnoid space. The likely aetiology is an aneurysmal bleed given the background of ADPKD which is associated with Berry aneurysms. Most aneurysms are now managed by interventional radiology with coils, therefore is the most appropriate definitive intervention.

Thrombectomy is used in at management of acute ischaemic stroke.External ventricular drains are used to treat complications such as hydrocephalus and therefore is not treating the aneurysm itself.

Haematoma evacuation via craniotomy is a neurosurgical procedure used in the management of moderate to large-sized subdural haematomas.

Aneurysm clipping by neurosurgery is also used to manage aneurysmal bleeds but is not the firstline treatment option.

Question 156 of 189

A 44-year-old man presents with a fever. He states that it came on a couple of days ago. Today he developed a headache. The headache is frontal, dull in character and was gradual in onset. He explains that he generally keeps well however did experience an episode of fever with associated joint pain a few weeks ago. On examination he has nuchal rigidity. You also note the presence of sensory loss within the right ulnar nerve distribution.

Blood results are as follows:

Hb	134 g/l	Na	143 mmol/l
Platelets	388 * 10 /l	K	3.7 mmol/l
WBC	14.2 * 10 /l	Urea	5.8 mmol/l
Neuts	7.4 * 10 /l	Creatinine	51 µmol/l
Lymphs	4.7 * 10 /l	CRP	82 mg/l
Glucose	6.2 mmol/l		

An ECG was performed:

12 lead ECG	First degree heart block

CSF results are as follows:

White cell count	104/mm*
White cell differential	95% lymphocytes
Glucose	2.8 mmol/l
Proteins	1250 mg/L (normal 15-450

What is the most likely pathogen?

A. Neisseria meningitidis
B. Streptococcus pneumoniae
C. Borrelia burgdorferi
D. Cryptococcus neoformans
E. Mycobacterium tuberculosis

C. Borrelia burgdorferi

Central nervous system Lyme disease can be diagnosed with CSF analysis. The results are similar to the 'typical' bacterial picture with low glucose and high protein, however in Lyme disease we would expect a lymphocytic pleocytosis

The patients CSF results are suggestive of a bacterial infection with a glucose < 50% of plasma and a very high protein. Common bacterial infections (such as Pneumococcus and Meningococcus) usually result in a neutrophilic pleocytosis. However in this case the patient has a lymphocytic pleocytosis. Causes of this type of picture include partially treated bacterial infection, Lyme disease, tuberculosis, and Cryptococcus.

The extra-CNS clinical features of arthralgia, peripheral neuropathy and first degree heart block are suggestive of Lyme disease. This diagnosis is further supported by the CSF results. Borrelia burgdorferi is the bacteria which causes Lyme disease. Intravenous administration of ceftriaxone is the treatment of choice for disseminated Lyme disease.

A partially treated bacterial infection (e.g. Pneumococcus and Meningococcus) could results in the CSF results given, however this patient has yet to be started on treatment.

Mycobacterium tuberculosis and Cryptococcus neoformans could also result in this CSF picture, however they are less common generally, and tend to occur in specific patient cohorts with certain risk factors such as HIV. They are less likely diagnoses in this case

Question 157 of 189

A 67-year-old woman presents to her GP with progressive numbness and difficulty walking. Furthermore her daughter who was present mentions that she has been behaving strange over the past few months.

She is otherwise fit and well, apart from a ileal resection for treatment-resistant Crohn's disease 9 years ago.

Laboratory tests showed a low haematocrit and mean corpuscular volume of 110 fL. Blood smear analysis noted macrocytic red blood cells with hypersegmented neutrophils.

Which of the following is the most likely cause of the patient's presentation?

A. Ferrochelatase deficiency
B. Folate deficiency

C. Intrinsic factor deficiency
D. Iron deficiency anaemia
E. Cobalamin deficiency

E. Cobalamin deficiency

The ileal resection suggests that the patient is not absorbing the vitamin B12-intrinsic factor complex, leading to vitamin B12 deficiency (aka. cobalamin deficiency), and subsequently subacute combined degeneration. This is further supported by the macrocytic anaemia with hypersegmented neutrophils. Folate deficiency causes the same blood film picture but does not present with neurological symptoms.

Question 158 of 189

A 85-year-old lady presents to her GP with patchy dysesthesia affecting her feet bilaterally. She doesnt complain of any back pain and there has been no change in her bowel habit. She has stress incontinence, but no recent change in her urinary symptoms. On examination there is no weakness and reflexes are preserved. Her past medical history includes hypertensive nephropathy and diet controlled type two diabetes. She takes amlodipine 10mg, ramipril 5mg and bendroflumethazide 2.5mg for her hypertension and for the last year nitrofurantoin 100mg as prophylaxis for urinary tract infections.

Na	135 mmol/l
K	4.2 mmol/l
Urea	10.8 mmol/l
Creatinine	186 µmol/l
Glucose	8.3 mmol/l

What is the most likely cause for her symptoms?

A. Nitrofurantoin induced peripheral neuropathy
B. Uraemic peripheral neuropathy
C. Diabetic neuropathy
D. B12 deficiency
E. Thiazide induced peripheral neuropathy

A. Nitrofurantoin induced peripheral neuropathy

Nitrofurantoin can cause a peripheral neuropathy, especially in patients with pre-existing renal impairment. Painful neuropathy can be caused by both uraemia and diabetes but would not be expected without more advanced disease.

Question 159 of 189

A 64-year-old woman attends neurology clinic after referral from her GP with intermittent episodes of facial pain. She had first noticed symptoms around 10 months previously and recalled her first attack had occurred when taking her grand-children to a fireworks display. Pain episodes were described as a severe 'sawing' pain affecting the right side of her face that lasted one to two minutes before resolving completely. Since the onset the patient reported suffering from at least one attack on most days, with the frequency seeming to increase over time. On direct questioning she reported that on some occasions her nose had become blocked and she had felt sweaty during an episode but that these symptoms were not a major concern in comparison to the severe pain. The patient denied any other symptoms either at the time of the attack and was otherwise in good health with no recent history of weight loss. There was no family history of neurological disease.

A full neurological examination was performed with particular findings of normal pupillary reflexes, visual acuity and colour vision. There was no evidence of facial sensory deficit or facial nerve palsy. A peripheral neurological examination was likewise unremarkable.

Helpfully (although uncomfortably for the patient), a new episode of pain began during the course of the consultation. A further examination was conducted and conjunctival injection and slight eyelid oedema of the right eye were noted. In addition, the patient was noted to be sweating, markedly more profuse on the right side of her face. She also confirmed the onset of a blocked nose sensation at the onset of pain.

What is the most likely diagnosis causing the patients symptoms?

A. Trigeminal neuralgia
B. Multiple sclerosis
C. Horners syndrome
D. Short unilateral neuralgiform pain with autonomic symptoms
E. Atypical trigeminal neuralgia

D. Short unilateral neuralgiform pain with autonomic symptoms

The patients history certainly has features suggestive of trigeminal neuralgia, in particular the character and episodic nature of the pain and that the first episode was particularly memorable. However, the presence of autonomic features associated with attacks points strongly towards thevariant short unilateral neuralgiform pain with autonomic symptoms (SUNA) as the correct diagnosis. The distinction is clinically relevant as individuals with autonomic symptoms achieved less benefit from microvascular decompression compared to individuals with trigeminal neuralgia.

Atypical trigeminal neuralgia is the diagnosis made when an individual suffers from persistent lower intensity pain between exacerbations, in contrast to the complete resolution of pain seen in trigeminal neuralgia. Horners syndrome would not cause episodic autonomic symptoms and is not normally associated with pain. Multiple sclerosis is an important differential for trigeminal neuralgia but the patients normal baseline neurological examination and prominent autonomic symptoms make this less likely. If uncertainty persists after clinical assessment, MRI scanning to assess for demyelination plaques is the appropriate investigation.

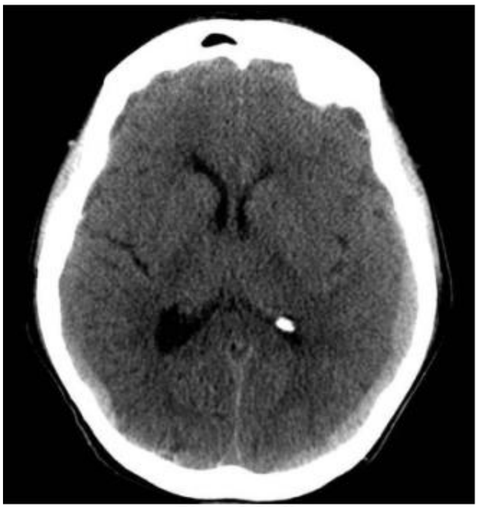
Question 160 of 189

An 81-year-old woman attends the emergency department following a mechanical fall. She has sustained a head injury and a CT head is arranged as part of her trauma survey. Her past medical history includes osteoarthritis of the right hip, recurrent falls, and atrial fibrillation for which she is anticoagulated.

On examination, her respiratory rate is 16/min and is saturating at 96% on air. Her heart rate is 81/min and her blood pressure is

91/64mmHg. Neurological examination elicits a Glasgow coma score of 14 due to confusion but there are no focal neurological deficits. She has no spinal, limb, chest, or abdominal tenderness, and a full painless range of movement in all four limbs.

Her CT head is displayed below:



What is the diagnosis in this instance?

A. Extradural haematoma
B. Intracerebral haematoma
C. Normal appearances
D. Subarachnoid haemorrhage
E. Subdural haematoma

E. Subdural haematoma

This woman has sustained a subdural haematoma. She is at increased risk of sustaining such an insult due to her advanced age and anticoagulation. Note that alcohol excess is also considered a risk factor. The diagnosis is confirmed on the CT scan which shows a concave bleed posteriorly.

An extradural haematoma typically presents with a convex-shaped bleed as it requires more force to detach the dura mater from the cranium. This CT shows a concave shape and is therefore consistent with a subdural rather than an extradural haematoma.

An intracerebral haematoma, as the name suggests, refers to a bleed within the brain parenchyma. As the bleed in this CT is of convex shape along the edge of the cranium, this is not indicative of an intracerebral haematoma.

This CT does not have normal appearances as it displays a haematoma posteriorly. This is therefore an incorrect answer.

A subarachnoid haemorrhage is not the correct answer here. CT images in subarachnoid haemorrhage show blood within the sulci of the brain parenchyma which is not the case here where the bleed is confined to the meninges.

Question 161 of 189

A 32-year-old male presents to clinic with shooting pain down both legs for one week and a mildly weak right hand. He does not recall ever having any other remarkable neurological symptoms and has not been diagnosed with any chronic medical illnesses.

He is right handed, and on examination, he has reduced fine motor control in the right hand with a brisk brachioradialis reflex on the right side. He also has subjective sensory disturbance over his trunk, but no objective sensory loss.

You suspect multiple sclerosis (MS), which findings are required to make the diagnosis of relapsing remitting MS?

A. A gadolinium enhancing lesion on MRI in a typical region for MS 1 not)
B. At least 2 separate MRI lesions typical of MS that are of different ages (i.e 1 enhancing and
C. Oligoclonal bands in CSF
D. Optic neuritis on examination and abnormal visual evoked potentials
E. Observe the patient and await a second clinical episode before a diagnosis can be made

B. At least 2 separate MRI lesions typical of MS that are of different ages (i.e 1 enhancing and

McDonald's criteria are MRI criteria used in the diagnosis of multiple sclerosis. Introduced in 2001, revised in 2005 and again recently in 2010. The latest revision improves sensitivity from 46-74% with a slight trade-off in specificity (slight deterioration from 94-92%)

The diagnosis of multiple sclerosis requires establishing disease disseminated in both space and time.

Dissemination in space:

Dissemination in space requires at least 1 T2 bright lesion in two or more of the following locations:

- periventricular
- juxtacortical
- infratentorialspinal
- cord Dissemination in time:

Dissemination in time can be established in one of two ways:

- A new lesion when compared to a previous scan (irrespective of timing) - T2 bright lesion and/or gadolinium-enhancing lesion
- ii) Presence of an asymptomatic enhancing lesion and a non-enhancing T2 bright lesion on any one scan (i.e 2 lesions of differing ages that satisfy the dissemination in space criteria)

Question 162 of 189

A 28-year-old lady presents to the emergency department with a 4-day history of generalised headache that is worse on lying down. She reports it has gradually become worse and she has also noticed blurred vision since yesterday. Her past medical history includes chronic back pain, acne and anxiety. On examination, she is noted to be overweight. Fundoscopy shows papilloedema. Further investigations point to a diagnosis of idiopathic intracranial hypertension.

Which of the following of her medications is associated with this condition?

A. Tramadol
B. Tetracycline antibiotics
C. Diazepam
D. Amitriptyline
E. Ibuprofen

A. Tetracycline antibiotics

Associated medications include, but are not limited to:

- tetracycline antibiotics
- isotretinoin
- contraceptives steroids
- levothyroxine
- lithium
- cimetidine

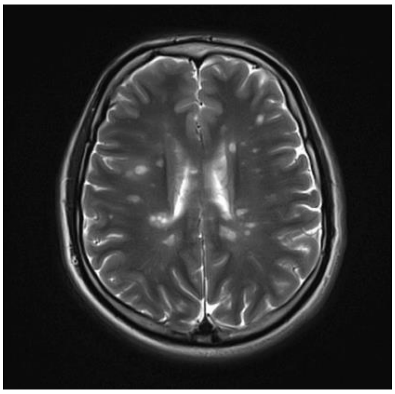
Question 163 of 189

A 24-year-old man is referred to the neurology clinic by his GP. He describes a four month history of left-sided numbness and intermittent tingling. This mainly affects his left arm but he occasionally has symptoms in the left leg. There is no history of headaches, visual problems or weakness.

His GP has performed a series of blood tests including a full blood count, urea and electrolytes, vitamin B12 and C reactive protein, all of which were normal.

Neurological examination today was normal other than reduced sensation in the left C6/7 dermatome.

A MRI head is performed. The T2 images are shown below:



What is the most likely diagnosis?

A. Creutzfeldt-Jakob disease
B. Multiple sclerosis
C. Adrenoleucodystrophy
D. Cerebral toxoplasmosis
E. Gliolastoma multiforme

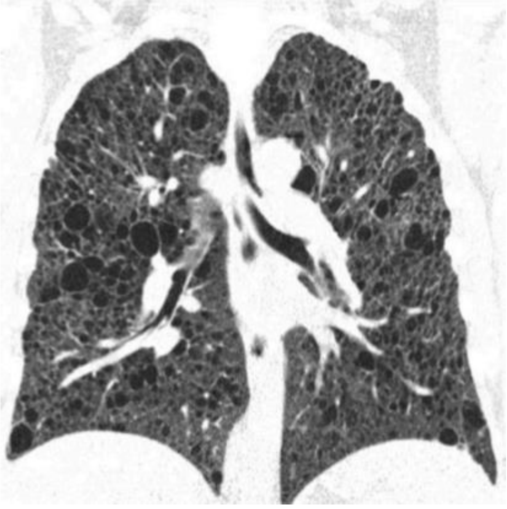
B. Multiple sclerosis

The MRI scan is consistent with multiple sclerosis. Widespread periventricular, juxtacortical, post fossa and upper cervical cord high T2 regions are noted. Note the difference in the lesions with varying degrees of contrast enhancement and restricted diffusion indicating active/recent demyelination. This satisfies the diagnostic criteria in terms of separation in terms of time space.

Question 164 of 189

A 39-year-old woman with known tuberous sclerosis is referred to the respiratory clinic after developing progressive dyspnoea. Her GP had requested a chest x-ray which showed significant changes.

The CT scan is shown below:



What complication has developed?

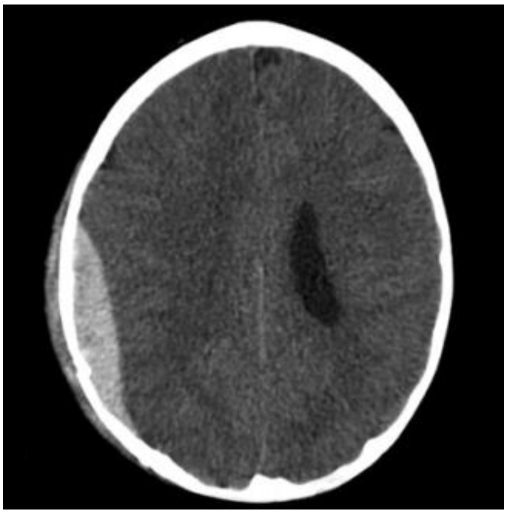
A. Metastatic angiomyolipoma
B. Lymphangioleiomyomatosis
C. Lung rhabdomyomas
D. Lung angiofibromas
E. Subependymal giant cell astrocytoma

B. Lymphangioleiomyomatosis

The CT demonstrate innumerable small regular lung cysts diffusely distributed throughout the lungs, the typical appearance of lymphangioleiomyomatosis (LAM). This disorder may occur alone on in association with tuberous sclerosis.

Question 165 of 189

A 7-year-old boy falls from the top of a slide and is taken to the Emergency Department. He is crying, complaining of a severe headache and regularly vomiting. A CT head is performed:



What does the scan show?

A. Subarachnoid haemorrhage
B. Brain contusion
C. Extradural haematoma
D. Subdural haematoma
E. Meningioma

C. Extradural haematoma

The CT scan demonstrates a bi-convex (lentiform) extra-axial hyperdense collection consistent with an extradural haematoma.

Question 166 of 189

A 62-year-old woman comes to the gastroenterology clinic for review. She has a history of watery diarrhoea over the course of the past 6 months, where she is opening her bowels some 4-6 times per day. There is other past medical history of hypertension, ischaemic heart disease, Type 2 diabetes and depression.

Investigations

Hb	11.5 g/l	Na	139 mmol/l	Bilirubin	12 µmol/l
Platelets	207 * 10 /l	K	3.9 mmol/l	ALP	95 u/l
WBC	8.9 * 10 /l	Urea	7.2 mmol/l	ALT	23 u/l
Neuts	5.6 * 10 /l	Creatinine	100 µmol/l	γGT	56 u/l
Lymphs	1.8 * 10 /l	Albumin	38 g/l		
Eosin	0.5 * 10 /l				

Colonoscopy: Mild mucosal oedema only, biopsy reveals lymphocytic infiltration

Which of the following agents is most likely to be the cause of her colonoscopy findings?

A. Amlodipine
B. Atorvastatin
C. Lisinopril
D. Metformin
E. Sertraline

E. Sertraline

Sertraline is recognised as highly likely to be associated with lymphocytic colitis, (microscopic colitis associated with lymphocytic infiltration). This conclusion results from a mix of association / epidemiology studies, and case series where removal and re-introduction of medication has been correlated with symptoms and changes in biopsy appearance.

Calcium channel antagonists are not thought to be associated with microscopic colitis, but are uncommonly reported as leading to change in bowel habit including diarrhoea. Metformin leads to bile salt malabsorption which may result in diarrhoea. Statins may be associated with microscopic colitis, although withdrawal and re-challenge evidence is less strong than for sertraline. ACE inhibitors are not known to be associated with microscopic colitis. Diarrhoea was a commonly reported adverse event in lisinopril clinical trials, but this is not thought to be due to microscopic colitis.

Question 167 of 189

A 32-year-old woman presents to clinic with a constant headache. She has attempted to control this by taking daily paracetamol, ibuprofen and codeine for the last two months. Her headache has not improved. She describes the headache as being present almost every single day but it is not disabling. There is a concern that she may have a medication overuse headache.

What is the most appropriate management?

A. Wean off codeine. Stop paracetamol and ibuprofen abruptly
B. Stop codeine abruptly. Reduce paracetamol and ibuprofen gradually
C. Wean off all analgesia gradually
D. Wean off codeine and ibuprofen.
E. Stop paracetamol abruptly Stop all medications abruptly

A. Wean off codeine. Stop paracetamol and ibuprofen abruptly

The duration of the headache and regular use of codeine makes the diagnosis of medication overuse headache most likely.

The correct answer is to stop paracetamol and ibuprofen abruptly, but gradually wean off codeine due to the adverse effects of acute opioid withdrawal. Whilst codeine and triptans are the most common cause, other types of analgesia can contribute. Improvement is often seen within a few days.

Question 168 of 189

A 62-year-old Afro-Caribbean female is brought to the Emergency Department by husband after a 3-day history of unusual, odd behaviour at home. The family had hosted a dinner party that evening and the patient was reported to have been very disinhibited, agitated and describing hallucinations around her guests. In the past 3 weeks, she had two episodes of generalised seizures witnessed by her husband, each lasting for up to 5 minutes before spontaneously terminating, associated with urinary incontinence and tongue biting. She has no history of epilepsy and is not on any regular medications, but was diagnosed with ovarian teratoma two years ago. On examination, she has no focal neurology but you note a dystonic orofacial movement disorder. A CT head was unremarkable, with no acute infarct, haemorrhage or space occupying lesion demonstrated.

Which investigation is most likely to produce the diagnosis?

A. MRI head
B. Lumbar puncture
C. Anti-NMDA receptor antibodies
D. Anti-MuSK antibodies
E. Anti-GM1 antibodies

D. Anti-MuSK antibodies

The syndrome described is strongly suggestive of an autoimmune-mediated limbic encephalitis.

Question 169 of 189

A 32-year-old female is seen in neurology clinic due to a 4-month history of headaches. She described having headaches most days on waking up, which were throbbing in nature. She found that they eased off after mobilising and that coughing made them worse. She reported a couple of episodes of blurred vision on waking, but no nausea or vomiting. Her general practitioner arranged for an outpatient magnetic resonance head scan which was normal. Her body mass index (BMI) had been 27 kg/m², but on advice from her general practitioner she had lost weight, and her BMI was now 23 kg/m². She was not on any regular medications, other than paracetamol and ibuprofen which she had been using regularly for her headaches.

There was no focal neurological deficit on examination, and her visual acuity was normal. On fundoscopy, there was a mild degree of papilloedema. Blood pressure was 125/82mmHg. Blood tests were unremarkable.

What is the most appropriate next step in management?

A. Lumbar-peritoneal shunt
B. Optic nerve fenestration
C. Cessation of paracetamol and ibuprofen
D. Acetazolamide
E. Sumatriptan

D. Acetazolamide

The postural nature of this patient's headaches, and the fact that they are exacerbated by coughing are suggestive of raised intracranial pressure. In a young woman with a normal magnetic resonance scan, this is suggestive of idiopathic intracranial hypertension.

In overweight patients, the initial management strategy is weight loss, which may be enough to relieve symptoms. This patient has already lost weight and has a normal body mass index, but her headaches persist, so additional measures are required. Cessation of any causative agents would also be important (e.g. tetracyclines, retinoids, lithium).

Acetazolamide is useful in controlling mild disease that is resistant to the conservative measures mentioned above. Repeated lumbar puncture may also be used to lower intracranial pressure. In acute disease, corticosteroids are sometimes beneficial. If there is significant visual loss despitemedical therapy surgical interventions such as optic nerve sheath fenestration or lumbarperitoneal shunt insertion may be necessary.

Analgesia-induced headache and migraine are important causes of recurrent headache, but would not cause the postural association seen in this case, so cessation of analgesic agents and commencement of sumatriptan are not appropriate treatments.

Question 170 of 189

A 35 year old mechanic attends the emergency department following an injury at work. He has suffered a serious laceration to the upper arm. While suturing, the doctor notices multiple cuts and burns on both arms.

On examination there is marked wasting of brachioradialis and the small muscles in both hands, with mild hyporeflexia of the biceps and brachioradialis tendons. He is weak in both arms, distally more so. His lower limb and cranial nerve examination is unremarkable. On testing upper limb sensation, vibration and proprioception are intact but there appears to be reduced pain and temperature sensation over the C3/C4/C5 deramatomes.

What is the most useful investigation?

A. Lumbar puncture
B. Nerve conduction studies
C. MRI Brain
D. Electromyography
E. MRI cervico-thoracic spine

E. MRI cervico-thoracic spine

The presence of loss of pain and temperature sensation in a 'cape like' distribution is highly suggestive of syringomyelia. A fluid filled cavity within the cord develops, typically between C2 to T9, compressing the cord from inside to out. Consequently the spinothalamic tracts are the first to be affected in a symmetrical distribution.

There are a number of aetiologies, but it should be noted that therw is an association with Arnold Chiari malformation Type 1. It is sensible to investigate for a compressive cord lesion in the first instance; imaging of the brain may be considered if syringomyelia is detected. An MRI cervicethoracic cord would be the most sensitive method of detecting syringomyelia.

Question 171 of 189

A 78-year-old man is brought to see you in clinic by his daughter. He has a diagnosis of Alzheimer's dementia and although currently coping well, has significantly impaired short-term memory.

Currently, his daughter attends daily for all meals, cleaning, and shopping. He continues to live in his own home and is alone overnight. She has, however, become concerned as he continues to drive 5 miles three times a week and she is unsure if this is safe.

Which of the following is the best course of action regarding his driving licence?

A. He is disqualified from driving
B. He is allowed to drive, but only if daughter is present
C. There is no need to contact the DVLA, continue to drive
D. Assess his risk factors, report to the DVLA and await advice
E. He is safe if his mini mental state examination score >11

D. Assess his risk factors, report to the DVLA and await advice

The DVLA guidance states this is a difficult decision to make. The presence of impaired short-term memory, disorientation or loss of insight suggests someone with dementia is not fit to drive.

In this case, the correct answer would be to contact the DVLA, assess the risk factors and take further advice. He should not be immediately disqualified; he warrants a more careful assessment and decision with support from the DVLA. The factors that suggest someone with dementia may not be safe to drive include significantly impaired short-term memory, poor attention and concentration, and impairment of planning.

Question 172 of 189

A 24 year-old university student presents with a 10 day history of visual disturbance. He reports changes in his visual acuity where he has been experienced some blurring of his vision which is considerably worse after having been for a run. He thinks it is related to some pain he developed on his right eye prior to the onset of his vision loss. He has no previous history of visual problems and is normally fit and well. He takes no regular medications.

On further questioning he reports that 6 months ago he had some sensory changes on his lower limbs. He felt they were numb and this persisted for a few weeks. He thought it was due to his sporting activities, as he is an avid hockey player.

He drinks 20 units of alcohol at the weekends and does not smoke. His blood results are shown below:

Hb	134 g/l
Platelets	250 * 10 /l
WBC	8 * 10 /l
Na	134 mmol/l
K	4.1 mmol/l
Urea	4 mmol/l
Creatinine	60 µmol/l

Which investigation below would be most useful to diagnose this patient?

A. EEG
B. CT head
C. HIV serology
D. Contrast MRI brain and spine
E. Anti-NMO antibodies

D. Contrast MRI brain and spine

This young man presents with the classic symptoms of optic neuritis. Changes in vision(usuallyblurriness but can occasionally present as loss of red colour vision). He describes Uhthoff's phenomenon.

His history of a previous episode of paraesthesia is consistent with a previous first CIN episode. This gentleman requires urgent investigations. He should have a lumbar puncture which would show oligoclonal bands- which should be paired with a serum sample for comparison.

The correct answer is contrast MRI brain and spine and this will show a gadolinium enhancing consistent with an acute demyelinating lesion. Most likely it would also show an old lesion in his cord which would be diagnostic of MS.

Neuromyelitis optica is a demyelinating condition associated with NMO antibodies (Aquaporin 4 antibodies) which presents with demyelination of the optic nerve and spinal cord. It follows a more severe course than traditional MS. In this instance, an MRI with contrast will be the most appropriate investigation to yield a diagnosis.

Question 173 of 189

A 31-year-old woman is referred to the neurology team after experiencing two seizures, having had no prior episodes. After a consultation and discussion, they agree for her to trial carbamazepine. She has a past medical history of asthma and gastro-oesophageal reflux disease, for which she uses salbutamol and beclometasone inhalers, montelukast, cimetidine and omeprazole; she also takes the combined oral contraceptive pill.

Three weeks later, she experiences several further seizures, despite being fully adherent to the carbamazepine regime.

Which medication may have led to the return of her episodes?

A. Carbamazepine
B. Cimetidine
C. Combined oral contraceptive pill
D. Montelukast
E. Omeprazole

A. Carbamazepine

Carbamazepine is known to exhibit autoinduction. hence when patients start carbamazepine they may see a return of seizures after 3-4 weeks of treatment

Carbamazepine is a commonly-used antiepileptic medication. It is also used for trigeminal neuralgia and bipolar disorder. Crucially, it is known to induce the P450 enzyme system, which breaks down the drug itself, and so it is considered an auto-inducer. As such, 3-4 weeks after treatment, it may lead to the return of seizures.

Cimetidine is an antihistamine H2-receptor antagonist, used for the control of gastric acid production. It is a P450 inhibitor, not an inducer, and so would not reduce the effectiveness of carbamazepine.The combined oral contraceptive pill is metabolised by the P450 system. It is not known to significantly induce or inhibit the P450 system and so is incorrect.

Like the pill, montelukast is also known to be metabolised by the P450 system. Similarly, it is not known to induce or inhibit the system and so is not the correct answer.

Omeprazole is considered a P450 inhibitor, rather than inducer. As such, it would not cause a reduction in carbamazepine levels and so would not be the cause of seizures returning.

Question 174 of 189

A 51-year-old patient with a history of schizophrenia presents after being found on the floor of his sheltered accommodation home surrounded by many packets of medications. There is no collateral history. On examination, the patient is only verbally responsive to pain. There is evidence of vomitus around the oral cavity. You note that he is generally tremulous. Observations show heart rate 110/min, blood pressure 101/61 mmHg.

On the 12 lead ECG the P waves are present followed by QRS complexes. PR interval 0.12 seconds, QRS 0.12 seconds, corrected QT 0.48 seconds.

What is the most likely causative agent?

A. Citalopram
B. Chlorpromazine
C. Diazepam
D. Digoxin
E. Cocaine

A. Citalopram

Other side effects of citalopram overdose to be aware of include:

- Nausea Vomiting Tremor
A. Nystagmus Convulsions

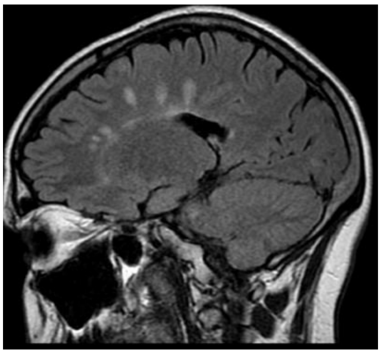
Management of SSRI poisoning is generally supportive. Convulsions can be managed with benzodiazepines.

Question 175 of 189

A 31-year-old woman is reviewed in the neurology clinic. For the past 6 months she has been presenting to her GP with a variety of symptoms including lethargy, heat intolerance, pins/needles and limb numbness. For the past 4 weeks she has also been complaining of shooting pains in her right hand.

Her GP has arranged a number of blood tests including thyroid function tests and vitamin B12 which were reported as normal.

A neurological examination today demonstrates no consistent neurological findings. A MRI is requested:



What is the most likely diagnosis?

A. Multiple sclerosis
B. Pituitary tumour
C. Ependymoma
D. Acute disseminated encephalomyelitis (ADEM)
E. Systemic lupus erythematosus

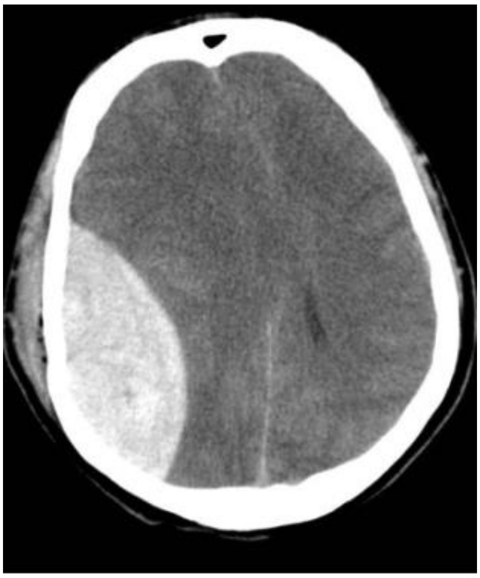
A. Multiple sclerosis

The MRI shows multiple white matter plaques penpendicular to the corpus callosum giving the appearance of Dawson fingers - a classic MRI finding in multiple sclerosis.

Lethargy is a clue in this question. It is very common feature in patients with multiple sclerosis. Other features such as pain and heat intolerance and also seen.

Question 176 of 189

A 27-year-old woman is admitted to the Emergency Department following a road traffic accident. Primary survey reveals a right-sided haemothorax but she is haemodynamically stable. She is only responding to voice. A CT scan of her head (with contrast) is performed:



What does the scan show:

A. Subdural haematoma

B. Subarachnoid haemorrhage
C. Extradural haematoma
D. Brain contusion
E. Meningioma

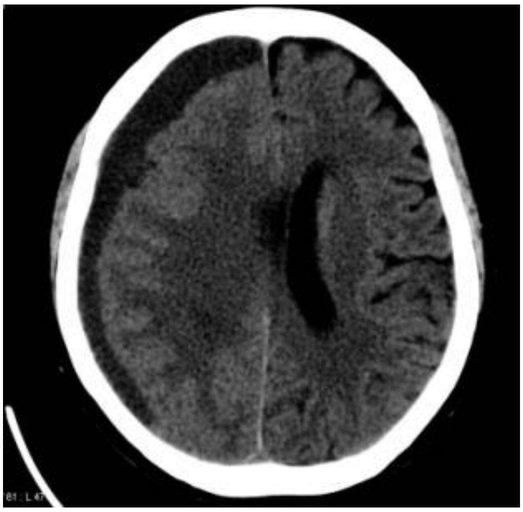
C. Extradural haematoma

The CT scan shows a extra-axial biconvex collection associated with fracture suggestive of extradural haematoma.

Question 177 of 189

A 73-year-old man who is a chronic alcoholic is brought to the Emergency Department by an ambulance. He was found collapsed in the street. On admission his airway, breathing and circulation are satisfactory. His GCS is 13/15 (eyes = 3, verbal = 4, movement = 6) although his level of consciousness appears to be fluctuating. There are no obvious signs of external head injury.

A CT head (without contrast) is performed:



What is the most likely diagnosis?

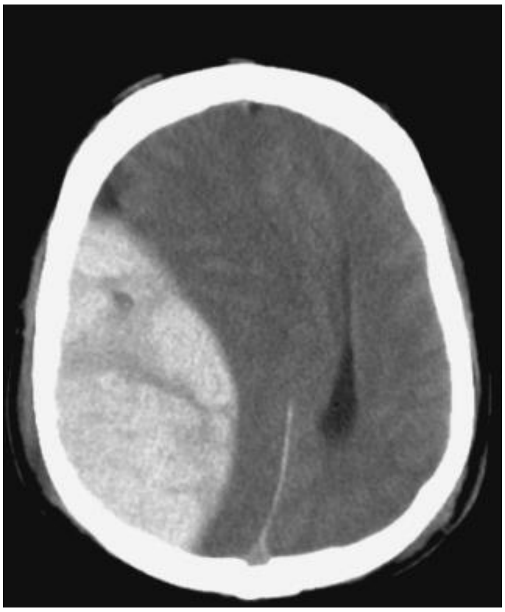
A. Subarachnoid haemorrhage
B. Wernicke's encephalopathy
C. Subdural haematoma
D. Meningioma
E. Extradural haematoma

C. Subdural haematoma

CT scan demonstrates a right sided chronic subdural haemorrhage resulting in midline shift.

Question 178 of 189

A 30-year-old man who has been seriously assaulted is brought to the Emergency Department. His GCS is 5/15 on arrival and he is immediately intubated and transferred for a CT head (with contrast):



Which blood vessel(s) is most likely to have ruptured?

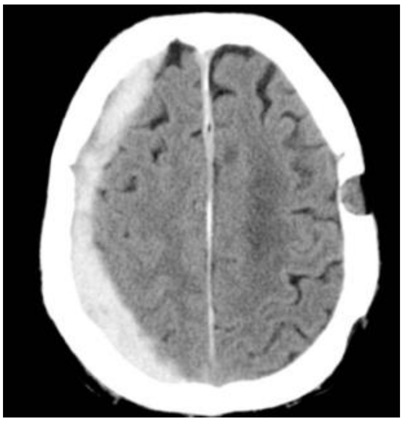
A. Anterior communicating artery
B. Emissary veins
C. Temporal artery
D. Middle meningeal artery
E. Posterior communicating artery

D. Middle meningeal artery

This scan shows a massive extradural haemorrhage, most likely caused by a ruptured middle meningeal artery.

Question 179 of 189

An 85-year-old complains of severe headaches and lethargy over the past 3 weeks. His past medical history includes atrial fibrillation for which he takes warfarin. A CT head (with contrast) is performed:



What is the most likely diagnosis?

A. Normal age-related changes
B. Extradural haematoma
C. Subdural haematoma
D. Meningioma

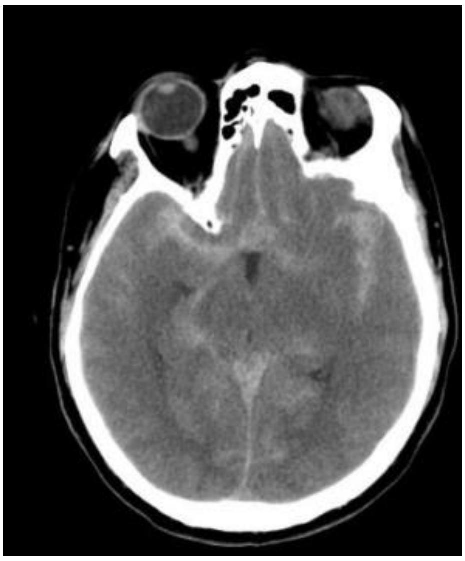
E. Subarachnoid haemorrhage

C. Subdural haematoma

The CT scan shows a crescent-shaped (concave surface away from the skull) extra-axial collection seen with subdural haematomas. A burr hole can also be seen on the left.

Question 180 of 189

A 33-year-old woman presents to the Emergency Department with a severe headache. She describes falling to the ground whilst walking to work and since having a severe occipital headache. Her GCS is 15/15 and her vital signs are stable, other than a low grade pyrexia of 37.5ºC. Her headache fails to improve with analgesia and a CT head with contrast is performed:



What does the scan show?

A. Extradural haematoma
B. Brain contusion
C. Subdural haematoma
D. Meningioma
E. Subarachnoid haemorrhage

E. Subarachnoid haemorrhage

The correct answer is Subarachnoid haemorrhage. This condition typically presents with a sudden onset, severe headache (often described as a 'thunderclap' headache). The patient's symptoms of collapsing and having an occipital headache are consistent with this. A subarachnoid haemorrhage can also cause fever due to blood being irritating to the meninges, which could explain the patient's low-grade pyrexia. On CT imaging, subarachnoid haemorrhage appears as areas of high density in the subarachnoid space.

The first incorrect option is Extradural Haematoma. This usually results from trauma leading to bleeding between the dura mater and skull. It often presents with a lucid interval followed by rapid neurological deterioration. The CT appearance is typically a lens-shaped hyperdensity that does not cross suture lines, which does not match the image shown.

The second incorrect option is Brain contusion. This refers to bruising of brain tissue following head injury. The clinical presentation might include loss of consciousness at the time of injury and focal neurological deficits depending on the area affected. On CT imaging, brain contusions appear as irregular areas of low density due to oedema and high density due to haemorrhage; however, these findings are not evident in this case.

Subdural Haematoma, the third incorrect option, occurs when there is bleeding into the space between the dura mater and arachnoid membrane, most commonly due to tearing of bridging veins during trauma. Clinically, patients may present with fluctuating consciousness level or focal neurological deficits. On CT scan, it appears as a crescent-shaped hyperdensity that can cross suture lines but not dural reflections - again inconsistent with our image.

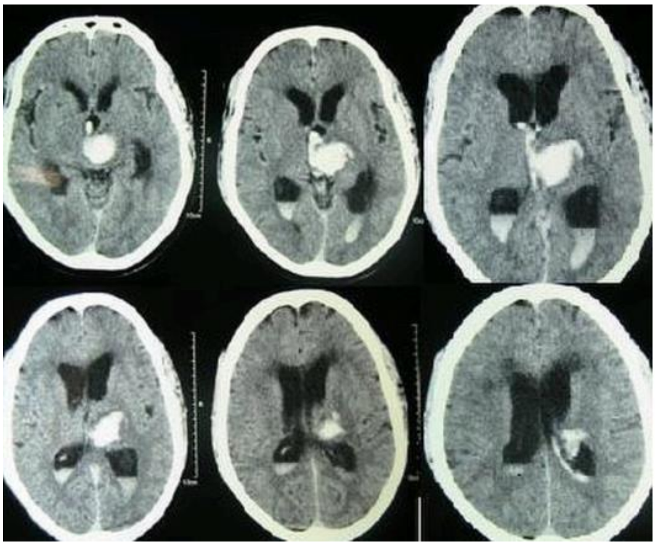
Lastly, Meningioma, another incorrect option, refers to benign tumours arising from meningeal layers surrounding the brain and spinal cord. Patients usually present with slowly progressive symptoms related to increased intracranial pressure or focal neurologic deficits based on tumour location. Meningiomas on CT scans appear as extra-axial masses that are typically homogenous and isodense or slightly hyperdense compared to brain parenchyma - features not seen in this case.

Question 181 of 189

A 72-year-old woman patient presents to the emergency department with a sudden onset of severe headache, worse than any she's ever experienced, which started an hour ago. She also reports weakness on the right side of her body and difficulty speaking. There is no history of trauma.

Her medical history reveals longstanding hypertension, which she admits to not managing well in recent months. On examination, she appears drowsy. Her blood pressure is 195/110 mmHg. Her neurological examination reveals right-sided hemiparesis and expressive aphasia.

Urgent head imaging is ordered.



What is the most likely diagnosis?

A. Brain tumour

B. Intracerebral and intraventricular hemorrhage
C. Intracerebral and subarachnoid haemorrhage
D. Ischaemic stroke
E. Subdural haemorrhage

B. Intracerebral and intraventricular hemorrhage

The correct answer is intracerebral and intraventricular haemorrhage. The CT shows bright hyper-dense intracerebral and intraventricular lesions, due to the presence of blood, which has a characteristic bright white appearance on CT imaging. An intracerebral hemorrhage is caused by the sudden rupture of a blood vessel within the brain. This leads to the accumulation of blood, causing damage to the surrounding brain tissue. Intraventricular hemorrhage represents bleeding inside the brain's ventricular system, which consists of interconnected spaces filled with cerebrospinal fluid (bleeding here is located within the lateral ventricles). Common presentations include a sudden severe headache, weakness, altered consciousness, and focal neurological deficits.

Brain tumour is incorrect. The rapid onset of symptoms in this case, paired with the CT findings and lack of previous history, are not in keeping with a brain tumour. Sometimes an intracerebral haemorrhage can be caused by an underlying brain tumour and further imaging is sometimes considered after the resolution of the haemorrhage.

Intracerebral and subarachnoid haemorrhage is an incorrect choice. While there are intraparenchymal and intraventricular haemorrhages on CT scans, no blood exists in the subarachnoid spaces. Subarachnoid haemorrhage typically results from the rupture of cerebral aneurysms, or, less commonly, from a sustained head trauma. Patients with subarachnoid haemorrhage typically present with a thunderclap headache, described as a sudden-onset headache usually occipital that is the worst headache of their life often accompanied by sensitivity to light (photophobia), signs of meningitis (meningism), and focal neurological deficits.

Ischaemic stroke although a potential differential, is ruled out in this case by the CT findings. The earliest CT sign visible for ischemic stroke is a hyperdense segment of a vessel, representing direct visualization of the intravascular thrombus/embolus and as such is visible immediately. Other signs include areas of low density in the grey and white matter of the territory. These changes may take time to develop and the CT may be normal initially. Clinically ischaemic stroke can be difficult to distinguish from haemorrhagic stroke.

Lastly, subdural haemorrhage is characterized by bleeding between the brain's surface and its outer covering, the dura mater, often caused by head trauma. They are thought to result from thestretching and tearing of bridging cortical veins as they traverse the subdural space to connect with a nearby dural sinus for drainage. It can lead to symptoms such as fluctuating levels of consciousness, headache, dizziness, and in severe cases coma. On CT, it presents with a crescentshaped homogeneously hyperdense extra-axial collection that spreads diffusely over the affected hemisphere.

Question 182 of 189

A 32-year-old woman presents with reduced sensation. She has noticed that slowly over six months she has not felt when hot water has splashed on her hands, despite blistering occurring afterwards. Her husband has become concerned and asked her to seek a medical opinion. She denies any other problems, including weakness, weight-loss or her activities of daily living being affected. She has a past medical history of asthma but only rarely needs her salbutamol inhaler. She has no other medications or allergies. On examination, she has sensory loss over her hands and arms when tested for temperature and pain. There is a dermatomal distribution affecting dermatomes C4 to C6 which is symmetrical. Cranial nerve and lower limb examination is normal. Spinal examination shows no tenderness.

What is the most likely diagnosis?

A. Multiple sclerosis
B. Cervical disc prolapse
C. Vasculitis
D. Myasthenia gravis
E. Syringomyelia

E. Syringomyelia

The correct answer is syringomyelia. The fact that she has primarily loss of spinothalamic function in a cervical nerve distribution with a distinct sensory loss makes syringomyelia the most probable diagnosis. Weakness can occur as well. Syringomyelia is caused by a tubular cyst within the central spinal cord, most commonly affecting the cervical region. It compresses corticospinal and spinothalamic tract as well as anterior horn cells. Presentation can be variable causing loss of temperature sensation, pain, paralysis, stiffness and weakness. Due to the common location of the cyst, this is most likely to affect hands, arms and shoulders. In half of the patients, there is only mild or no disability.

Multiple sclerosis is unlikely as there is no evidence of lesions separated by attacks. The absence of neck pain or tenderness makes a disc prolapse unlikely, whilst the absence of systemic features makes vasculitis unlikely. Myasthenia is associated with fatigability rather than a sensory loss.

Question 183 of 189

A 45-year-old Bangladeshi male presents with a 6-month history of bilateral reduced sensation on the tips of both his feet, which has gradually progressed on both legs to his low shins. His past medical history includes type 2 diabetes, diagnosed 7 years ago and reports good medication compliance with metformin 500mg BD alone, with a HbA1c of 48 mmol/mol (6.5%) two weeks ago. He is also currently in his ninth month of anti-tuberculosis treatment, having initially presented with a chronic cough, night sweats and weight loss. An induced sputum subsequently cultured positive for acid-fast bacilli. He did not bring in his medications but remembers being told they are 'the standard four then two drugs'. He takes no other medications and has no known drug allergies. On examination, tone, power and gait of his lower limbs are unremarkable. He demonstrates reduced sensation to light touch to his left lower shin and right mid-shin. Ankle jerks are absent bilaterally, plantars are downgoing bilaterally.

What is the most likely diagnosis?

A. Guillain-Barre syndrome (GBS)

B. Chronic inflammatory demyelinating polyneuropathy (CIDP)
C. Drug induced peripheral neuropathy
D. Diabetic neuropathy
E. Diabetic amyotrophy

C. Drug induced peripheral neuropathy

The patient describes a chronic sensory deficit in a peripheral nerve distribution. This is most likely isoniazid-induced peripheral neuropathy, classically interfering with vitamin B6 via an unknown mechanism. As a result, pyridoxine should be regularly prescribed in all patients taking isoniazid. GBS and CIDP classically present as combined motor and sensory syndromes, of duration less than and more than 4 weeks respectively. While diabetes-related peripheral neuropathy is possible, his glycosylated haemoglobin measurement, an accurate measure of the patient's serum glucose levels over the past 3 months, reflects very good control.

Question 184 of 189

A 28 year old female is referred to general medical clinic for review. She has a one year history of very severe right sided headaches. These are associated with eyelid swelling and lacrimation and never occur on the left. Paroxysms last around 2 minutes at a time and attacks occur upwards of 10 times per day. Attacks tend to occur every day for a week or two with a moth or so between attacks. She describes no nausea or vomiting associated with her headaches.

What treatment should you offer?

A. Low dose carbamazepine
B. Trial of indomethacin
C. Verapamil
D. Topirimate
E. Prednisolone

B. Trial of indomethacin

The history given above is one of severe, paroxysmal, unilateral headaches with associated autonomic features. The two most likely diagnoses would be cluster headache or paroxysmal hemicrania (PH), with the latter being more likely. It would be unusual for cluster headache attacks to last for less than 5 minutes and a daily frequency of greater than 10 is unusual for cluster headache but not PH. In addition, cluster headaches have a male predilection but PH tends to affect females. Paroxysmal hemicrania (or chronic paroxysmal hemicrania if attacks occur for over one year) tends to be highly responsive to treatment with indomethacin, so much so that a trial of this may be considered a diagnostic strategy.

Low dose carbamazepine is the treatment of choice for trigeminal neuralgia. Verapamil is first line for prophylaxis of cluster headaches. Topiramate may be used in migraine prophylaxis and oral steroids have been used to prevent cluster headaches but have little evidence to support their use.

It may be argued that due to the relative rarity of PH compared with cluster headaches that even with the history above the former may be more likely, however due to the diagnostic response to indomethacin seen in PH it would be appropriate to trial this first.

Question 185 of 189

A 42-year-old man presents to the emergency department with a sudden-onset, severe headache that he describes as the 'worst headache of his life'. He had a similar headache of lesser severity one week ago.

On examination, he appears to be in significant distress due to his pain and has significant neck stiffness. Full neurological examination is otherwise normal. Computerised tomography (CT) scanning of the brain is done within an hour, showing blood in the basal cisterns and sulci. CT angiography (CTA) confirms a posterior communicating artery aneurysm.

What is the most appropriate management for this patient?

A. Craniotomy and clipping
B. Digital subtraction angiography (DSA)
C. Endovascular coiling
D. Intravenous mannitol
E. Oral nimodipine

Question 186 of 189

A 48-year-old man presents to the emergency department with sudden onset, severe right eye pain and a headache. The pain started earlier this morning and worsened while watching television in a dark room. He also had 2 episodes of non-projectile vomiting. He has no significant past medical history except for migraine.

His vital signs are a temperature of 37 ºC, blood pressure 140/85 mmHg, pulse 55 beats/min and oxygen saturation 98% on room air. On examination, he is conscious and oriented but in distress due to severe pain. The pupils are unequal; the right pupil is semi-dilated and non-reactive to light.

Given the likely diagnosis, what is the definitive treatment for this patient?

A. Intravenous mannitol
B. Laser peripheral iridotomy
C. Laser trabeculoplasty
D. Oral propranolol
E. Tropicamide eye drops

B. Laser peripheral iridotomy

Laser peripheral iridotomy is the definitive treatment for acute angle-closure glaucoma

This scenario describes a patient with acute angle-closure glaucoma, for which peripheral laser iridotomy is the definitive treatment option. A history of sudden-onset eye pain precipitated by mydriasis (watching TV in a dark room), vomiting, and pupillary findings in this scenario point towards the diagnosis. This is confirmed by measuring intra-ocular pressure via tonometry and visualisation of the angle by gonioscopy. Emergency management includes drugs that reduce the secretion of aqueous humour (acetazolamide and timolol) and drugs that increase the outflow of aqueous humour (pilocarpine and apraclonidine). Laser peripheral iridotomy is the definitive treatment option as it creates a tiny hole in the peripheral iris, allowing aqueous humour to flow to the angle.Intravenous mannitol is not the definitive treatment for angle-closure glaucoma. Diuretics like mannitol and acetazolamide are sometimes used in medical management of acute angle-closure glaucoma to lower the intraocular pressure and symptomatic relief.

Laser trabeculoplasty lowers the intraocular pressure in open-angle glaucoma and has no role in treating acute angle-closure glaucoma. Unlike the patient's symptoms in this scenario, open-angle glaucoma exhibits no symptoms in the initial stage and only presents with problems in peripheral vision.

A sudden-onset headache and past history of migraine may suggest an acute migraine attack, which makes oral propranolol a reasonable option in this scenario, but a semi-dilated, nonreactive pupil points away from this.

Tropicamide eye drops will worsen this patient's symptoms as tropicamide causes pupillary block and worsens angle-closure glaucoma. Tropicamide is one of the causes of drug-induced acute angle-closure glaucoma.

Question 187 of 189

A 60-year-old woman presents to the Emergency Department with a 2-day history of vertigo and vomiting on movement. Each episode of vertigo lasts for around 1 minute after head movements and then resolves if she remains still. She awoke in the night with the symptoms and they have remained unchanged since. She was completely well prior to this and has no other past medical history. Her hearing is unaffected and she has no other symptoms affecting her ears, nose, or throat.

What proportion of patients with this condition will have an improvement in their symptoms after a single particle repositioning manoeuvre?

A. 10 %
B. 100 %
C. 20 %
D. 50 %
E. 80 %

E. 80 %

The Epley manoeuvre is successful in treating around 80% of cases of BPPV Important for me Less important

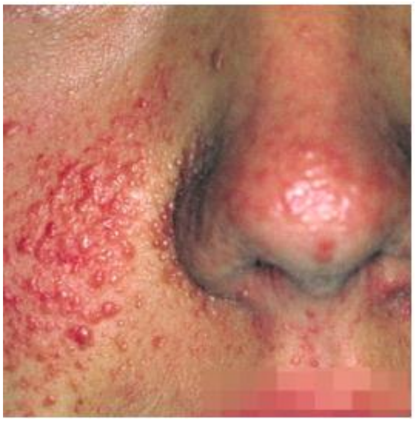
This patient has benign paroxysmal positional vertigo (BPPV). This condition causes the onset of vertigo after head movements and is due to the presence of calcium debris loose within the semicircular canals. This condition is more common in women, and in people over the age of 60. Without treatment, episodes tend to last for around 2 weeks. Episodes often recur.

The most effective treatment is the Epley manoeuvre. This procedure involves a set series of movements of the patient's trunk and head and is designed to encourage the debris to move out of the semicircular canal.

A single manoeuvre leads to complete symptom resolution in 70-80% of patients, and many of the remaining patients will respond to a second or third manoeuvre.

Question 188 of 189

The patient below is being treated for epilepsy:



What is the most likely underlying diagnosis?

A. HIV
B. Neurofibromatosis
C. Arteriovenous malformation
D. Tuberous sclerosis
E. Lennox-Gastaut syndrome

D. Tuberous sclerosis

Tuberous sclerosis - adenoma sebaceum

The correct answer is Tuberous sclerosis. Tuberous sclerosis is a genetic disorder that causes noncancerous (benign) tumours to grow in different parts of the body. It often affects the brain and can lead to conditions such as epilepsy. The image shows characteristic adenoma sebaceum on the nose.

HIV is not the most likely underlying diagnosis in this case. While HIV can have neurological manifestations due to direct effects of the virus or secondary to opportunistic infections, it does not typically present with benign brain tumours. Neurological complications of HIV usually include cognitive impairment, myelopathy, neuropathy, and potentially opportunistic infections of the CNS like toxoplasmosis or progressive multifocal leukoencephalopathy (PML).

The next option, Neurofibromatosis, is a genetic disorder causing tumours to form on nerve tissue. These tumours can develop anywhere in your nervous system, including your brain and spinal cord. However, these tumours are typically neurofibromas and would have a different appearance on imaging compared to those seen in tuberous sclerosis.

Arteriovenous malformation (AVM) is an abnormal connection between arteries and veins, bypassing the capillary system. This vascular disorder disrupts normal blood flow and oxygen circulation. Brain AVMs could possibly cause seizures but they would create a different pattern on imaging studies than what is presented here.

Finally, Lennox-Gastaut syndrome is a type of childhood-onset epilepsy that results in multiple seizure types and cognitive decline. However, it does not cause benign brain tumours as seen in the provided image.

In conclusion, based on UK guidelines for managing patients with epilepsy and considering the characteristics shown in the image provided - benign brain tumours - Tuberous Sclerosis represents the most likely underlying diagnosis for this patient's condition.

Question 189 of 189

A 35-year-old lady was referred to the neurology clinic for investigation of facial weakness. Over the past 2 months, she noticed that her eyelids had tended to drop towards the end of the day, and she had occasional diplopia. She also felt that the corners of her mouth drooped a bit, and she reported some difficulty smiling. There was no limb weakness, and she had not had any difficulty swallowing.

On examination, there was a bilateral facial droop, and bilateral partial ptosis. She was sitting with her head tilted up to compensate for this. She had almost complete ptosis after trying to keep her eyes in elevation for more than 15 seconds. Eye movements were otherwise normal. Palatal movement was equal on both sides, and there were no abnormalities in tongue movements. Tone, power, reflexes and sensation were normal in the upper and lower limbs.

What is the most appropriate initial management?

A. Mycophenolate mofetil
B. Thymectomy
C. Prednisolone
D. Intravenous immunoglobulin
E. Pyridostigmine

E. Pyridostigmine

Pyridostigmine is a long-acting acetylcholinesterase inhibitor that reduces the breakdown of acetylcholine in the neuromuscular junction, temporarily improving symptoms of myasthenia gravis

This lady presents with weakness affecting her facial and extraocular muscles, demonstrating fatigability. This is characteristic of myasthenia gravis. Treatment choice depends on the severity of symptoms.

In mild disease such as in this case, acetylcholinesterase inhibitors such as pyridostigmine are useful in control of symptoms. In more severe disease, with limb weakness or bulbar dysfunction immunomodulatory agents are often required. Steroids are often employed, with the addition of steroid-sparing agents such as mycophenolate mofetil, ciclosporin or azathioprine if necessary.Intravenous immunoglobulin and plasma exchange are useful in myasthenic crises. Thymectomy improves symptoms in cases associated with thymoma, and may also be beneficial in young patients with recent onset of symptoms, but would not be used as an initial treatment option.

PASSMEDICINE PART 2 RESPIRATORY 2024

Question 1 of 231

A 60-year-old male is admitted to hospital under the medical team with breathlessness. The patient is able to give a history of rapid onset breathlessness this afternoon, with no associated chest pain. He has recently started an an ACE inhibitor for hypertension. On examination, there are bilateral crepitations to the mid-zones. There are no added heart sounds. The patient is tachypnoeic and saturations are 90% on room air. Urinalysis is negative. A chest X-Ray demonstrates acute pulmonary oedema. An ECG shows sinus rhythm with a rate of 95. Blood results show:

Na +	135 mmol/l
K +	5.1 mmol/l
Urea	12.6 mmol/l
Creatinine	188 µmol/l

Which investigation will confirm the most likely underlying diagnosis?

A. Magnetic Resonance (MR) Renal Angiography
B. Computed Tomography (CT) Pulmonary Angiography
C. Coronary Angiography
D. Echocardiography
E. High Resolution Computed Tomography (HRCT)

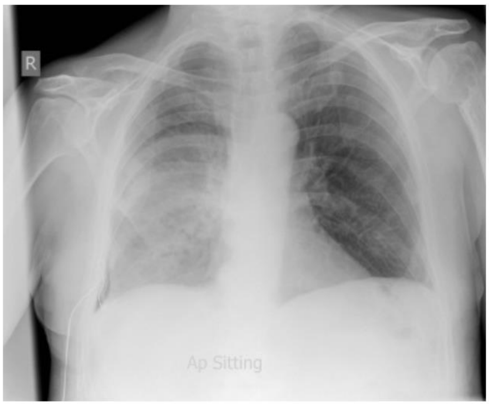
A. Magnetic Resonance (MR) Renal Angiography

This patient gives a history of flash pulmonary oedema. The clue in the question as to the cause is the recent initiation of an ACE inhibitor. In patients with undiagnosed renal artery stenosis, initiation of ACE inhibitor therapy is a recognised cause of flash pulmonary oedema.

Although a echocardiography would be part of the initial work-up, it would not reveal the underlying diagnosis. From the history, and based on the unremarkable ECG, cardiogenic pulmonary oedema is unlikely to be the cause in this scenario.

Question 2 of 231

A 76-year-old man presents with dyspnoea. A chest x-ray is performed:



What is the main finding on the film?

A. Right upper lobe consolidation
B. Right sided pneumothorax
C. Pulmonary oedema
D. Right middle + lower lobe consolidation
E. Bronchiectasis

D. Right middle + lower lobe consolidation

The presence of consolidation above the horizontal fissure and the obscured right heart border suggest the presence of right middle lobe consolidation. There is some loss of definition (silhouette sign) of the medial aspect of the right hemidiaphragm suggesting some right lower lobe consolidation as well.

A chest drain is also seen on the right hand side. This had been inserted to drain an associated pleural effusion.

Question 3 of 231

A 75-year-old male presents to his GP with three weeks of shortness of breath. He developed a cold a few weeks prior and has remained short of breath since. He was bringing up green sputum but the cough is now dry. He has no pains in his chest and no fevers. He is now retired but remains a keen gardener with an allotment of vegetables and tubers. He previously worked as an aerospace engineer making and fixing electronic parts. He is unsure of any asbestos exposure.

On examination, he has clubbing and appears cachectic. There are bilateral apical crepitations and he appears breathless with activity. Oxygen saturation on air is 94% and respiratory rate is 28/min.

Na +	138 mmol/l
K +	4.2 mmol/l
Urea	4.3 mmol/l
Creatinine	78 µmol/l
Hb	135 g/l
Platelets	450 * 10 /l9
WBC	14 * 10 /l9
C-reactive protein	12 mmol/l
Chest x-ray	reticular shadowing prominent at the apices

What is the likeliest diagnosis?

A. Aspergillosis
B. Asbestosis

C. Berylliosis
D. Hypersensitivity pneumonitis
E. Idiopathic pulmonary fibrosis

C. Berylliosis

Aeronautical engineers -> risk of berylliosis

This gentleman has shortness of breath and reticular changes consistent with a form of interstitial lung disease (formerly pulmonary fibrosis). The cause is reliant on the history. Asbestosis is usually a lower lobe fibrosing process. Aspergillosis typically occurs in weakened immunosuppressed individuals. Hypersensitivity pneumonitis classically occurs in those exposed to moulds and hay which is possible in a gardener but not common. Berylliosis is linked to beryllium heavily used in the aeronautical industry.

Question 4 of 231

A 35-year-old female banker from Scotland presents with breathlessness on exertion. She is a non smoker and has two budgies at home. She had severe pneumonia 5 years ago and required intubation on intensive care for 5 days. She recovered but has reported ongoing dyspnoea and on examination has an inspiratory wheeze. This has not improved despite her GP starting inhaled steroids for asthma. Her chest X-ray was unremarkable, peak flow was reduced and eosinophil count was normal.

What is the most likely diagnosis?

A. Cystic fibrosis
B. Severe asthma
C. Posterior subglottic stenosis
D. Chronic obstructive pulmonary disease
E. Allergic bronchopulmonary aspergillosis

C. Posterior subglottic stenosis

Subglottic stenosis can occur from birth, idiopathically and in patients who have been intubated. It worth considering in patient with lung function tests that show an obstructive picture and as a differential diagnosis in the 'difficult asthma clinic'.

This patients lack of response to inhaled steroids and predominance of inspiratory rather expiratory wheeze may asthma less likely. A patient with cystic fibrosis would probably have an abnormal CXR by the age of 35 and the normal eosinophil count makes ABPA less likely. COPD is unusual in non smokers but plausible if their is a family history of early onset dyspnoea (ie alpha- 1-antitrypsin deficiency).

Question 5 of 231

A 64-year-old man presents to the respiratory clinic for review. He has been diagnosed with idiopathic pulmonary fibrosis which has not responded to a course of oral corticosteroids. He is finding it difficult to manage the stairs more than once per day and is finding it difficult to get out of the house. On examination his blood pressure is 138/88 mmHg, his pulse is 80 beats per minute and regular. There are inspiratory crackles on auscultation of the chest consistent with pulmonary fibrosis, and his O2 saturation is 92% at rest. His FVC is 65% of predicted.

Which of the following is the next most appropriate intervention?

A. Cyclophosphamide
B. Infliximab
C. Methotrexate
D. Nintedanib
E. Rituximab

D. Nintedanib

Nintedanib is a small molecule tyrosine kinase inhibitor including the receptors platelet-derived growth factor receptor (PDGFR) and , fibroblast growth factor receptor (FGFR) 1-3, and VEGFR 1-3. It is licensed for the treatment of idiopathic pulmonary fibrosis, and is endorsed by NICE guidelines when:

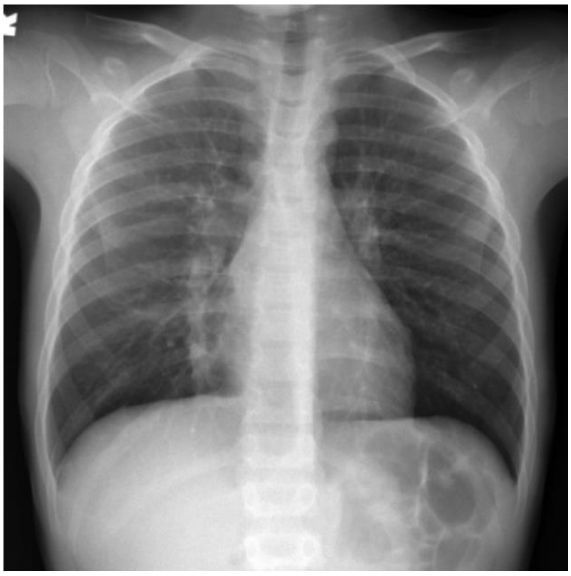
a. **The person has a forced vital capacity (FVC) between 50% and 80% of predicted**

b. **The company provides nintedanib with the discount agreed in the patient access scheme and**

c. **Treatment is stopped if the disease progresses (a confirmed decline in percent predicted FVC of 10% or more) in any 12month period.**

Question 6 of 231

A 9-year-old is referred to the Children's Ward with pyrexia and cough:



What does the x-ray show?

A. Right middle lobe consolidation
B. Perihilar lymphadenopathy
C. No abnormality
D. Left lingual consolidation
E. Right upper lobe consolidation

A. Right middle lobe consolidation

The correct answer is **Right middle lobe consolidation**. This is because the x-ray image shows an area of increased opacity in the right middle zone of the lung, which corresponds to the location of the right middle lobe. The loss of the right heart border is a common finding in right middle lobe consolidation. Consolidation refers to a region of lung tissue filled with liquid instead of air, often due to infection such as pneumonia. The child's symptoms of pyrexia and cough also support this diagnosis.

The option **Perihilar lymphadenopathy** is incorrect because it refers to enlargement of lymph nodes around the hilum, a region where blood vessels and nerves enter or exit an organ. In this case, it would be seen as enlarged shadows near the centre (mediastinum) of the chest x-ray. However, there are no such findings in this image.

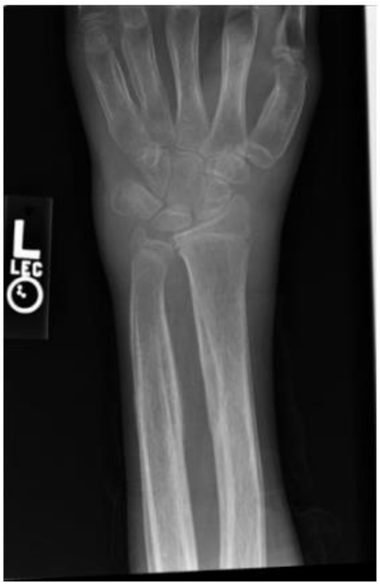
The option **No abnormality** is incorrect as there is clearly an area of increased opacity in the right middle lobe indicating a pathological process.

Left lingual consolidation is also incorrect. The lingula is a part of the left upper lobe that corresponds anatomically to the right middle lobe. However, there are no signs on this x-ray that suggest any abnormalities in this area.

Lastly, **Right upper lobe consolidation** would typically show increased opacity in the upper part of the right lung field on an x-ray image. However, in this case, it's clear from the image that there's an increase in density more centrally located which corresponds with a right middle lobe consolidation rather than upper.

Question 7 of 231

A 75-year-old man is admitted to hospital with haemoptysis and dyspnoea. He is a life-long smoker and a coin lesion is seen in the right middle zone on chest x-ray. He also complains of pain in his left forearm. An x-ray is requested:



What is the most likely cause of the patients arm pain?

A. PTHrP-induced subperiosteal bone resorption and osteopaenia
B. Pathological fracture of the radial head
C. Long-standing osteoarthritic changes
D. Hypertrophic pulmonary osteoarthropathy
E. Metastatic lung cancer

D. Hypertrophic pulmonary osteoarthropathy

The x-ray shows the periosteal reaction on the shafts of the ulnar and radius. This is typical of hypertrophic pulmonary osteoarthropathy.

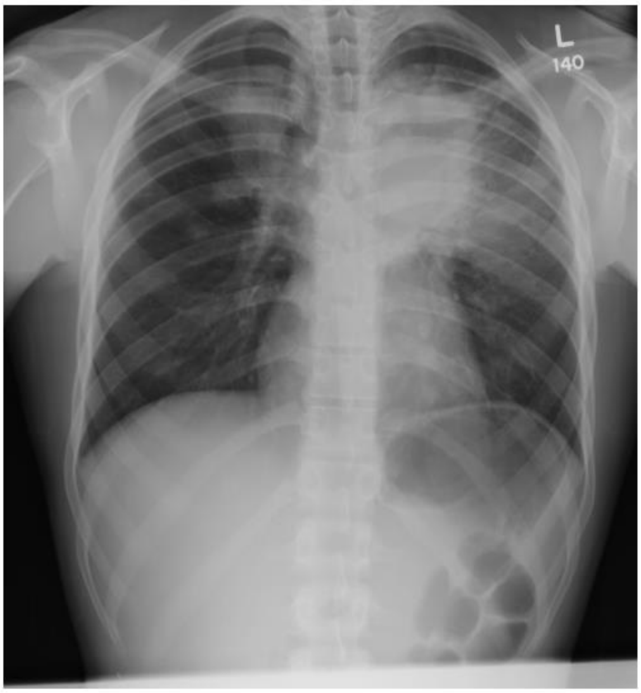
Question 8 of 231

A 23-year-old man presents with dyspnoea and haemoptysis to the Emergency Department. He initially thought his symptoms were due to a chest infection but a course of amoxicillin from his GP has not helped. He now feels short of breath on mild exertion and has coughed up fresh blood on a number of occasions today.

On examination his oxygen saturations are 92% on air. On examination he has crackles predominately in the upper and lower zones of the left lung. Temperature is 37.7ºC.

Hb	13.1 g/dL
WCC	11.3 *10^9/l
Sodium	137 mmol/l
Potassium	4.2 mmol/l
Urea	6.4 mmol/l
Creatinine	123 µmol/l
CRP	188 mg/L

Urine dip: blood +++, leucocytes + A chest x-ray is requested:



Later tests during his admission show the following;

c-ANCA	Positive
p-ANCA	Positive
Anti-GBM	Negative

What is the most likely diagnosis?

A. Granulomatosis with polyangiitis
B. Cryptogenic organizing pneumonia

C. Churg-Strauss syndrome
D. Tuberculosis
E. Goodpasture's disease

A. Granulomatosis with polyangiitis

This patient has both the pulmonary and renal manifestations (raised creatinine, heamaturia) of granulomatosis with polyangiitis.

Question 9 of 231

A 67-year-old gentleman comes for review following a two-week-wait referral to the respiratory clinic. He is a current smoker with a 60 pack-year history. He has been suffering from a worsening cough and haemoptysis for the last month and has had a weight loss of 3kg over one month. On examination he looks cachectic, his fingers are clubbed and tar-stained. His wrists are tender. His chest shows reduced expansion on the right side with reduced breath sounds and dullness.

What is the wrist tenderness likely to indicate?

A. Osteoarthritis
B. Osteoporosis
C. Osteopenia
D. Paraneoplastic rheumatoid-like disease
E. Hypertrophic pulmonary osteoarthropathy

E. Hypertrophic pulmonary osteoarthropathy

The correct answer is hypertrophic pulmonary osteoarthropathy. This is a patient who is very likely to have lung cancer. He has a heavy smoking history, haemoptysis and weight loss with worrying examination features. Wrist tenderness is likely to be secondary to this in the form of a paraneoplastic hypertrophic pulmonary osteoarthropathy due to squamous cell lung cancer. This is suggested by the clubbing, caused in a similar way. Wrist tenderness is unlikely to occur with osteoarthritis, osteopenia and osteoporosis. Paraneoplastic rheumatoid-like disease is more likely to be asymmetrical and affect the lower limbs.

Question 10 of 231

A 44-year-old man attends with a one-week history of fever and cough. A systematic enquiry was otherwise unremarkable. On examination, you note right-sided coarse crepitations. The examination was otherwise unremarkable.

Blood results are as follows:

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	524 * 10 /L 9	(150 - 400)
WBC	18.2 * 10 /L 9	(4.0 - 11.0)
Neuts	14.8 * 10 /L 9	(2.0 - 7.0)
Lymphs	3.0 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.2 * 10 /L 9	(0.0 - 0.4)
Na +	132 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	24.2 mmol/L	(2.0 - 7.0)
Creatinine	381 µmol/L	(55 - 120)
CRP	22 mg/L	(< 5)
ANCA PR3	8.2 IU/ml = Positive	(< 2)
Total serum IgE	246 KU/l	(5 - 120)
Aspergillus specific IgG or IgE	Positive	

A CT chest is performed:

CT chest	Hazy consolidation or ground-glass infiltrates in the right lower lobe lung parenchyma suggestive of an intra-alveolar haemorrhage

What is the most likely diagnosis?

A. Allergic bronchopulmonary aspergillosis (ABPA)
B. Churg-Strauss syndrome
C. Goodpasture's disease
D. Hypereosinophilic syndrome
E. Wegener's granulomatosis

E. Wegener's granulomatosis

Consider granulomatosis with polyangiitis when a patient presents with ENT, respiratory and kidney involvement

Wegener's granulomatosis is correct. This condition is characterised by necrotizing granulomatous inflammation of the upper and/or lower respiratory tract, and vasculitis of smallto-medium-sized vessels. The presence of a pulmonary haemorrhage and renal failure, combined with a strongly positive ANCA makes this the most likely diagnosis.

Allergic bronchopulmonary aspergillosis (ABPA) is incorrect. Although the patient has a positive aspergillus-specific antibody result and raised total serum IgE, the clinical features, in this case, do not support a diagnosis of ABPA. ABPA presents with shortness of breath, cough, and wheezing. As *Aspergillus fumigatus* spores are common in the environment and almost everyone is exposed to them, low levels of antibodies to *A. fumigatus* are found in many patients and are often not clinically significant.

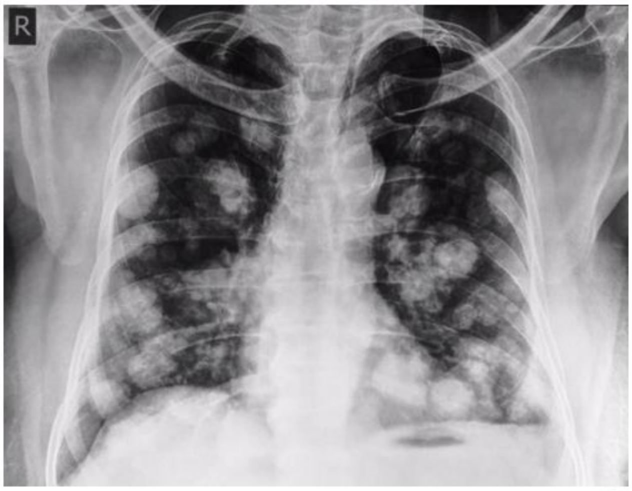
Churg-Strauss syndrome is incorrect. Churg-Strauss syndrome, also known as allergic granulomatous angiitis, is a rare disease characterised by the triad of asthma, pulmonary infiltrates, and hypereosinophilia. Although this remains within the differential diagnosis, the acute onset, presence of renal failure, and strongly positive ANCA with a PR3 subtype favours the diagnosis of Wegener's granulomatosis. Churg-Strauss syndrome is classically associated with the MPO subtype of ANCA.

Goodpasture's disease is incorrect. Pulmonary haemorrhage and renal failure are classical features of this condition. However, this condition is associated with anti-GBM antibodies rather than ANCA, making this a less likely diagnosis.

Hypereosinophilic syndrome is incorrect. Hypereosinophilic syndrome (HES) is a diagnosis of exclusion and should be made only after reactive and clonal eosinophilia have been excluded. The absence of eosinophilia makes this a less likely diagnosis.

Question 11 of 231

A 53-year-old man is admitted to the Emergency Department complaining of a 'chest infection'. His symptoms have not improved despite a course of antibiotics from his GP. The admission chest x-ray is shown below:



What is the most appropriate next-line investigation?

A. High resolution CT thorax
B. CT abdomen
C. Testicular ultrasound
D. Bronchoscopy
E. Sputum culture

B. CT abdomen

The chest x-ray shows cannonball metastases which are most commonly caused by renal cell cancer. A CT abdomen is the most appropriate test to investigate this possibility.

Other tests should of course be considered including a prostate specific antigen.

Question 12 of 231

A 52-year-old man presents with a 5 day history of cough, feeling hot and facial pains. He is generally fit and well although does currently take sertraline for anxiety and depression. He describes a cough productive of pale yellow sputum. He also describes difficulty breathing through his nose and pain in his face, particularly when coughing on leaning forward.

On examination he is alert, pulse rate is 84/min, temperature is 37.3º and respiratory rate is 16/min. His blood pressure is 122/74 mmHg. Chest auscultation is unremarkable. He is tender over the maxilla.

What is the most appropriate next step in management?

A. Check serum urea for CURB-65 scoring
B. Oral amoxicillin + review in 3-4 days if not improving
C. Advise paracetamol for symptoms + review in 3-4 days if not improving
D. Arrange a chest x-ray
E. Oral clarithromycin + review in 3-4 days if not improving

C. Advise paracetamol for symptoms + review in 3-4 days if not improving

This patient has a viral upper respiratory tract infection. His examination findings are essential normal other than some facial pain associated with rhinosinusitis. He requires supportive treatment only as per NICE guidelines.

Question 13 of 231

A 63-year-old man with a new diagnosis of idiopathic pulmonary fibrosis is reviewed is respiratory clinic following initial baseline investigations. He has been suffering from progressive shortness of breath for nine months with a non-productive cough. His GP has tried to give him inhalers and antibiotics but this has not helped. He has a past medical history of hypertension, depression and gout. He is concerned about his new diagnosis, especially about his prognosis.

What test is most useful in determining prognosis?

A. Forced vital capacity
B. 6-minute walking test
C. High resolution CT of the chest
D. Carbon monoxide transfer factor
E. FEV1/FVC ratio

D. Carbon monoxide transfer factor

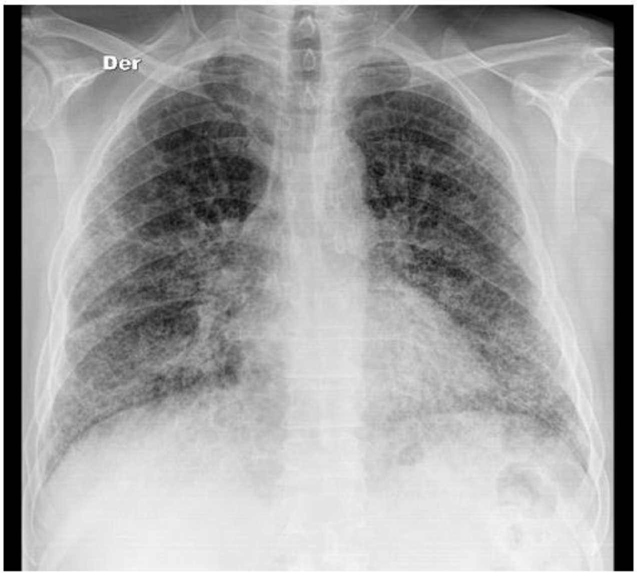
The correct answer is carbon monoxide transfer factor. The 6-minute walking test is not useful for prognosis, whilst CT is more useful in determining aetiology. The FEV1/FVC ratio would confirm a restrictive pattern consistent with fibrosis, but this would not help defining prognosis. Serial measurements of forced vital capacity can be helpful in understanding the disease course and establishing progression, but at the first appointment this is unlikely to be helpful.

Question 14 of 231

A 63-year-old retired car mechanic is referred to the respiratory clinic by his GP due to progressive dyspnoea and low oxygen saturations. The GP had performed an ECG and BNP level, both of which were within normal limits.

The dyspnoea had been getting progressively worse for the past 2 years and is now limiting his daily activities. He also describes a dry cough which is worse after walking. There is no history of chest pain, On examination there is no clubbing, pulse is 84/min, respiratory rate 18/min and oxygen saturations are 91% on room air.

An x-ray is requested:



What is the most likely diagnosis

A. Sarcoidosis
B. Extrinsic allergic alveolitis
C. Silicosis
D. Bronchiectasis
E. Idiopathic pulmonary fibrosis

E. Idiopathic pulmonary fibrosis

The chest x-ray shows reitcular opacities predominantly in the bases, a classic finding of idiopathic pulmonary fibrosis.

His occupation is not a risk factor for silicosis. This condition also most commonly affects the upper zones of the lungs.

There is no hilar lymphadenopathy to support a diagnosis of sarcoidosis.

Whilst there is some traction bronchiectasis of the lungs (seen most easily on the associated CT below) this is not the primary diagnosis and the history is not supportive.

With extrinsic allergic alveolitis there is often a relevant occupational history and the upper/mid zones are more commonly affected.

Question 15 of 231

An 81-year-old man is seen in the respiratory clinic due to poor control of his chronic obstructive pulmonary disease (COPD). Despite being prescribed inhaled salbutamol as required, he remains breathless on minimal exertion which is limiting his ability to carry out daily activities. He reports that these symptoms are consistently present with no diurnal variation.

He has a 50 pack year smoking history. His past medical history includes hypertension for which he takes ramipril and he has no allergies. Recent blood tests performed by the general practitioner show the following:

Hb	141 g/L	Male: (135-180)Female: (115 - 160)
Platelets	301 * 10 /L 9	(150 - 400)
WBC	6.3 * 10 /L 9	(4.0 - 11.0)
Neuts	4.1 * 10 /L 9	(2.0 - 7.0)
Lymphs	1.7 * 10 /L 9	(1.0 - 3.5)
Mono	0.4 * 10 /L 9	(0.2 - 0.8)
Eosin	0.1 * 10 /L 9	(0.0 - 0.4)

Which of the following would be most appropriate to initiate?

A. Add a leukotriene receptor antagonist
B. Add a long acting beta agonist + muscarinic antagonist (LABA + LAMA)
C. Add an inhaled corticosteroid (ICS)
D. Add prophylactic antibiotics
E. Assessment for long term oxygen therapy

B. Add a long acting beta agonist + muscarinic antagonist (LABA + LAMA)

COPD - still breathless despite using SABA/SAMA and **no** asthma/steroid responsive features → add a LABA + LAMA

This man has presented with COPD that has not been adequately controlled by a SABA/SAMA. The next step in management depends on whether he shows asthma/steroid-responsive features. A lack of any history of asthma/atopy, variation in symptoms (including diurnal), and a normal eosinophil count indicates that this man is unlikely to be steroid responsive. Therefore the most appropriate second-line treatment is to add a LABA + LAMA.

Leukotriene receptor antagonists are not used second line in COPD.

ICS is indicated second line if there are any features suggestive of asthma/steroid responsiveness. As these are not present in the history or blood results, a LABA + LAMA is more appropriate.

Prophylactic antibiotics could be considered in cases of recurrent infective exacerbation however this is not the case here.

This man is not yet on optimal medical therapy so an assessment for long-term oxygen therapy would be premature at this stage.

Question 16 of 231

A 52-year-old woman presents with worsening exercise tolerance. Her GP has recently increased her asthma treatment but this has not helped, nor does she have any relief from her salbutamol inhaler. She has no other known medical history. On examination, her lung fields sound clear on auscultation but she has an early diastolic murmur. She has already had a chest X-ray demonstrating enlarged proximal pulmonary arteries.

Which investigation is most likely to provide the correct diagnosis?

A. ECG
B. Renal function blood tests
C. Echocardiogram
D. High-resolution CT chest
E. Right heart catheterisation

E. Right heart catheterisation

The correct answer is right heart catheterisation to diagnose pulmonary arterial hypertension. The history is primarily of worsening shortness of breath in a middle-aged person with clear lung fields and a diastolic murmur. The chest X-ray with enlarged proximal pulmonary arteries is highly suggestive. Whilst an ECG or echocardiogram may show features of pulmonary arterial hypertension right heart catheterisation is the gold standard and would be most diagnostic.

Question 17 of 231

A 69-year-old man with a history of rheumatoid arthritis well controlled on methotrexate presents with gradual pain and swelling in his wrists and ankles.

The pain is described as a dull ache that is intermittent, often worse in the evenings. There is associated swelling which can sometimes feel warm. He has tried regular paracetamol but this has had limited effect.

He also describes a chronic cough and shortness of breath on exertion for the past 6 months that he has not mentioned to his GP. There has been no haemoptysis and he denies any fevers. His wife has noticed that he has been losing weight recently.

He has a past medical history of rheumatoid arthritis, hypertension, hypercholesterolaemia and type 2 diabetes mellitus. He currently takes methotrexate weekly, folic acid 5mg weekly, ramipril 5mg, simvastatin 20mg at night, metformin 500mg three times a day and paracetamol 1g four times daily.

He is a retired accountant and a current smoker with a 50 pack year smoking history. He drinks approximately 30 units of beer a week. He denies any recent foreign travel.

On examination, he is cachectic and short of breath on exertion. His pulse is 80/min and regular, blood pressure 140/93 mmHg, oxygen saturations of 93% on air. He has marked fingernail clubbing. Examination of his wrists reveals slightly swollen and tender joints. Swan neck and ulnar deviation deformities are noted in both hands. Other than his wrists, no other joint abnormalities are detected. Examination of the peripheral nervous system is normal.

Examination of his chest is normal with no focal consolidation.

Initial bloods are as follows:

Na+	134 mmol/L
K+	3.9 mmol/L
Urea	7.8 mmol/L
Creatinine	105 µmol/L
Hb	100 g/L
WBC	6.0x10^9/L
Platelets	200x10^9/L
LFTs	Normal
Serum uric acid	410 µmol/L
CRP	12 mg/L

Chest X-ray reveals a discrete opacification at the periphery of the right middle lobe.

What is the most likely cause of his joint pains?

A. Rheumatoid arthritis flare
B. Gout
C. Hypertrophic pulmonary osteoarthropathy secondary to bronchogenic carcinoma
D. Reiter's syndrome
E. Osteoarthritis

C. Hypertrophic pulmonary osteoarthropathy secondary to bronchogenic carcinoma

This man has a history of intermittent swelling and pain in his wrists and to a lesser degree in his ankles. He has a past medical history of rheumatoid arthritis with some evidence of joint deformities but seems to be well controlled on methotrexate. There is no synovitis present in the typical pattern of rheumatoid arthritis.

He has a strong smoking history, a 6-month history of cough, weight loss, is clubbed and has an abnormal chest x-ray all highly suspicious of an underlying lung malignancy. Hypertrophic pulmonary osteoarthropathy occurs in about 5% of case of lung cancer and typically presents with intermittent aching and swelling in the wrists and ankles.

This man's serum uric acid is normal and gout typically presents in the first metatarsophalangeal joint. He has no previous history of gout but does have some risk factors for this.

Osteoarthritis is a possible diagnosis but does not typically present with signs of synovitis.

Reiter's syndrome is a seronegative arthritis characterised by the triad of urethritis, conjunctivitis and arthritis which doesn't fit with this patient's clinical picture.

Question 18 of 231

A 57-year-old male is seen in the respiratory clinic with a three months history of a productive cough, weight loss and drenching night sweats. He reports that he is producing approximately 1 cup of green sputum each day and has lost 4 kgs during the same time period. He has smoked 20 cigarettes a day since he was 15 years old. He last traveled abroad 2 years ago, visiting family in North America.

The GP has performed routine blood tests which are unremarkable and a HIV test is negative. Several sputum samples have been sent for routine microscopy, culture & sensitivities (MC&S) growing only normal respiratory flora. Following a normal chest X-ray, you perform a high resolution CT (HRCT) scan. This demonstrates right middle lobe and left lower lobe bronchiectasis with multiple nodules in both lungs.

What other initial investigation would you perform to help reach a diagnosis?

A. Sweat test
B. PET-CT Scan
C. Repeat HRCT scan in 3-6 months
D. Sputum for acid fast bacilli (AFB)
E. Bronchoscopy +/- biopsies

D. Sputum for acid fast bacilli (AFB)

The correct answer is to send sputum for acid fast bacilli (AFB).

Whilst the causative organism could potentially be either tuberculosis or non-tuberculosis mycobacterial (NTM) infection, the latter is the more appropriate here given the radiological findings on HRCT, which are classically seen in atypical mycobacterial infection. This question tests your understanding of the common presentations of pulmonary non-tuberculous mycobacterium (NTM) infection in immunocompetent individuals. NTM infection in the non-HIV population is becoming increasingly common and is often a challenging diagnosis to make due to the environmental nature of NTM.

Question 19 of 231

A 24-year-old woman with a history of cystic fibrosis comes to the endocrinology clinic for review. She has been losing weight and a recent fasting plasma glucose has been measured at 8.1 mmol/l. Over the past year there has been three admissions to hospital with exacerbations of her CF. On examination her blood pressure is 122/81 mmHg, pulse is 71 beats per minute and regular. Auscultation of the chest reveals coarse crackles and scattered wheeze. Abdomen is soft and on tender, her body mass index is 19.5 kg/m².

Which of the following is the best way to manage her diabetes?

A. Low calorie diet
B. Insulin and high calorie diet
C. Metformin and low calorie diet
D. Gliclazide and standard calorie diet
E. Dapagliflozin and low calorie diet

B. Insulin and high calorie diet

Patients with cystic fibrosis suffer significant difficulties in maintaining their weight even before or if they never develop diabetes. Weight loss in cystic fibrosis is closely allied to both risk of exacerbations of the disease and an increase in overall mortality. For this reason it's important for patients to maintain a high calorie diet and take insulin to allow them to convert those calories into stored energy.

All of the other options which include either a standard or low calorie diet are incorrect because they won't allow the patient to maintain her body weight. Dapagliflozin promotes spilling of carbohydrate into the urine, and hence leads to a calorie deficit, this is therefore incorrect. Gliclazide can be used in the initial period of diabetes associated with cystic fibrosis, although it's important in this situation to also encourage patients to maintain a high calorie intake.

Question 20 of 231

A 73-year-old man is referred to the respiratory outpatient clinic with exertional shortness of breath. He has no past medical history and does not take any regular medications. He does not smoke or drink alcohol. He worked for 51 years at a paper mill.

On examination, he is mildly dyspnoeic at rest. There are bibasal inspiratory crackles heard on auscultation. The fingers are clubbed. Cardiovascular examination is unremarkable.

A high-resolution CT chest demonstrates parenchymal bands, traction bronchiectasis and honeycomb lung. There is no involvement of the pleura.

Given the likely diagnosis, what treatment is likely to be recommended?

A. Chemotherapy
B. Conservative management
C. Prednisolone
D. Radiotherapy
E. Surgery

B. Conservative management

Asbestosis is treated conservatively - no interventions offer a significant benefit

Conservative management is the correct answer. The patient presents with exertional shortness of breath and crackles and undergoes an HRCT chest, which demonstrates classic changes of fibrotic lung disease (parenchymal bands, honeycombing and traction bronchiectasis). The most likely cause of fibrosis is asbestos exposure. Historical work in a paper mill is a significant occupational risk for asbestos exposure.

Chemotherapy is incorrect. Asbestos exposure puts the patient at risk of developing mesothelioma, which is a malignant cancer of the pleura. Chemotherapy is an option in this condition. However, we are specifically told there is no pleural involvement and therefore this is unlikely.

Prednisolone is incorrect. This is often trialled in interstitial lung disease if the condition is felt to be steroid-responsive. However, asbestosis is not felt to respond to medical treatment in this way. Additionally, HRCT appearances of ground glass (suggesting inflammation) rather than honeycombing (suggesting established fibrosis) tend to be more steroid responsive.

Radiotherapy is incorrect. This may be an option for treating lung cancer or mesothelioma. However, the HRCT chest does not describe pleural involvement or a primary lung malignancy and therefore this is not likely to be recommended.

Surgery is incorrect. Occupational exposure to asbestosis has been associated with lung cancer, which in some cases can be treated surgically. However, the description, in this case, is of pulmonary fibrosis, rather than a malignancy.

Question 21 of 231

A 24-year-old woman with cystic fibrosis (CF) is reviewed in the endocrinology clinic. She has lost weight over the past few months despite maintaining a high-calorie diet and wakes three times per night to pass urine. Over the past year she has suffered two exacerbations of her CF and has seen a more rapid deterioration in her lung function. On examination her blood pressure is 122/82 mmHg, her pulse is 82 beats per minute and regular, and her body mass index is 19 kg/m². There are coarse crackles and wheeze on auscultation of the chest. A fasting blood glucose is 8.1 mmol/l, and her HbA1c is 60 mmol/mol.

Which of the following is the most appropriate way to manage her diabetes mellitus?

A. Switch to a low calorie diet
B. Start metformin monotherapy and continue high calorie diet
C. Start gliclazide monotherapy
D. Start sitagliptin monotherapy
E. Start basal bolus insulin and continue high calorie diet

E. Start basal bolus insulin and continue high calorie diet

Patients with cystic fibrosis and diabetes should follow a high calorie diet and use extra insulin to control their blood sugar

It's clear that the development of diabetes in patients with cystic fibrosis is associated with weight loss and the development of more frequent respiratory exacerbations. As such it's crucial to maintain adequate nutrition with a high calorie diet and adequate insulin to control blood glucose levels. This is at odds with management of diabetes in other conditions.

Gliclazide is of value in early diabetes associated with cystic fibrosis, although it rarely controls blood glucose levels adequately to allow patients to maintain a high calorie diet, hence insulin is preferred

. Insulin resistance isn't the primary problem in CF related diabetes, therefore metformin is of little value, and DPPIV inhibitors are less effective in lowering blood glucose versus sulphonylureas in this situation.

Question 22 of 231

A 54-year-old man presents to the respiratory clinic. He was found to have three pleural plaques on a chest X-ray when being screened for tuberculosis due to immigration purposes. He worked as a builder for four years 21 years ago. He has no shortness of breath or chest pain. A diagnosis of benign pleural disease is made. He is keen to seek compensation.

What is the most appropriate advice?

A. Seek compensation by criminal law suit
B. Seek compensation by civil law suit
C. Seek compensation via GP
D. Seek compensation via department of social security
E. Unlikely to receive compensation currently

E. Unlikely to receive compensation currently

The correct answer is that he is unlikely to receive compensation currently. This is a gentleman who been identified to have pleural plaques, likely secondary to asbestos exposure but who is suffering no symptoms. These patients do not qualify for compensation. If a diagnosis of asbestosis or mesothelioma is made then the patient would qualify. Compensation can be obtained through Industrial Injuries Disablement Benefit from the Department of Social Security or a civil law claim for damages from the employer under which the exposure occurred. Patients should be advised to consult their local Department of Work and Pensions benefit agency for advice

Question 23 of 231

A 61-year-old man with known lung cancer presents to the emergency department with shortness of breath. He was diagnosed with squamous cell lung cancer two years ago and has had several courses of radiotherapy but stopped as he was not tolerating the treatment. He has noticed worsening of his chronic shortness of breath and struggled to walk from his car to the hospital, a distance that he was managing well previously. On examination, he appears slightly pale, has dullness on right side of his chest with a few bronchial breaths. A chest X-ray demonstrates an effusion and an aspirate withdraws 40ml of blood. His observations show hypoxia with saturations at 91% but are otherwise normal, and blood tests, including a crossmatch, is requested.

What is the most appropriate management?.

A. Surgical chest drain
B. Seldinger chest drain
C. Repeat aspiration
D. Conservative management only
E. IV antibiotics

A. Surgical chest drain

The correct answer is a surgical chest drain. The key in this question is that blood, rather than blood-stained fluid, is aspirated. This means that a surgical chest drain rather than a narrow bore chest drain, a Seldinger chest drain, will be needed. Repeating the aspiration is unlikely to gain any further information, and would only be useful if it is suspected that the sample was due to aspiration of an artery. However, it is unlikely that 40ml could have been aspirated from an artery. There is no indication for antibiotics and treatment is clearly needed as the patient is hypoxic.

The correct answer is a surgical chest drain. The key in this question is that blood, rather than blood-stained fluid, is aspirated. This means that a surgical chest drain rather than a narrow bore chest drain, a Seldinger chest drain, will be needed. Repeating the aspiration is unlikely to gain any further information, and would only be useful if it is suspected that the sample was due to aspiration of an artery. However, it is unlikely that 40ml could have been aspirated from an artery. There is no indication for antibiotics and treatment is clearly needed as the patient is hypoxic.

Question 24 of 231

A 45-year-old man presents to the emergency department with reports of 8 days of fever, headache, epistaxis, diarrhoea and cough. He has no past medical history. He drinks 32 units of alcohol a week. He keeps parrots and enjoys open water swimming in rivers.

Observations:

Heart rate 88 beats per minute Blood pressure 115/74 mmHg Respiratory rate 21/minute Oxygen saturations 94% on room air

On examination, there is splenomegaly. Chest auscultation reveals crackles in both lungs. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	2.9 * 10 /L 9	(4.0 - 11.0)

Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	52 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)

Chest radiography reveals bilateral patchy airspace opacification.

Which organism is most likely responsible for his illness?

A. Chlamydia psittaci
B. Klebsiella pneumoniae
C. Legionella pneumophilia
D. Leptospira alexanderi
E. Staphylococus aureus

A. Chlamydia psittaci

Chlamydia psittaci is a cause of atypical pneumonia. It is transmitted via aerosol inhalation of faecal and urinary products on bird feathers

Chlamydia psittaci is the correct answer. This organism can cause Psittacosis, which is a cause of atypical pneumonia. The prodrome can involve diarrhoea, epistaxis and high fevers. Splenomegaly and a low white blood cell count are common. This organism should be suspected in cases of respiratory infection together with splenomegaly and epistaxis, which is rare as a constellation of symptoms. The classic zoonotic exposure for this condition is birds (including parrots).

Klebsiella pneumoniae is incorrect. This is common in those people who drink to excess, as this patient does. However, it tends to cause cavitating pneumonia and is not associated with epistaxis.

Legionella pneumophilia is incorrect. This can cause atypical pneumonia and diarrhoea. However, the white cell count will be elevated and it tends not to cause epistaxis and splenomegaly is less common. Sodium may be low and liver function may be deranged. Patients are typically exposed to poorly ventilated air conditioning systems.

Leptospira alexanderi is incorrect. This causes Leptospirosis. This is typically characterized by jaundice, subconjunctival haemorrhages and deranged liver function. While freshwater swimming may expose the patient to this organism, it does not cause atypical pneumonia.

Staphylococcus aureus is incorrect. This causes typical cavitating pneumonia. Often this occurs as a secondary bacterial infection after an episode of influenza.

Question 25 of 231

A 26-year-old man is reviewed in the asthma clinic. Despite therapy with high dose fluticasone / salmeterol montelukast and oral theophylline, he has suffered a 4th exacerbation in the past year and is now unable to reduce his dose of oral prednisone below 10mg without a significant increase in shortness of breath and wheeze. On examination his blood pressure is 123/80 mmHg, his pulse is 80 beats per minute and regular. Auscultation of the chest reveals quiet wheeze. His peak flow is 429 ml/min, (550 predicted). Eosinophils are elevated at 3.9 x 10(9)/l. IgE is within the normal range.

Which of the following is the most appropriate next intervention?

A. Mycophenolate
B. Mepolizumab
C. Infliximab
D. Tiotropium
E. Regular nebulisers

B. Mepolizumab

Mepolizumab may be used for asthma with high eosinophils

Mepolizumab is an anti-IL5 monoclonal antibody and represents the optimal intervention here. It binds to IL5 and prevents it from binding to its receptor. IL5 is a cytokine which promotes growth in eosinophil numbers and activity. By blocking IL5 mepolizumab down-regulates eosinophil activity and has been shown to significantly improve symptoms in resistant asthma. Omalizumab is an anti-IgE monoclonal antibody, it is effective in treating resistant asthma with evidence of raised IgE and allergic symptoms and is often considered for similar patients to those treated with mepolizumab, although eosinophil count and IgE drive which of the two therapies are used.

Mycophenolate is not utilised as a disease modifying agent in resistant asthma, but is primarily used for the treatment of lupus nephritis and as an anti-rejection agent. Infliximab is an anti-TNF monoclonal antibody used in the treatment of inflammatory bowel disease and arthritides. Tiotropium is primarily used in the treatment of COPD, and is less effective than other options listed in the treatment of resistant asthma. Nebulisers only have a role in treating asthma where patients are unable to administer beta agonist therapy using a conventional inhaler and spacer device.

Question 26 of 231

A 64-year-old is referred to the respiratory clinic by his general practitioner. He has had four exacerbations of chronic obstructive pulmonary disease in the last 12 months, having previously been well controlled. His forced expiratory volume in one second (FEV1) is 44% of the predicted normal. His inhaled medications include a long-acting muscarinic antagonist, a long-acting beta-2 agonist and an inhaled corticosteroid. He quit smoking five years previously. His six-minute walk distance is 100m.

On examination, he is barrel-chested and there is mild wheeze heard bilaterally. The jugular venous pulse is not raised and there is no peripheral oedema.

What is the most appropriate next step in management?

A. Add furosemide
B. Add oral prednisolone
C. Add roflumilast
D. Refer for lung volume reduction surgery
E. Add zafirlukast

C. Add roflumilast

Roflumilast should be used in COPD for patients who are losing control on triple inhaled therapy

Add roflumilast is correct. This is a long-acting inhibitor of the enzyme phosphodiesterase-4. This is an option for treating severe COPD in cases where the FEV1 is < 50% and the person has had 2 or more exacerbations in the previous 12 months despite triple inhaled therapy with a long-acting muscarinic antagonist, a long-acting beta-2 agonist and an inhaled corticosteroid.

Add furosemide is incorrect. The patient presents with worsening symptoms of COPD rather than right heart failure. He is euvolemic and furosemide would not be of benefit in this case.

Refer for lung volume reduction surgery is incorrect. To be a candidate for lung volume reduction surgery, patients need to be able to complete a six-minute walk distance of at least 140m.

Add zafirlukast is incorrect. This is an orally administered leukotriene receptor antagonist used for the chronic treatment of asthma rather than COPD.

Add oral prednisolone is incorrect. This is typically used to treat acute exacerbations of COPD rather than prevent further exacerbations.

Question 27 of 231

A 25-year-old man attends the clinic. He is planning an expedition to the peak of Mount Everest. He is keen to take a medicine to prevent against acute mountain sickness. He has no past medical history and takes no regular medications.

What treatment will you prescribe?

A. Dexamethasone
B. Nifedipine
C. Sildenafil
D. Dorzolamide
E. Acetazolamide

E. Acetazolamide

Acetazolamide (a carbonic anhydrase inhibitor) can be used to prevent acute mountain sickness

If pharmacological prophylaxis of acute mountain sickness is required, then acetazolamide is first line. This drug is a carbonic anhydrase inhibitor which acts on the kidneys to generate a primary a metabolic acidosis. A compensatory respiratory alkalosis occurs in response, resulting in hyperventilation and improved oxygenation.

Dexamethasone, nifedipine and phosphodiesterase type V inhibitors (e.g. sildenafil) can be used both in the treatment and prophylaxis of acute mountain sickness, however for prophylaxis they are second line agents.

Dorzolamide is a topical carbonic anhydrase inhibitor used in glaucoma.

Question 28 of 231

A 27-year-old woman with brittle asthma presents to the Emergency department. She is managed with high dose salmeterol/fluticasone and montelukast but reports steadily worsening symptoms since starting with a cold some 48hrs earlier. She has been admitted to the intensive care unit on 3 previous occasions. On examination her blood pressure is 122/82 mmHg pulse rate is 88 beats per minute. On auscultation of her chest you hear quiet breath sounds with polyphonic wheeze, her respiratory rate is 30/min. She is given back to back salbutamol nebulisers, ipratropium nebulisers, and IV hydrocortisone. These interventions only lead to minimal improvement in her PEFR from 110 to 140, (330 predicted). Oxygen saturation is 92% measured by pulse oximeter, on 60% oxygen delivered via mask. You call the anaesthetist for possible intubation.

Which of the following is the most appropriate next step?

A. IV aminophylline
B. IV chlorpheniramine
C. IV magnesium
D. IV salbutamol
E. IV omalizumab

C. IV magnesium

This patient has acute severe asthma with little or no improvement from initial nebuliser therapy. As such she requires assessment for possible intubation. In the mean time however, guidelines support the use of IV magnesium. A dose of 2g is commonly given over a period of 20 mins, where it has been shown to improve pulmonary function when added to standard therapy.

Both IV aminophylline and salbutamol may be associated with significant tachyarrhythmias and hold limited benefit over and above inhaled beta agonists, they are therefore not recommended in this situation. Anti-histamines are of limited benefit, and IV omalizumab is used as a treatment for patients with allergic asthma which is resistant to other therapeutic options

Question 29 of 231

A 49-year-old man attends the emergency department after becoming unwell with symptoms of progressive shortness of breath. The man is a Saudi Arabian national, who arrived in the UK 3 days previously on a business trip. The patient reported his shortness of breath had gradually worsened over the previous 2 days to the point whereby even minor physical activity had become challenging. In addition, the patient had noticed a dry cough, runny nose, myalgia and fever over a similar period. The patient denied any history of a productive cough, haemoptysis or gastrointestinal symptoms.

The patient reported being in generally good health aside from the type 2 diabetes mellitus and hypertension. To control these conditions, the patient took regular metformin and captopril. The patient had no known allergies to medications. The patient worked as an international businessman and normally resided in Riyadh with his family. He denied any contact with domestic animals in recent months and had not knowingly spent time with any unwell contacts.

General examination of the patient revealed a slightly overweight middle aged man who appeared unwell and diaphoretic. Basic physical observations are recorded in the below table. Examination of the respiratory system revealed mild tachypnoea at rest but with unremarkable percussion and auscultation of both lung fields. Examinations of the cardiovascular and abdominal systems were unremarkable. No clinical evidence of deep vein thrombosis was identified. Please see below for results of initial investigations requested following assessment by the respiratory medicine team.

Heart rate	95 beats / minute
Respiratory rate	23 respirations / minute
Blood pressure	128 / 85 mmHg
Oxygen saturations (room air)	89 %
Oxygen saturations (O2 3 L / minute via nasal cannulae)	95 %
Glasgow coma scale score	15
Haemoglobin	145 g / dL
Mean cell volume	80.2 fl
White cell count	3.1 x 10>3 / microlitre
Lymphocytes	1.0 x 10>3 / microlitre (reference 1.5-4.0)
Platelets	115 x 10>3 / microlitre
Urea	6.4 mmol / L

Creatinine	85 micromol / L
eGFR	85 ml / min / 1.73 m2
Sodium	139 mmol / L
Potassium	4.0 mmol / L
C-reactive protein	74 mg / L (reference < 7)
Urinalysis	no abnormality detected
Chest x-ray	no pneumothorax; lung fields generally clear with no focal consolidation; no mass lesions
Electrocardiogram	normal sinus rhythm
Nasopharyngeal swab RTPCR	MERS-CoV RNA detected

What is appropriate medical management for the patient's condition?

A. Treatment in the community with anti-pyretic
B. Intravenous ganciclovir (5 mg / kg twice daily for 14 days)
C. In-patient supportive treatment to relieve symptoms and prevent or treat complications
D. Oral oseltamivir (75 mg twice daily for 5 days)
E. Inhaled zanamivir (10 mg twice daily for 5 days)

C. In-patient supportive treatment to relieve symptoms and prevent or treat complications

Middle East respiratory syndrome (MERS) is an acute viral respiratory tract infection caused by the betacoronavirus MERS-CoV. Infection with MERS-CoV is believed to originate from individuals coming in close contact with dromedary camels or consuming camel products (for example, unpasteurised camel milk). However, the majority of cases, are the result of human-to-human transmission via respiratory droplets, particularly secondary to outbreaks in the hospital setting. MERS is limited to the countries of the Arabian Peninsula, but individuals who have travelled from or through that region may present in other countries given the 2-14 day incubation period.

Most patients with MERS present with respiratory symptoms and fever. A cough secondary to MERS is typically dry, but may be productive in up to one-third of patients; haemoptysis is less common, occurring in around 10 % of patients. The clinical spectrum of MERS ranges from asymptomatic or minor respiratory symptoms through to severe pneumonia associated with multiorgan failure. Severe disease is more likely to occur in older individuals or in those with comorbidities.

Routine blood tests in MERS can show lymphocytopenia, thrombocytopenia, acute kidney injury or deranged liver function tests. MERS is confirmed via detection of viral RNA by reverse transcription polymerase chain reaction analysis of respiratory tract secretions.

Management of MERS requires intervention to minimise symptoms and prevent harm from complications such as respiratory failure or septic shock from superadded bacterial pneumonia. No specific drug treatment is available to treat MERS-CoV. The specific treatments given as possible answers are all anti-viral agents used in the treatment of other conditions: oseltamivir and zanamivir for influenza and ganciclovir for cytomegalovirus infections.

Given the patient's hypoxaemia, tachypnoea and comorbidities, it would not be appropriate to manage this patient in the community due to the high risk of clinical deterioration secondary to complications.

Question 30 of 231

A 50-year-old man is admitted under the respiratory team with a left lower lobe pneumonia. He has a history of chronic obstructive pulmonary disease and continues to smoke. He also suffers with with hypertension and high cholesterol.

He is treated with steroids, nebulisers and antibiotics. After 5 days he continues to be hypoxic with saturations of 86% on air, ongoing left basal crepitations and wheeze.

A CT scan of the chest is performed which shows emphysematous changes and resolving left basal consolidation. There is also a 7mm lung nodule in the right upper lobe with surrounding ground glass change.

Over the next 3 days his saturations improve to 93% on air and his symptoms resolve. He is discharged home.

What imaging does he require to follow up his pulmonary nodule?

A. PET CT 2 weeks
B. PET CT 4 weeks
C. Repeat chest x-ray 4 weeks
D. Repeat CT chest 1 year
E. Repeat CT chest 3 months

E. Repeat CT chest 3 months

Risk stratification of incidental pulmonary nodules is complex and needs to take into account the risk factors for lung cancer or metastases, as well as size and character of the nodule. Algorithms for surveillance are well defined in the British Thoracic Society Guidelines published in 2005.

Broadly:

- Nodules < 5 mm require no further surveillance.
- Nodules 5-6mm require CT at 1 year
- Nodules 6-8 mm require CT at 3 months

- Nodules > 8 mm require malignancy risk calculation using the Brock model and should then have CT or PET according to whether this risk is > 10%.

The Brock model (see McWilliams et al) takes into account age, gender, family history and features of the nodule

Question 31 of 231

A 51 year-old man is referred by her GP to the respiratory outpatient clinic. He has had several episodes of sinusitis over the past three years and is currently being referred to plastic surgery as the bridge of his nose has partially collapsed. A chest X-ray that was performed three weeks ago show five nodules and blood tests reveal a urea of 11.6 mmol/l and a creatinine of 198 µmol/l.

Which of the following is the most appropriate initial treatment for this condition?

A. Methotrexate
B. Cyclophosphamide
C. Azathioprine
D. Corticosteroids
E. Cyclophosphamide and corticosteroids

E. Cyclophosphamide and corticosteroids

This man has a likely diagnosis of granulomatosis with polyangiitis, as suggested by the recurrent sinusitis, collapsed nasal bridge and x-ray nodules. First-line treatment is with cyclophosphamide and corticosteroids in patients with moderate to severe disease.

Question 32 of 231

An 88-year-old man presents with increasing shortness of breath over the past three months. He lives with his wife and is usually independent, but is recovering after an admission 6 months ago for pneumonia.

He has lost 10kg in weight compared to before the admission. He has not had any fevers or night sweats. His chest feels tight at times.

He feels short of breath with minimal exertion and this is not worse at any time of day. He has a constant dry cough. He takes ramipril for hypertension and has never smoked. He had tuberculosis as a child.

On examination, he is frail and has bilateral crepitations in the left mid and upper zones and right middle and lower zones. The chest is resonant to percussion and his respiratory rate is 24 breaths/min. His saturation are 92% at rest but on standing drop to 86% and his lips turn purple. He has a palpable heave and his ankles are both swollen.

B-natriuretic peptide	upper limit of normal
CRP	13
FEV1 (% predicted)	87%
FVC (% predicted)	75%
ECG	right bundle branch block, sinus, rate 70/min
Chest X-Ray	reticular shadows bilaterally with reduced chest expansion
ABG in air	
pH	7.35
PaO2	7.9 kPa
PaCO2	6.8 kPa
HCO3	28 mmol/l

What is the most likely diagnosis?

A. Tuberculosis reactivation
B. Asthma
C. Pulmonary fibrosis
D. Congestive cardiac failure
E. Physiological ageing

C. Pulmonary fibrosis

Pulmonary fibrosis can occur following pneumonia

This gentleman has a compensated respiratory acidosis with hypoxia which suggests that he has been ill for at least a few weeks. He also has a restrictive picture on his lung function tests with a relatively preserved FEV1. These changes are abnormal and do not reflect ageing.

He has no sputum and no systemic features making TB unlikely.

He has no wheeze. Asthma would also have obstructive lung function tests.

His BNP is not supportive of cardiac failure.

Question 33 of 231

A 70-year-old woman presents to her GP with increasing shortness of breath over the last 4 months. She also reports an occasional productive cough. Her past medical history includes two previous heart attacks, both treated with percutaneous coronary intervention and hypercholesterolaemia that is treated with simvastatin. She has a 35 pack-year history and does not drink alcohol.

The GP refers her for lung function tests which reveal:

Forced expiratory volume in 1 second (FEV1)	0.78L
Forced vital capacity (FVC)	1.68L
Total lung capacity	5.08L

What is the most likely diagnosis?

A. Chronic obstructive pulmonary disease (COPD)
B. Congestive cardiac failure
C. Pulmonary embolism
D. Bronchiectasis
E. Asthma

A. Chronic obstructive pulmonary disease (COPD)

The most likely diagnosis in this case is COPD, based on the reduced FEV1 and and FEV1/FVC. The high pack-year history and the patient's age also points towards a diagnosis of COPD, as opposed to asthma.

Question 34 of 231

A 24-year-old woman is admitted to Accident and Emergency with acute shortness of breath. She is unable to detail a clinical history due to shortness of breath. Her medication includes;

Cetirizine 10mg Orally Once Daily Clobetasone butyrate (Eumovate) Topical

Her initial examination revealed bilateral widespread polyphonic wheezes. Her pulse rate was 102 beats per minute and blood pressure 128/75 mmHg. Her respiration rate was 33. Her oxygen saturations were 96% on 4L/min via face mask. She had a dry flaking rash in her elbow flexures with signs of excoriation.

The following blood tests were obtained;

Hb	11.2 g/dl
Platelets	204*10^9/l
WBC	10.3 *10^9/l
Eosinophil	0.56 *10^9/l
CRP	65
Na+	135 mmol/l
K+	4.4 mmol/l
Urea	7.6 mmol/l
Creatinine	101 µmol/l

Chest x-ray was clear. A peak expiratory flow was 200 L/min(expected 402). Initial arterial blood gas on 4L/min oxygen via face mask;

pH	7.46
pCO2	3.5 kPa
pO2	14 kPa
HCO3	19 mmol/l
Lactate	1.8 mmol/l

She is treated with nebulised salbutamol and ipratropium bromide and oral prednisolone 40mg and oxygen 4L/min.

You re-review the patient 30 minutes later on the Admissions Unit. Her examination reveals symmetrical quiet breath sounds and quiet bilateral wheezes. She has symmetrical chest wall movement. Her pulse rate is 80 beats per minute. Blood pressure 103/68 mmHg. Her respiratory was 18 with oxygen saturations 94% on 6L/min via face mask. Peak expiratory flow was 120 L/min.

Repeat arterial blood gas on 6L/min oxygen via face mask;

pH	7.33
pCO2	6.2kPa
pO2	13kPa
HCO3	20 mmol/l
Lactate	2.2 mmol/l

What is the most appropriate next step in management?

A. Intravenous Magnesium
B. Reduce oxygen levels
C. Intravenous Salbutamol
D. Referral to intensive care
E. Biphasic positive airway pressure

D. Referral to intensive care

According to British Guideline on Management of Asthma BTS/SIGN 2011.

This patient had acute severe asthma as highlighted by her first set of results and examination.

Acute Severe

- **PEF 33-50% best or predicted**
- **RR >25, HR >110**
- **Inability to complete sentances**

Her ABG was consistent with type one respiratory failure with hypocapnia due to hyperventilation. Her condition deteriorated to life threatening with raised PaCO2 suggesting of near fatal asthma

Life Threatening

- PEF <33%
- SpO2 <92% or PaO2 <8kPa
- Normal PaCO2
- Silent chest, cyanosis, poor respiratory effort, arrhythmia, exhaustion

Near Fatal

- Raised PaCO2
- Requiring mechanical ventilaion with raised inflation pressures

The patient had a deteriorating picture. Her respiratory rate was decreasing suggesting exhaustion, worsening hypoxia, hypercapnic acidotic ABG, deteriorating PEF indicating deterioration.

Intravenous Magnesium - This patient would certainly require consideration of IV Magnesium however as the picture is deteriorating they would require ITU referral immediately.

Reduce oxygen levels - Incorrect. Retention of CO2 is not secondary to her oxygen therapy, it is more likely due to exhaustion.

Intravenous Salbutamol - Not utilised in current guidance.

Referral to intensive care - Correct answer. The patient has near fatal asthma with deterioration despite nebulisers and steroids.

Biphasic positive airway pressure - No evidence to support NIV use in acute asthma.

Question 35 of 231

A 27-year-old woman presents for review to the respiratory clinic. She has a past medical history of cystic fibrosis and has been struggling at home. Her GP sent a sputum sample prior to her clinic appointment as he was concerned with the worsening nature of her cough and shortness of breath.

Which microorganism is associated with the worst prognosis?

A. Burkholderia
B. Klebsiella pneumoniae
C. Pseudomonas aeruginosa
D. Staphylococcus aureus
E. Haemophilus influenzae

A. Burkholderia

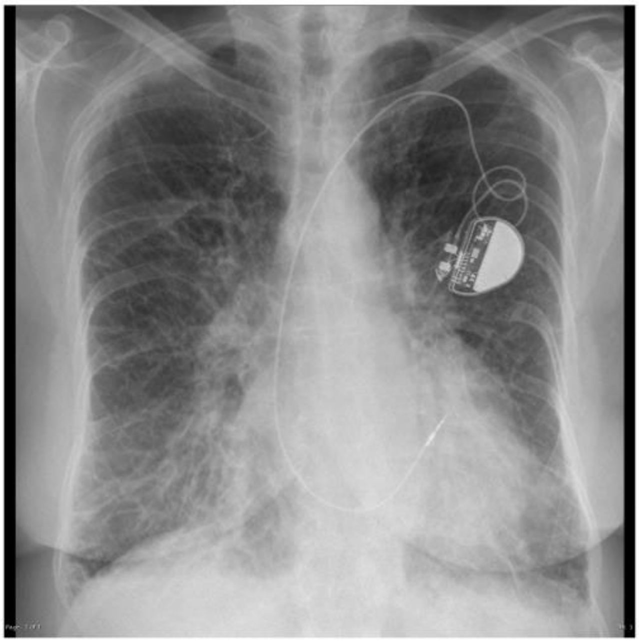
The correct answer is Burkholderia. All of the pathogens listed are potential pathogens which commonly cause exacerbation of cystic fibrosis, but Burkholderia and Pseudomonas are two pathogens which are very difficult to eradicate. Of those, Burkholderia has the worst prognosis.

Question 36 of 231

An 80-year-old woman presents with dyspnoea to the Emergency Department. According to her daughter she has been getting progressively worse over the past 4 weeks. Her past medical history includes a myocardial infarction 20 years ago following which she had a 'pacemaker' inserted. She still smokes 20 cigarettes/day.

On examination her pulse is 120/min irregularly irregular. Blood pressure is 102/72 mmHg, oxygen saturations are 94% on 40% oxygen via a Venturi mask.

Her chest x-ray is shown below:



What is the most appropriate initial treatment?

A. Oral beta-blocker
B. Low-molecular weight heparin
C. Intravenous loop diuretic
D. Reduce oxygen to 24% and nebulised bronchodilator
E. Intravenous broad-spectrum antibiotic

C. Intravenous loop diuretic

The chest x-ray is consistent with acute pulmonary oedema. Single lead PPM in situ. The heart is enlarged and there is marked prominence of the interstitial lines. Minimal blunting of the left costophrenic angle.

Question 37 of 231

You are caring for 54 year-old lady on the respiratory ward. She has community acquired pneumonia and large left sided pleural effusion. She is dyspnoeic at rest and hypoxic - oxygen saturations are 96% on 60% high flow oxygen.

A bedside ultrasound scan shows an anechoic effusion with no apparent loculations. You proceed to perform a diagnostic aspirate and the results are as follows:

pH	6.9
Glucose	2.9mmol/L
Protein	32g/dL
Gram stain	No organisms seen

What is the correct course of action?

A. 18Fr chest drain and intravenous antibiotics
B. Therapeutic aspiration and intravenous antibiotics
C. Referral to thoracic surgeons
D. Broad spectrum intravenous antibiotics
E. 18Fr chest drain, intravenous antibiotics and intrapleural fibrinolysis

A. 18Fr chest drain and intravenous antibiotics

Although the ultrasound appearances in this case are suggestive of a simple parapneumonic effusion the aspirate results suggest an empyema. Empyema must be treated promptly and aggressively with broad spectrum antibiotics and drainage*. Intra-pleural fibrinolysis is useful in loculated effusions and thoracic surgery should be considered if initial management fails

Question 38 of 231

A 56-year-old gentleman was admitted to the Emergency Department with a two-week history of progressively increasing shortness of breath, with frank haemoptysis for the last couple of days. He had recently returned from a holiday in Turkey a few weeks ago. By the point of admission, he was short of breath on minimal exertion and at rest and was unable to complete full sentences. He also complained of increasing orthopnoea for the last few weeks. He had a long history of recurrent epistaxis, rhinitis and sinusitis, as a well as a past medical history of diabetes, hypertension, hypercholesterolaemia and gout. His medication regimen comprised of mometasone nasal spray, allopurinol 100mg OD, ramipril 2.5 mg OD, amlodipine 5mg OD, simvastatin 40mg OD, metformin 500mg TDS and gliclazide 80mg OD. He smoked 20 cigarettes per day and did not consume alcohol.

On examination, he appeared very unwell with obvious respiratory distress. His respiratory rate was 28/min, his oxygen saturations were 90% on air, his blood pressure was 108/72 mmHg, his heart rate was 129 and his temperature was 37.9 degrees celsius. Examination of his cardiovascular system revealed normal heart sounds with a JVP of 3cm. Examination of the respiratory system revealed the use of accessory muscles with bibasal fine crackles. Examination of the gastrointestinal and neurological systems was unremarkable.

Initial investigations revealed the following:

Hb	82 g/l
Platelets	342 * 10 /l
WBC	14.2 * 10 /l
ESR	88 mm/hr
Na	128 mmol/l
K	6.1 mmol/l
Urea	28 mmol/l
Creatinine	762 µmol/l
CRP	42 mg/l
Glucose	5.6 mmol/l

Chest x-ray: bilateral patchy infiltration

ECG: heart rate 132 bpm normal sinus rhythm, no other changes Urinalysis blood ++++ protein +++ leuc/nit negative glucose negative

ABG on 15 l/min oxygen:

PaO2	16.9 kPa
PaCO2	2.8 kPa
HCO3	18.2 mmol/l
pH	7.49

He was catheterized, commenced on an intravenous infusion of normal saline, as well as coamoxiclav 625mg TDS and quickly transferred to the Intensive Care Unit. A decision was made to institute immediate haemodialysis, for which preparations were being made.

Further investigations revealed the following: Urine MCS: nil grown

Blood culture - interim results: nil grown

Transoesophageal echocardiogram: normal systolic function, valvular appearances and no vegetations seen

C3	1.22 (NR 0.65 1.65g/L)
C4	0.32 (NR 0.16 0.60 g/L)
ANA	negative
ENA	negative
dsDNA	negative
cANCA	positive
pANCA	negative
Rheumatoid factor	negative

Given the likely underlying diagnosis, which of the following interventions is the next best step whilst awaiting haemodialysis?

A. Stop IV augmentin, commence IV meropenem
B. Commence IV immunoglobulins
C. Commence high dose IV methylprednisolone and cyclophosphamide
D. Institute immediate plasma exchange
E. Commence intravenous activated protein C

C. Commence high dose IV methylprednisolone and cyclophosphamide

This patient has granulomatosis with polyangiitis, with severe pulmonary and renal involvement. He requires urgent immunosuppression. Of the available options, the next best step is therefore to institute cyclophosphamide and methylprednisolone. The options may serve a role, but this question is asking what the most appropriate next best step is. Therefore the best option is option 3

Question 39 of 231

An 83-year-old female presents to A&E with a four day history of increasing shortness of breath and worsening of a chronic productive cough. She speaks no English but you know from her medical records that she recently emigrated from rural India to live with her family two years ago. She has no diagnosed underlying lung condition. On examination, she has bilateral expiratory wheeze and hyperexpanded lungs with no clear inspiratory crackles. Heart sounds appear normal and mild bilateral pitting oedema. Her saturation measures 88% on air via pulse oxymeter, respiratory rate is 24 to 28 per minute. Her chest radiograph is hyperexpanded with mild bibasal fibrotic changes but demonstrates no focal signs of consolidation. She has no smoking or alcohol history. Her blood tests are as follows:

Hb	15.0 g/dl
Platelets	211 * 10 /l9
WBC	11.4 * 10 /l9
Neutrophils	9.5 * 10 /l9
Urea	8.4 mmol/l
Creatinine	112 µmol/l
CRP	37 mg/l

What is the most likely diagnosis?

A. Exacerbation of congestive cardiac failure
B. Infective exacerbation COPD
C. Community acquired pneumonia
D. Tuberculosis
E. Progression of pulmonary fibrosis

B. Infective exacerbation COPD

Although COPD is often associated as a disease of smokers, it is prudent to remember other causes of chronic emphysematous changes. In patients from the developing world, non-smokers from the Indian subcontinent and African countries often present with a COPD-like history from using open fires in their homes, particularly if burnt indoors for cooking or heating. The World Health Organisation (WHO) estimate that up to 3 billion people cook in this manner, accounting for up to 1 million deaths worldwide as a result of COPD without smoking history . The clinical findings are consistent with an obstructive picture and hyperexpansion of the lungs suggest a chronic element to an underlying lung condition, despite no formal previous diagnosis. Mild oedema may simply represent a degree of right heart failure from the underlying lung pathology. Bibasal fibrotic changes may be consistent with lung fibrosis but you would expect a restrictive picture instead. Community acquired pneumonia would be the main differential diagnosis but again, does not account for the chronic cough or hyperexpanded lungs.

Question 40 of 231

A 52-year-old man presents to the emergency department with shortness of breath. This started recently following a flight from Australia. He is morbidly obese and has a past medical history of type two diabetes mellitus, high cholesterol, hypertension and a previous cholecystectomy. He denies any leg pain or swelling and denies any chest pain. Observations are stable, and an ECG demonstrates sinus rhythm. A chest X-ray is clear. He undergoes a CT pulmonary angiogram (CTPA) to exclude a pulmonary embolus (PE). The CTPA is reported as finding no evidence of PE but notes a 7mm pulmonary nodule in the left lower lobe.

How should the pulmonary nodule be investigated or monitored?

A. Urgent CT-PET
B. Urgent image-guided biopsy
C. CT chest in three months
D. CT chest in one year
E. No further investigations needed

Not answered in the file

Question 41 of 231

A 40-year-old lady presents with dyspnoea. She describes a gradual onset of shortness of breath on exercise over several months. She has a past medical history of wheeze as an infant. She has recently commenced a intranasal steroid spray for rhinitis. She is a non-smoker.

On examination she has oxygen saturations of 91% on air. She has blood stained crusting around her anterior nares. On auscultation her chest has bilateral reduced air entry and coarse crepitations on both lung bases. Her temperature is 37.8 degrees centrigrade.

Hb	13.2 g/dL
WCC	10.3 *10^9/l
Neutrophil	7.8 *10^9/l
Eosinophil	0.07 *10^9/l
Sodium	135 mmol/l
Potassium	4.5 mmol/l
Creatinine	113 µmol/l
Urea	5.4 mmol/l
CRP	230 mg/L
Chest X - ray	Bilateral basal consolidation
Urine microscopy	Culture negative RBC +++ WCC +
c-ANCA	Positive
p-ANCA	Positive
Anti-GBM	Negative

What is the most likely diagnosis?

A. Pneumonia
B. Churg-Strauss Syndrome
C. Microscopic polyangiitis
D. Granulomatosis with polyangiitis
E. Goodpastures disease

D. Granulomatosis with polyangiitis

Consider granulomatosis with polyangiitis when a patient presents with ENT, respiratory and kidney involvement

Definitive diagnosis of vasculitis will require biopsy. However, granulomatosis with polyangiitisis the most likely as the presentation includes sinus disease, lung disease with likely renal involvement. Both ANCA tests can be positive but it is most associated with c-ANCA.

This patient had wheeze as a child, which is very common. Churg-Strauss is more associated with a progressive presentation of asthma, which may present later in life. The patient also does not have eosinophilia which is associated with this diagnosis.

Goodpasture's is a possibility but less likely with a negative anti-GBM. Pnemonia is less likely with such a prolonged presentation.

Microscopic polyangiitis can present very similar to granulomatosis with polyangiitis but is more associated with renal involvement, which is mild in this case. It is less associated with ENT disease.

Question 42 of 231

A 67-year-old man attends with reduced consciousness and shortness of breath. His wife accompanying him reports some diarrhoea over the past few days and he has taken himself to bed but was weak and unable to get up today. He is usually well but has been reporting morning headaches and is being referred to the sleep clinic. He takes no regular medications.

On examination, he has a respiratory rate of 11 breaths/minute and is saturating at 94% on 4 litres through a face mask. His chest clear is clear and his abdomen is soft and non tender. He is generally weak but is able to follow commands. It is difficult to understand him and you can only hear whispers when he speaks to you. His calves are soft with mild oedema in the ankles and he is overweight.

Na +	139mmol/l
K +	4.2 mmol/l
Urea	6.5 mmol/l
Creatinine	98 µmol/l
CRP	34
Hb	119 g/l
Platelets	298 * 10 /l9
WBC	5.6 * 10 /l9
ABG (in air)	
pH	7.30
pO2	7.9 kPa
pCO2	6.5 kPa
HCO3	24mmol/l
Lactate	2.4 mmol/l
Chest x-ray	poor inspiratory effort, clear lung fields, heart size within normal parameters
ECG	sinus tachycardia

What is the likely diagnosis?

A. Obstructive sleep apnoea
B. Myasthenia gravis
C. COPD exacerbation
D. Pneumonia
E. Pulmonary embolism

B. Myasthenia gravis

Type 2 respiratory failure with normal CXR -> neuromuscular weakness

This gentleman has presented with a type 2 respiratory failure. His bicarbonate is normal suggesting this is an acute deterioration and is less likely to be a COPD exacerbation or obstructive sleep apnoea where there is CO2 retainers and a raised bicarbonate. His chest x-ray shows no evidence of pneumonia. A pulmonary embolism is possible but usually presents with type 1 respiratory failure. Given that he has a poor respiratory effort and is not tachypnoeic, this should prompt thoughts of whether the ventilation is inadequate and this may reflect neuromuscular failure. These patients have shallow ventilation and spirometry shows a hugely reduced functional vital capacity.

Question 43 of 231

A 35-year-old woman is investigated for lethargy, fever, cough and weight loss. She has been treated by her GP with five courses of

antibiotics over the past six months for a combination of chest and sinus infections. Her symptoms, however, have continued unabated.

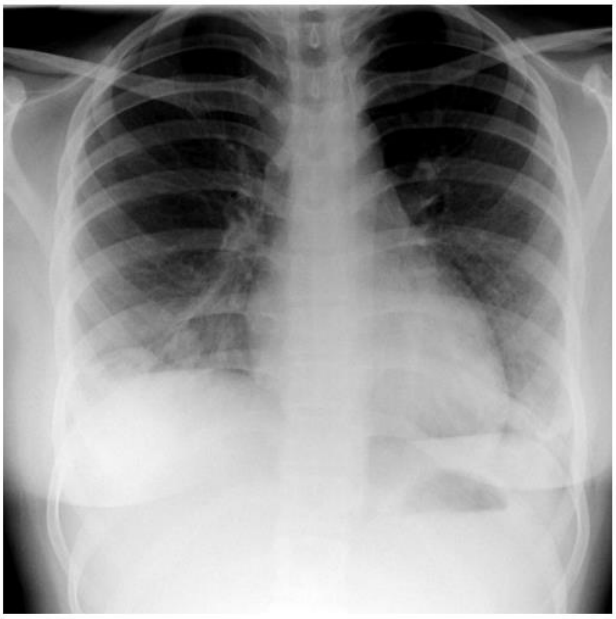
Clinical examination is unremarkable other than some scattered crackles in the right base. She is apyrexial. Urine dipstick: blood ++, protein +

Lung function tests and blood tests show the following

FEV1	4.3 L (99% of predicted)
FVC	5.1 L (101% of predicted)
FEV1/FVC	84%

Hb	13.1 g/dl	Na +	141 mmol/l
Platelets	459 * 10 /l 9	K +	3.6 mmol/l
WBC	6.9 * 10 /l 9	Urea	10.9 mmol/l
Creatinine	131 µmol/l		
CRP	78 mg/l		

A chest x-ray is requested:



What is the most likely diagnosis?

A. Lung cancer
B. Tuberculosis
C. Granulomatosis with polyangiitis
D. Cryptogenic organizing pneumonia
E. Churg-Strauss syndrome

C. Granulomatosis with polyangiitis

Whilst the changes are subtle the chest x-ray demonstrates a number of ill-defined nodules the largest of which projects over the dome of the right hemidiaphragm. This nodule appears to have a central lucency suggesting cavitation. Please see the accompanying CT scan from the same patient below.

Question 44 of 231

A 42-year-old lady presents to the Emergency Department with a 3-week history of a dry cough, fever and lethargy. She has no past medical history and takes no regular medications. There is no history of recent foreign travel. Clinical examination reveals inspiratory crepitations affecting the left upper zone and R lower zone. Saturations are 91% on room air. Chest x-ray shows bilateral peripheral pulmonary infiltrates.

Bloods show:

Hb	110 g/L
MCV	78 fL
WCC	13 x 10^9/L
Neutrophils	8 x 10^9/L
Lymphocytes	1 x 10^9/L
Eosinophils	3.1 x 10^9/L
Platelets	560 x 10^9/L
CRP	115mg/l

What is the most appropriate treatment given the likely diagnosis?

A. Oral prednisolone
B. High dose co-trimoxazole
C. Plasma exchange
D. Rifampicin, isoniazid, ethambutol and pyrazinamide
E. Amoxicillin and clarithromycin

A. Oral prednisolone

Eosinophilic pneumonia is the most likely diagnosis. It is characterised by sub acute respiratory symptoms, alveolar and/ or blood eosinophilia, and peripheral pulmonary infiltrates on imaging. Treatment with oral corticosteroids leads to a rapid improvement of symptoms and the prognosis is good. Tuberculosis is usually associated with upper lobe consolidation and eosinophilia is not typical. Pneumocystis jirovecii pneumonia and community-acquired pneumonia are not usually associated with eosinophilia and are less likely.

Question 45 of 231

An 18-year-old-female is brought into the emergency room after having a tonic-clonic seizure. On examination she has a Glasgow coma scale of 11 (M4, E3, V4). Her blood pressure is 85/65 mmHg. Her heart rate is 135bpm and an ECG demonstrates atrial fibrillation. She has a past medical history of asthma which she takes betamethasone, salbutamol, salmeterol, montelukast and theophylline. She has recently started erythromycin for a chest infection. She has been taking 6g of paracetamol per day for the last 3 days for fever and chest discomfort.

You commence fluid resuscitation with 0.9% saline and treat the supraventricular tachycardia with a beta blocker.

You suspect theophylline toxicity and administer repeated doses of activated charcoal. However the patient continues to deteriorate.

What treatment is indicated?

A. N-acetylcysteine (NAC)
B. Sodium bicarbonate
C. Flumazenil
D. Hydroxocobalamin
E. Intermittent haemodialysis or charcoal haemoperfusion

E. Intermittent haemodialysis or charcoal haemoperfusion

In cases of severe theophylline toxicity, charcoal haemoperfusion can be used

The patient has presented with several features of theophylline toxicity - seizures, reduced Glasgow coma score, and a tachyarrhythmia. The drug erythromycin which has recently been started, is an enzyme inhibitor which can precipitate theophylline toxicity.

The severity of symptoms warrants use of haemodialysis orcharcoal haemoperfusion.

Activated charcoal should also be considered. Since many products are slow release formulations, charcoal given more than 1 hour after ingestion may be of benefit. Repeated doses should also be administered.

Although the patient has been exceeding the maximum dose of paracetamol (4g / 24 hours), the clinical features are not in keeping with paracetamol toxicity.

Hydroxocobalamin is the antidote for cyanide poisoning.

Flumazenil is the antidote for benzodiazepine overdose.

Question 46 of 231

A 35 year old chronic alcoholic male is admitted with severe epigastric pain. Laboratory investigations confirmed a significantly raised amylase. He is started on treatment for severe pancreatitis but his condition deterioriated over the next 2 days and he developed acute kidney injury with severe respiratory distress to an extent needing mechanical ventilation. Initial chest radiographs revealed widespread bilateral infiltrates.

Which of the following therapies has been shown to most likely decrease overall mortality of ARDS?

A. Immediate initiation of glucocorticoid therapy to limit inflammatory progression
B. Placing patient in the prone position, allowing for greater recruitment of unaffected alveoliand improving PaO2/FiO2 ratio
C. Implementing a low tidal volume ventilation protocol
D. Changing from O2 to Nitric oxide at 5 ppm and titrating up until pt has an acceptablePaO2/FiO2 ratio
E. Aggressive diuresis to reduce pulmonary edema and vascular congestion

C. Implementing a low tidal volume ventilation protocol

Choice A - glucocorticoids to this point have not been shown to help patients in the acute phase of ARDS. There is some evidence that they may help in the fibroproliferative stage but not acutely

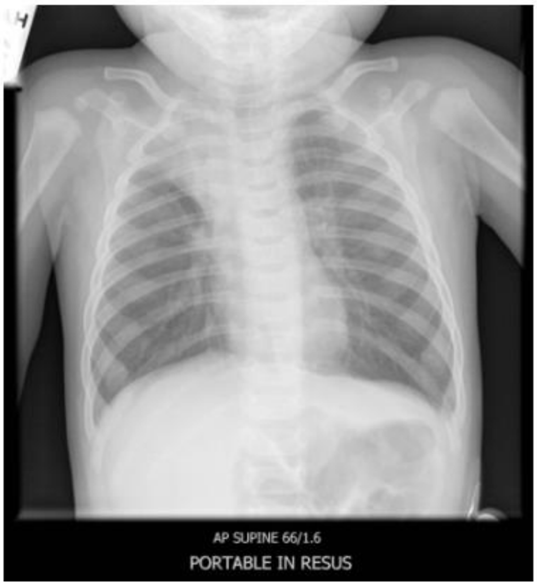
Choice B - While this is true, there is as of yet no good evidence showing improved overall mortality.

Choice C - ARDS causes severe hypoxaemia, almost always requiring invasive artificial ventilation. However, mechanical ventilation itself can injure the damaged lungs causing ventilation-induced lung injury. The main goal of treatment is to minimise any additional damage while maintaining adequate gas exchange. This has been effectively done by maintaining low tidal volume ventilation. A Cochrane Database review (1) and meta-analysis (2) suggest that a strategy of low tidal volume ventilation reduces the absolute mortality by about 7-9% as compared to using higher tidal volumes. This converts to a Number needed to treat (NNT) of between 11-15 people with ARDS to prevent one death by using low tidal volume ventilation.

Choice D - Nitric oxide does improve PaO2/FiO2 ratio but has not shown improved survival Choice E - Since the infiltrate of ARDS is primarily inflammatory, diuretics are not particularly effective. Overdiuresis also runs the risk of hemodynamic compromise, further decreasing the patient's already insufficient oxygen delivery to tissues

Question 47 of 231

The x-ray below was taken from a 7-year-old child who presented to the Emergency Department with respiratory symptoms:



What does the x-ray show?

A. Cystic fibrosis
B. Right upper lobe collapse
C. Lung cancer
D. Right-sided pneumothorax
E. Normal

B. Right upper lobe collapse

There is increased opacity in the right upper zone, The lateral / inferior border of the shadowing actually represents the horizontal fissure which has been 'dragged' upwards.

Question 48 of 231

A 56-year-old male presents with symptoms and signs consistent with exacerbation of chronic obstructive pulmonary disease (COPD). This is his fourth exacerbation in the last two months. His most recent FEV 1 is 40%. He is currently taking salbutamol as required once daily regimen.

On reviewing his peak flow diary you note a significant (> 20%) diurnal variation in his peak flow.

Which of the following drugs should be added next to his regular control of COPD?

A. Combined salmeterol and fluticasone inhaler
B. Salmeterol
C. Theophylline
D. Ipratropium bromide
E. Long term oxygen therapy

A. Combined salmeterol and fluticasone inhaler

COPD - still breathless despite using SABA/SAMA and **asthma/steroid responsive features** → add a LABA + ICS

As this patient has a feature suggestive of asthma/steroid responsiveness (significant diurnal variation) the next step in management is a long-acting beta agonist (e.g. salmeterol) + an inhaled corticosteroid. NICE now recommend the use of combined inhalers where possible.

Question 49 of 231

A 22-year-old agricultural student presents to the respiratory clinic with cough, breathlessness, fatigue and weight loss of 2 kg in 6 weeks. Examination reveals bilateral wheeze and crackles. His GP has tried 2 courses of antibiotics and a salbutamol inhaler with no real benefit; he had some relief from a short course of oral prednisolone. He denies any fever, haemoptysis, foreign travel or exposure to TB. He has never smoked.

His chest radiograph shows mid to upper zone alveolar fine nodular shadowing bilaterally. His lung function shows a FVC (forced vital capacity) of 70% and FEV1/FVC of 85% predicted. Bloods show:

CRP	3 mg/l
ESR	45mm/hr

What is the most likely diagnosis?

A. Pulmonary embolus (PE)
B. Community acquired pneumonia
C. Asthma
D. Extrinsic allergic alveolitis
E. Silicosis

D. Extrinsic allergic alveolitis

Extrinsic allergic alveolitis is associated with upper/mid zone lung fibrosis

Extrinsic allergic alveolitis is the most likely diagnosis in this agricultural student with a restrictive picture on spirometry. Extrinsic allergic alveolitis is caused by acute neutrophilic inflammation followed by lymphocytic infiltration & collagen deposition. Broncho alveolar lavage would show an excess of eosinophils. The presence of crepitations and wheeze make the diagnosis of PE less likely. Community acquired pneumonia would be associated with a higher CRP. Asthma would not cause a restrictive picture on spirometry. Silicosis is unlikely as there is no occupational exposure to silicon dioxide.

Question 50 of 231

A 53-year-old gentleman presents to the respiratory clinic for review. He has a history of chronic recurrent coughing episodes lasting for months. This has been worse over winters. He also has found that over the last two years his exercise tolerance has reduced and that he is more easily short of breath. He has no past medical history and takes no regular medications. He has a 20 pack-year history. He has undergone spirometry with shows an FEV1/FVC ratio of 63%, whilst FEV1 is 74% of predicted. His chest X-ray is unremarkable. Blood tests are normal as well. Previous sputum sample from during an exacerbation shows growth with pseudomonas.

What factor is not in keeping with a diagnosis of COPD?

A. FEV1/FVC ratio
B. Pseudomonas
C. FEV1
D. Smoking history
E. Clinical history

B. Pseudomonas

The correct answer is Pseudomonas. This is a patient with an otherwise straightforward diagnosis of COPD. COPD is an obstructive disease and therefore an FEV1/FVC ratio of 63% is matching, as does a low FEV1. Smoking is the main cause of COPD as well, and the history, describing winter bronchitis with a general decline in exercise tolerance fits COPD too. Pseudomonas is more common in bronchiectasis but may be a contaminant rather than a pathogen

Question 51 of 231

A 66-year-old retired farmer presents with a 4-week history of increasing shortness of breath, nonspecific non-pleuritic chest pain and weight loss. His past medical history includes previous angina, for which he was previously prescribed a GTN spray that he has not required for 3 years and hypertension. He is known to keep racing pigeons in a barn on his property. He keeps active and lives with his wife, drinks moderate amount of alcohol and is an active smoker with a 40 pack year history. He has no known allergies. On examination, you note bilateral clubbing and tar staining. Respiratory examination revealed a respiratory rate of 19 breaths per minute, sats 94% on air, reduced bilateral chest expansion and reduced air entry in both bases associated with dullness to percussion.

A chest radiograph demonstrates moderate right >left bilateral pleural effusions and patchy opacities across both lung fields in a non-lobar distribution. CT thorax with high-resolution slices demonstrates bilateral pleural effusion, thickened pleura with no lung parenchyma abnormalities.

Lung function testing demonstrates FEV1 1.7ls, FVC 55% of predicted.

What is the most appropriate next investigation?

A. CT chest/abdomen/pelvis with contrast
B. High resolution CT chest (HRCT)
C. Video assisted thoracoscopic biopsy (VATS)
D. Chest drain
E. Bronchoscopy with bronchoalveolar lavage (BAL)

C. Video assisted thoracoscopic biopsy (VATS)

An underlying pleural pathology should be strongly suspected in the case of thickened pleura, restrictive lung function and non-specific constitutional symptoms. The bilateral pleural effusions do not appear to be causing respiratory compromise and hence a chest drain is not indicated. In the absence of parenchymal lesions to target for tissue diagnosis, VATS is appropriate to differentiate pleural thickening described between organised empyema or mesothelioma, and also to obtain tissue to differentiate mesothelioma from other primary or metastatic cancers. VATS is optimally performed with a small amount of pleural fluid in situ.

A diagnosis of extrinsic allergic alveolitis (EAA) should also be considered as presentations with weight loss, dyspnoea and chest tightness can be similar to pleural pathology. BAL would be indicated if EAA is a significant differential. However, the lack of reticulonodular changes on chest radiograph and fibrotic changes on CT make hypersensitivity pneumonitis less likely. Be aware that only 20% of mesothelioma patients present with radiographic changes consistent with asbestosis, although the majority present with pleural abnormalities.

Question 52 of 231

A 72 year-old woman has been referred to the chest clinic by her General Practitioner (GP). The patient describes a 3-year history of cough and progressive shortness of breath. Over the past 3 years the GP had prescribed numerous courses of antibiotics and steroids but these had had little benefit. She was a non-smoker, did not drink alcohol and was on no regular medications. The cough was productive of purulent sputum with occasional streaks of blood. There was no history of weight loss or fever, but the patient did note lethargy. The rest of her family were well and the only medical history of note was an episode of pneumonia as a child.

Respiratory examination revealed bilateral crackles but no other added sounds. You note that the patient was not clubbed.

A chest x-ray, organised by the GP, shows minor bilateral atelectasis and opacities.

What is the most appropriate diagnostic test?

A. Bronchoscopy
B. Genetic testing for Primary Ciliary Dyskinesia
C. High resolution CT scan of chest
D. Serum α1-antitrypsin level
E. Tuberculin skin test

C. High resolution CT scan of chest

The history is highly suggestive of bronchiectasis, which often presents as a lower respiratory tract infection with a productive cough. Patents may also present with haemoptysis, chest pain and shortness of breath. Over time the condition can progress to respiratory failure.

The most common findings on examination are crackles (75%) and wheeze (22%). Clubbing is only found in 2%.

A chest x-ray should be performed in all suspected cases and, indeed, anyone presenting with a chronic cough. In some cases a suggestive history and chest x-ray will be enough to diagnose bronchiectasis. However, the best diagnostic test for bronchiectasis is high-resolution CT scan (HRCT). A HRCT will show the classic features of bronchial wall thickening and dilatation, it may also demonstrate features that suggest a cause for the underlying cause, e.g. allergic bronchopulmonary aspergillosis (ABPA) of cystic fibrosis (CF).

The routine work up for patients with suspected bronchiectasis should include bloods for serum immunoglobulins and protein electrophoresis, total IgE and skin prick testing or serum IgE testing to Aspergillus species. Bronchoscopy is not performed routinely unless there is a suspicion of a lesion or foreign body. α1-Antitrypsin levels are not routinely requested but may be of help if the HRCT shows evidence of emphysema. A tuberculin skin test is very unlikely to be helpful in a patient of this age and is not the test of choice. Tuberculin skin tests can identify cases of latent tuberculosis but must be interpreted with the patients immunisation history.

Genetic testing, although potentially diagnostic, would not be appropriate in this case. Primary Ciliary Dyskinesia is an autosomal recessive disorder that can cause bronchiesctasis but patients usually present as newborns or in childhood and not in the elderly.

Question 53 of 231

A 30 year old gentleman returns from a camping holiday in the Nile Delta with nocturnal wheeziness and dry cough, weight loss, and fever. He recalls multiple mosquito bites. Chest X-ray demonstrates pulmonary infiltrates. His blood results are shown below.

Hb	14 g/dl
Platelets	385 * 10 /l9
WBC	14 * 10 /l9
Neutrophils	7.5 * 10^9/l (reference range 2.0-7.5 * 10^9/l)
Eosinophils	1.2 * 10^9/l (reference range 0.04-0.44 * 10^9/l)
Serum IgG	90 mg/dl (reference range 80 - 350 mg/dl)
Serum IgM	200 mg/dl (reference range 45 - 250 mg/dl)
Serum IgE	6.0 mg/dl (reference range 0.002 - 0.2 mg/dl)

Given the likely diagnosis which of the following treatments will be most effective?

A. Antiretrovirals
B. Tazocin
C. Steroids
D. Diethylcarbamazine
E. Quinine

D. Diethylcarbamazine

The diagnosis here is tropical pulmonary eosinophilia. HIV and indeed plasmodium falcipirum malaria could present with fever and weight loss however the blood picture along with wheeze is suggestive of an eosinophilic lung disease. The eosinophilic lung diseases are allergic reactions to some environmental toxin and all present with cough, wheeze, pulmonary infiltrates on chest Xray, raised serum IgE, and a raised eosinophil count. They are a differential for asthma, which can present in a similar fashion clinically and on bloods, and therefore a careful history (particularly travel and medications) is important. It is important to recognise them as the management is different to asthma. Here are some examples worth knowing for the exam:

Allergic bronchopulmonary aspergillosis: an allergic reaction to the fungus aspergillus fumigates. The course is characterised by recurrent episodes of eosinophilic pneumonia, especially in the autumn and winter. Test for precipitating antibodies to Aspergillus species, which will be present in 90% of cases. Also order sputum microscopy and culture, which can show fungal spores or hyphae. A skin-prick test can be ordered and almost always positive to Aspergillus fumigates. Management is with steroids. Simple pulmonary eosinophilia, aka Loeffler's syndrome. This is caused by Ascaris lumbricoides, Strongyloides, or Ancylostoma. Infection with these worms is prevalent worldwide, especially in tropical and subtropical countries. Their eggs are passed in the stool of an infected person and then ingestion in food that has had contact with human sewage (they are surprising resilient eggs). The ingested eggs mature into larval worms in the gut and seed into the blood stream via the duodenal walls, from where they circulate around in the blood to eventually enter the lungs were they are coughed up (the pulmonary eosinophilia phase with wheeze and cough for around 2 weeks) and then swallowed back down and settle into mature worms in the small intestine, resulting in a chronic malabsorption condition. The pulmonary condition is self-limmiting although mebendazole given for 3 days can help.

Tropical pulmonary eosinophilia: caused by the roundworms Wuchereria bancrofti or Brugia malayi, common in the Asian Subcontinent and Africa. The worms are spread via a mosquito vector. It takes a human blood meal and thereby ingests microfilariae (worm-like sheathed eggs) from an infected patient and deposits them into a new host. They spread through the blood to settle in the lymphatics where they mature into adults and reside there for 15 or more years, reproducing sexually, and causing elephantiasis. The pulmonary involvement happens as there is intense inflammation of lung parenchyma to microfilariae which are periodically released into the circulation by those adult worms. There is therefore a history of paroxysmal nocturnal cough, wheeze, and breathlessness. Diagnosis is aided by a clinical response to diethylcarbamazine, which is also the main treatment. Churg-Strauss syndrome: a pANCA positive small to medium vessel vasculitis that presents with a refractory asthma type of picture, mononeurtitis multiplex (look out for e.g foot drop in a stem that sounds like asthma), and sinusitis. Biopsy of affected tissue is helpful diagnostically. Management is largely with steroids but can progress to the need for steroid-sparing agents such as cyclophosphamide/azathioprine. Drugs-induced pulmonary eosinophilia: sulphonamides (e.g. sulfasalazine), nitrofurantoin, penicillin, tetracycline. Stop the offending drug.

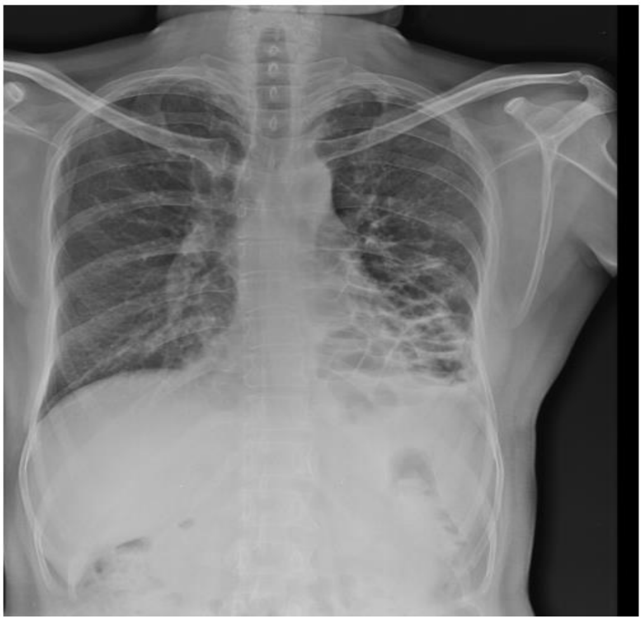
Question 54 of 231

A 46-year-old man presents with a persistent cough. This has been present for around 2 months and is productive of yellow-green sputum. He feels more short-of-breath on exertion but is experiencing chest pain. He has not lost any weight and has not coughed up blood.

He has a 25-pack-year history of smoking although is trying to give up. He does not drink alcohol.

On examination his respiratory rate is 18/min, heart rate 84/min, blood pressure 114/72 mmHg and temperature 37.3ºC. His oxygen saturations on room air are 96%. Scattered crackles are heard in both bases.

A chest x-ray is requested:



What is the most likely diagnosis?

A. Pneumonia
B. Sarcoidosis
C. Chronic obstructive pulmonary disease
D. Bronchiectasis
E. Pulmonary fibrosis

D. Bronchiectasis

The chest x-ray has classical changes of bronchiectasis - tramlines are seen, most prominently in the left lower zone.

Question 55 of 231

A 66 year old gentleman, who is a known heavy smoker, presents with a non infective exacerbation of chronic obstructive pulmonary disease (COPD). Upon admission despite maximal medical therapy his blood gasses worsen and he is commenced on non invasive ventilation and transferred to the high dependency unit. The nurses call you in the middle of the night to come and urgently review the patient. They have been titrating up the patient's non invasive ventilation (NIV) as they felt his blood gasses were not improving on standard settings. On arrival the patient is diaphoretic and complaining of chest pain. He is unable to tolerate his face mask. Observations are recorded as a pulse of 110/min regular, respiratory rate 32/min, Sats 75% on air, Blood pressure 100/82 mmHg.

What is the most likely cause for this patient's acute deterioration?

A. Ventilator associated pneumonia
B. Acute myocardial infarction

C. Ventilator associated pneumothorax
D. Worsening of his COPD
E. Panic attack

C. Ventilator associated pneumothorax

This question assesses candidates ability to recognise some of the complications of NIV. This patient has developed a pneumothorax secondary to the increasing pressures used as part of his NIV. Although less common these days due to nurse training, ventilation associated pneumothorax is an important complication of NIV to be aware of and therefore, prompt assessment and treatment will be essential in the management of this patient.

Ventilator associated pneumonia tends to present in patients who have been ventilated for long a long period of time and would not present so acutely.

Acute myocardial infarction would be unlikely as the question makes a point of mentioning the increasing pressures that are needed.

Candidates should also familiarise themselves with some of the contraindications to NIV:

- Recent facial or upper airway surgery or facial injuries.
- Recent upper gastrointestinal surgery.
- Confusion/agitation.
- Bowel obstruction.
- Upper airway obstruction.
- Excessive upper airway secretions.
- Patient actively vomiting

Question 56 of 231

A 66-year-old man, presented with two episodes of mild haemoptysis in the past 3 months. He also had lost 5 kilograms of weight in the past 3 months. He was a smoker with 50 pack years history and a social drinker. He was actively mobile and had no significant past medical history.

Clinical examination revealed no abnormality except clubbing.

A contrast enhanced CT chest showed a 4 cm mass in the right upper lobe periphery close to the chest wall and enlarged right hilar (2 cm) and subcarinal (2 cm) lymph nodes. A positron emission tomography (PET) scan was done which showed a standard uptake value (SUV) max of 20 for the lung mass. The ipsilateral hilar and subcarinal lymph nodes were also found to be FDG (fluorodeoxyglucose) avid. There was no evidence of distant metastasis.

What is the next appropriate step in the management?

A. CT guided biopsy of the lung mass
B. Ultrasound guided biopsy of the lung mass
C. Flexible bronchoscopic biopsy of the lung mass
D. Endobronchial ultrasound (EBUS) guided mediastinal lymph node sampling
E. Video-Assisted Thoracoscopic Surgery (VATS) biopsy of the mediastinal lymph nodes

D. Endobronchial ultrasound (EBUS) guided mediastinal lymph node sampling

This is probably a stage IIIA (T2aN2M0) lung cancer. Diagnosis and staging has to be confirmed by tissue sampling. EBUS guided mediastinal lymph node sampling provides diagnosis and staging in a single step whereas CT guided or ultrasound guided or bronchoscopic biopsy of the lung mass yields only tissue diagnosis (not staging). Wherever possible minimally invasive procedures should be undertaken first for mediastinal node sampling (e.g., EBUS) before embarking into more invasive procedures like VATS.

Question 57 of 231

A 17-year-old male is admitted to the resuscitation area of the emergency department with an acute exacerbation of asthma. It is his 3rd hospital attendance this winter. He has widespread wheeze, globally poor air entry and looks tired. He cannot complete full sentences. His arterial blood gases reveal:

pH	7.4
PaO2	9.3 kPa
PaCO2	3.3 kPa
HCO3-	26 mmol/L

You treat him with 100% oxygen, high dose steroids, back to back salbutamol nebulisers and commence intravenous magnesium sulphate infusion. 1 hour later his arterial blood gases reveal:

pH	7.35
PaO2	15.4 kPa
PaCO2	4.7 kPa
HC03-	22 mmol/L

What is the next management step?

A. Start BIPAP
B. Intensive care review
C. Move to medical ward with close monitoring
D. Intravenous adrenaline
E. Start CPAP

B. Intensive care review

Rising CO2 is an indication that the patient is becoming tired. Oxygenation has only mildly improved despite 100% oxygen. Patients with life-threatening features of asthma do not always appear distressed. The patient will likely require mechanical ventilation.

Question 58 of 231

An 83-year-old male presents with his third admission of right lower zone community-acquired pneumonia in 5 months. A CT thorax demonstrates a 2.2cm mass in right lower lobar bronchus with no regional lymph nodes. Bronchoscopy reveals non-small cell lung Ca 4cm from the carina, CT staging reveals no other metastases. A final staging diagnosis of T1b N0 M0 is made, at stage 1A. The patient undergoes lung function testing as follows:

FVC	2.2l
FEV1	1.7l/s
TLCO	42% of predicted

What is the most appropriate treatment?

A. Right pneumonectomy
B. Right lower lobectomy
C. Chemotherapy
D. Radiotherapy
E. Palliative care

B. Right lower lobectomy

The patient has been diagnosed with surgically resectable non-small cell lung carcinoma (NSCLC). All NSCLC with stage I or II disease should undergo resection surgery where possible, stage III disease generally is focused on chemotherapy while stage IV disease is managed with symptomatic palliative treatments. However, while the disease burden may be amenable to surgery, the patient's lung function testing may restrict management options. Multiple studies have demonstrated FEV1 and transfer coefficients to be the most accurate predictors of postoperative dyspnoea, with the British Thoracic Society recommending the patient to demonstrate FEV1 >2l/s for pneumonectomy and 1.5l/s for lobectomy. TLCO is similarly recommended to be greater than 40% of predicted for resective surgery1. Forced vital capacity is not demonstrated to be a significant predictor of post-operative outcomes.

Question 59 of 231

A 39-year-old lady presented to the emergency department acutely unwell with fever, weight loss and malaise. She had been finding it increasingly difficult to mobilise in recent weeks due to weakness in her right ankle. She had diarrhoea and was passing loose brown stool up to five times a day. She had a previous medical history of asthma and sinusitis. Her medications included a salbutamol inhaler, salmeterol inhaler, montelukast and intermittent courses of prednisolone and antibiotics as required.

On examination, she appeared unwell, had petechial purpura in the nail beds of her fingers and on her feet, expiratory wheeze on auscultation of her chest, a soft abdomen with no palpable masses and weakness of dorsiflexion of her right ankle. Her temperature was 37.4 degrees Celsius, her pulse was 115 beats per minute and regular, her blood pressure was 140/95 mmHg, her respiratory rate was 24 breaths per minute and her oxygen saturations were 94% on room air.

Investigations:

Urine dip: blood++, protein+

Haemoglobin	95 g/L
White cell count	23.6 x10^9 /L
Platelet Count	181x10^9/L
Neutrophils	12.3 x10^9/L
Eosinophils	9.6 x10^9/L
Basophils	0.2 x10^9/L
Lymphocytes	1 x10^9/L
Monocytes	0.5 x10^9/L
Erythrocyte sedimentation rate	65mm/hr
INR	0.9

Serum sodium	138mmol/L
Serum potassium	4.6mmol/L
Serum urea	15.4mmol/L
Serum creatinine	220micromol/L

Antinuclear antibody	negative
C-terminus antineutrophil cytoplasmic antibodies	negative
Myeloperoxidase anti-neutrophil cytoplasmic antibodies	positive

What is the most likely diagnosis?

A. Infective endocarditis
B. Wegener's granulomatosis
C. E.Coli gastroenteritis
D. Churg-Strauss syndrome
E. Crohn's disease

D. Churg-Strauss syndrome

This lady with a history of asthma and sinusitis has presented systemically unwell with diarrhoea, a right common peroneal nerve palsy, vasculitic rash and has evidence of a nephritis. Investigations show a significant eosinophilia and immunological screen has shown she is P-ANCA positive. The most likely diagnosis is, therefore, Churg-Strauss syndrome. This is a small vessel vasculitis with eosinophilic infiltration and granulomatous formation that is characterised by chronic sinusitis, asthma and eosinophilia. Systemic features of malaise, myalgia, fever and weight loss are common. Other symptoms and signs depend on other organ systems involved which most commonly are the lung (asthma, pneumonitis) and skin (purpura, subcutaneous nodules); however, any organ system can be affected including the cardiovascular (heart failure, myocarditis), gastrointestinal (gastroenteritis, ischaemia, bleeding), renal (glomerulonephritis, hypertension), and central nervous systems (mononeuritis multiplex). ANCA is positive in approximately 60% of cases and is predominantly P-ANCA.

Infective endocarditis could account for some of her symptoms however the absence of a heart murmur and the multisystem involvement, in this case, makes it less likely. Wegener's granulomatosis is another granulomatous small vessel vasculitis which most commonly presents with lesions in the upper respiratory tract (rhinorrhoea, sinusitis, saddle nose deformity), lungs (infiltrates and pulmonary haemorrhage) and kidneys (rapidly progressive glomerulonephritis). It is classically C-ANCA positive. The history of immunological screen of this case is, therefore, more typical of Churg-Strauss syndrome. E.coli gastroenteritis would be unlikely to present in this fashion.

Crohn's disease is a chronic inflammatory bowel disease that classically presents with abdominal pain, weight loss and change in bowel habit. There are often extra-intestinal manifestations involving the mouth, skin, eyes, joints and episodes of perianal abscess or anal fissure. Crohn's disease could account for some of this lady's symptoms but again is less likely than Churg-Strauss syndrome.

Question 60 of 231

A 70-year-old gentleman is admitted with three days of shortness of breath and arrives to the emergency department where he is started on non invasive ventilation for a suspected infective exacerbation of COPD.

On examination, he is in respiratory distress with cyanosis and a retention flap. He has widespread wheeze throughout and crepitation at the right base. There is no oedema and he has a capillary refill time of 3 seconds. Blood pressure 90/65mmHg, respiratory rate 24 breaths per minute, oxygen saturations are 84% on arrival and rise to 92% with 28% oxygen.

He is treated with full maximal therapy but fails to improve. He appears comfortable with the mask on and there is hissing heard with each inflation breath. The machine is set to 12cmH2O IPAP and 4cmH2O EPAP but the pressures recorded are 8cmH2O IPAP and 3cm H2O EPAP.

ABG	on arrival
pH	7.32
pCO2	8.2kPa
pO2	7.1 kPa
HCO3	26mmol/l
Lactate	3.02 mmol/l
ABG	current
pH	7.31
pCO2	8.3kPa
pO2	8kPa (on FiO2 0.28)
HCO3	26mmol/l
Lactate	2.78 mmol/l
Chest x-ray	hyperexpanded lung fields, consolidation on right middle zone

What is the most likely explanation of the failure to improve?

A. Carbon dioxide narcosis
B. Dyssynchrony
C. Mucus plugging
D. Mask leak
E. Pneumothorax

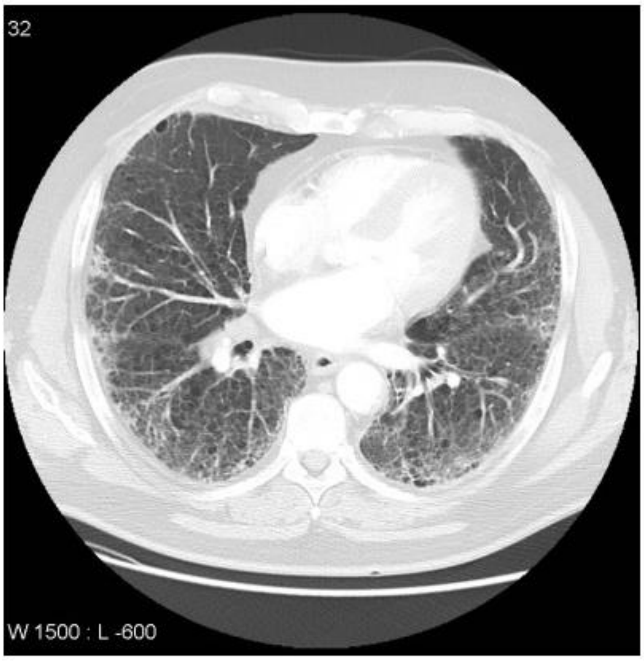
D. Mask leak

Significant air leak from the mask will prevent adequate pressures being achieved with noninvasive ventilation

The patient has a clear COPD exacerbation and starts non invasive ventilation but fails to improve. The clues are the audible hiss of air that can be heard from the mask and the failure of the machine to achieve the pressures set. Poor mask application or facial dysmorphia can lead to a poor seal to the face. Air will leak and the pressure will fall with this. The patient is unlikely to have deteriorated due to reducing consciousness secondary to CO2 narcosis as he continues to breathe at an elevated respiratory rate. There is no suggestion of a pneumothorax and this usually presents as a deterioration rather than a failure to improve. The patient is comfortable and does not appear to be fighting the machine as in dyssynchrony. A large mucus plug usually presents with sudden desaturation which is not seen here.

Question 61 of 231

A 59-year-old man is investigated for dyspnoea. Over the past 12 months he has become more breathless on exertion and has been troubled by a cough. He stopped smoking 10 years ago but prior to this had a 30-pack-year history. There is no history of chest pain, fever, night sweats or asbestos exposure. A CT chest is requested and shown below:



What does the CT scan show?

A. Lung cancer
B. Idiopathic pulmonary fibrosis
C. Multiple pulmonary embolisms
D. Bronchiectasis
E. Emphysema

B. Idiopathic pulmonary fibrosis

The CT scan shows advanced pulmonary fibrosis including 'honeycombing'.

Question 62 of 231

A 75-year-old man with a background of chronic kidney disease, hypertension and type 2 diabetes presents to the Emergency Department with cough and breathlessness on minimal exertion. On examination, he has bilateral inspiratory crepitations and bilateral pitting oedema up to his sacrum. His chest radiograph shows a moderate right-sided effusion and smaller left-sided effusion.

What single management would be most appropriate?

A. Fluid restriction to 1L daily
B. IV furosemide
C. Oral spironolactone
D. Referral for dialysis
E. Therapeutic aspiration of right-sided effusion

B. IV furosemide

In the assessment of a pleural effusions, if the clinical picture suggests a transudate, then you should treat the cause initially. If this does not resolve the effusion then perform a diagnostic aspiration

This patient presents with signs and symptoms of fluid overload, possibly due to worsening chronic kidney disease. While he has bilateral pleural effusions, they are most likely transudative and initial management should be to offload with **IV diuretics such as furosemide**. This may lead to the resolution of his fluid overload and pleural effusions.

Fluid restriction to 1-1.5L daily would be appropriate as part of medical management. It should be recommended alongside diuresis with medication as on its own it would not lead to significant offloading in a patient who is significantly fluid overloaded.

Oral spironolactone is a diuretic that would help to offload the patient. However, it is not commonly used as a first-line diuretic in a patient who is significantly fluid overloaded. It also cannot be given intravenously. Intravenous diuresis may be clinically more effective as patients who are significantly fluid overloaded may also have gut oedema and thus have poor absorption of oral diuretics.

The patient may need to eventually be **referred for dialysis** if they have end-stage renal disease. However, many patients with chronic kidney disease may be safely treated with diuretics without their renal function significantly worsening. IV diuresis should thus be attempted first. Should this fail, a renal physician could be consulted for advice, including regarding dialysis.

Therapeutic aspiration of the larger right-sided effusion involves aspirating up to 1.5L of fluid or inserting a chest drain to reduce the size of the effusion. This may relieve symptoms but would be unlikely to lead to the resolution of the contralateral effusion or improvement of this patient's peripheral oedema. If there are atypical features, or the patient has failed to respond to treatment such as with IV diuretics, he can be referred for therapeutic aspiration.

Question 63 of 231

A 66-year-old gentleman presented with a 4 day history of cough associated with green sputum. He has also been feeling more breathless, wheezy, feverish at times and having some right sided pleuritic chest pains. His past medical history includes chronic obstructive pulmonary disease, hypertension and diabetes. He has a 40 pack year history of smoking but he stopped 3 years ago.

On examination, he looks unwell, flushed and breathless at rest. His heart sounds are normal and he has right basal crackles with bronchial breathing and wheeze. There is no leg oedema or tenderness. His vital signs show pulse of 120 beats per minute, blood pressure of 120/70 mmHg, SaO2 = 89% on 24% oxygen, respiratory rate of 32 breaths per minute and T=38.5oC.

His Electrocardiogram reveals sinus tachycardia and the chest X-ray confirms right basal consolidation.

The following bloods tests have been obtained:

Hb	13.1 g/dl
Platelets	180 * 10 /l9
WBC	15.4 * 10 /l9
Na +	135 mmol/l
K +	4.9 mmol/l
Urea	10 mmol/l
Creatinine	120 µmol/l
CRP	180 mg/l
pH	7.28
pCO2	5.0 kPa
pO2	8.5 kPa
HCO3-	15 mEq/l

What is the best management?

A. Intravenous fluids, intravenous antibiotics, steroids, nebulisers and non-invasive ventilation
B. Intravenous fluids, intravenous antibiotics, nebulisers and steroids
C. Intravenous fluids, oral antibiotics, nebulisers and steroids
D. Oral fluids, intravenous antibiotics, nebulisers and non-invasive ventilation
E. Oral fluids, oral antibiotics, nebulisers and steroids

B. Intravenous fluids, intravenous antibiotics, nebulisers and steroids

The aim of this question aims to increase awareness about the use of non-invasive ventilation (NIV) in patients with chronic obstructive pulmonary disease (COPD).

The guidelines mention that NIV should be considered in patients with COPD exacerbation in whom a respiratory acidosis persists despite immediate maximum standard medical treatment on controlled oxygen for no more than one hour. Patients with COPD can develop community acquired pneumonia (CAP) with metabolic acidosis due to the sepsis, but in these cases NIV is not indicated.

This patient presented with CAP and he had metabolic acidosis. His CURB65 score is 3 and he also has acute kidney injury. He should be treated with intravenous fluids, intravenous antibiotics, nebulisers and steroids but not NIV.

Question 64 of 231

A 69-year-old man with a history of rheumatoid arthritis well controlled on methotrexate presents with gradual pain and swelling in his wrists and ankles.

The pain is described as a dull ache that is intermittent, often worse in the evenings. There is associated swelling which can sometimes feel warm. He has tried regular paracetamol but this has had limited effect.

He also describes a chronic cough and shortness of breath on exertion for the past 6 months that he has not mentioned to his GP. There has been no haemoptysis and he denies any fevers. His wife has noticed that he has been losing weight recently.

He has a past medical history of rheumatoid arthritis, hypertension, hypercholesterolaemia and type 2 diabetes mellitus. He currently takes methotrexate weekly, folic acid 5mg weekly, ramipril 5mg, simvastatin 20mg at night, metformin 500mg three times a day and paracetamol 1g four times daily.

He is a retired accountant and a current smoker with a 50 pack year smoking history. He drinks approximately 30 units of beer a week. He denies any recent foreign travel.

On examination, he is cachectic and short of breath on exertion. His pulse is 80/min and regular, blood pressure 140/93 mmHg, oxygen saturations of 93% on air. He has marked fingernail clubbing. Examination of his wrists reveals slightly swollen and tender joints.

Swan neck and ulnar deviation deformities are noted in both hands. Other than his wrists, no other joint abnormalities are detected. Examination of the peripheral nervous system is normal.

Examination of his chest is normal with no focal consolidation.

Initial bloods are as follows:

Na+	134 mmol/L
K+	3.9 mmol/L
Urea	7.8 mmol/L
Creatinine	105 µmol/L
Hb	100 g/L
WBC	6.0x10^9/L
Platelets	200x10^9/L

Chest X-ray reveals a discrete opacification at the periphery of the right middle lobe.

What is the most likely underlying diagnosis?

A. Methotrexate induced pulmonary fibrosis
B. Bronchogenic carcinoma
C. Caplan's syndrome
D. Chronic obstructive pulmonary disease
E. Pneumonia

B. Bronchogenic carcinoma

This man has a strong smoking history, chronic cough, weight loss and an abnormal chest x-ray. He also has symptoms suggestive of hypertrophic pulmonary osteoarthropathy which is associated with bronchogenic carcinoma in 90% of cases. His case would warrant urgent investigation.

Pneumonia is unlikely in the context of normal inflammatory markers

Methotrexate-induced fibrosis is unlikely in view of the chest x-ray findings and normal auscultation of the chest.

COPD may be a concomitant diagnosis in a man with such an extensive smoking history, but the presence of weight loss and hypertrophic pulmonary osteoarthropathy should raise suspicions of the more pressing diagnosis of malignancy.

Caplan's syndrome is an interstitial lung disease described in coal miners with rheumatoid arthritis. Chest x-ray usually demonstrates multiple nodules often at the lung peripheries.

Question 65 of 231

You are asked to review the results of a long term oxygen therapy (LTOT) assessment for a 74- year-old female. She has a past medical history of COPD. She has developed dyspnoea at rest.

Results of the LTOT assessment are as follows: ABG on air:

PaO2	7.1 kPa
PCO2	5.1 kPa
pH	7.41
HCO3	26

ABG after 1 litre of O2 via a nasal cannula:

PaO2	9.3 kPa
PCO2	6.5 kPa
pH	7.33
HCO3	26

The patient feels less short of breath at the end of the trial.

You decide that further medical optimisation and reassessment of arterial blood gas in 4 weeks is required.

She returns to the clinic in 4 weeks time. Her COPD appears to be stable and the medical management is optimised with salbutamol, ipratropium and carbocysteine.

A repeat LTOT assessment is as follows:

ABG on air:

LFTs	Normal
Serum uric acid	410 µmol/L
CRP	12 mg/L
PaO2	6.9 kPa
PCO2	5.0 kPa
pH	7.42
HCO3	26

ABG after 1 litre of O2 via a nasal cannula:

PaO2	9.5 kPa
PCO2	6.6 kPa
pH	7.32
HCO3	26

How will you manage this patient?

A. LTOT with nocturnal BiPAP
B. LTOT
C. LTOT with nocturnal CPAP
D. Decline LTOT
E. Palliation of breathlessness with morphine

A. LTOT with nocturnal BiPAP

Patients who develop a respiratory acidosis and/or a rise in PaCO2 of >1 kPa (7.5 mmHg) during an LTOT assessment on two repeated occasions, while apparently clinically stable, should only have domiciliary oxygen ordered in conjunction with nocturnal ventilatory support

The ABG on room air meets the criteria for LTOT as the PaO2 is < 7.3 kPa. After a 1 hour trial of low flow oxygen, the patients symptoms have improved, and his PaO2 has significantly improved. However it is important to note that his PCO2 has significantly increased resulting in a respiratory acidosis.

Patients who develop a respiratory acidosis and/or a rise in PaCO2 of >1 kPa (7.5 mmHg) during an LTOT assessment may have clinically unstable disease. These patients should undergo further medical optimisation and be reassessed after 4 weeks.

The patient is medically optimised and returns after 4 weeks for further LTOT assessment. This again demonstrates a respiratory acidosis with oxygen therapy. Patients who develop a respiratory acidosis and/or a rise in PaCO2 of >1 kPa (7.5 mmHg) during an LTOT assessment on two repeated occasions, while apparently clinically stable, should only have domiciliary oxygen ordered in conjunction with nocturnal ventilatory support. BiPAP is the modality of choice for treating CO2 retention.

Question 66 of 231

A 67-year-old man presents to the emergency department with a 24-hour history of shortness of breath. Also, he complains of a worsening cough with green sputum. He has a 20 pack-year smoking history and drinks 10 units of alcohol a week. He has a past medical history of COPD, for which he takes inhaled corticosteroids, formoterol and salbutamol.

On auscultation of his chest, there are crackles at the right base, no wheezes. He has a respiratory rate of 23 breaths per minute, a heart rate of 98bpm, BP is 115/62mmHg, SpO2 is 91% on 4L through a 28% Venturi mask, and he is afebrile.

A chest X-ray shows right lower zone consolidation. An arterial blood gas shows the following:

HCO3	28	(22-26 meq/L)
pH	7.37	(7.35 - 7.45)
pCO2	6.2	(4.5 - 6.0 kPa)
pO2	9.8	(10 - 14 kPa)

You have prescribed appropriate IV fluids and administered IV co-amoxiclav and clarithromycin.

Which of the following is the most appropriate additional treatment?

A. BIPAP
B. Decrease oxygen
C. Increase oxygen
D. Prednisolone
E. Prednisolone and increase oxygen

D. Prednisolone

Patients diagnosed with pneumonia who have COPD should be given corticosteroids even if no evidence of the COPD being exacerbated

This man is suffering from community-acquired pneumonia (CAP). Patients diagnosed with pneumonia who have COPD should be given corticosteroids even if no evidence of the COPD being exacerbated.

We do not routinely give non-invasive ventilation (NIV) or continuous positive airways pressure (CPAP) support in patients with respiratory failure due to CAP, though it ought to be considered if there is evidence of type 2 respiratory failure.

If not critically ill and history of moderate-severe COPD or other condition predisposing to hypercapnia (e.g. neuromuscular disease) then aim for 88-92% with a 28% Venturi mask initially. Then do a blood gas:

- If pH<7.35 and pCO2 >6KPa then consider NIV
- If pH>7.35 and pCO2 >6KPa then continue with 88-92% with a repeat in 30-60mins
- If pH>7.35 and pCO2 <6KPa titrate O2 to sats 94-98% with a repeat in 30-60mins

Decreasing his oxygen supply would not be appropriate as the single best answer, as his oxygen sats are in an appropriate range and he also requires corticosteroids.

Essentially, this man likely has a degree of chronic CO2 retention, as indicated by the fact that he has a compensatory metabolic alkalosis which has managed to maintain his pH within a normal range. Thus increasing his oxygen at this point is not necessary, as he may well be relying on his low O2 to drive his respiratory rate, and a target of 88-92% is satisfactory. As he is not acidotic NIV is not indicated at present.

Question 67 of 231

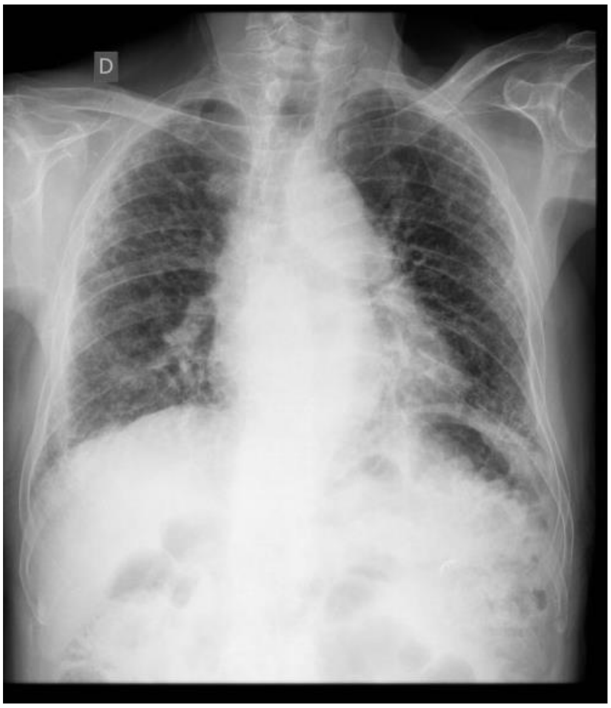
A 59-year-old man is investigated for increasing shortness-of-breath. This has been getting progressively worse for the past 6 months and is associated with a dry cough. He has received two courses of antibiotics from his GP which only temporarily improved his symptoms. He was diagnosed with asthma as a child but has not had to use an inhaler since he was around 10-yearsold. He stopped smoking 20 years ago.

On examination he is noted to have scattered crackles bilaterally, predominantly in the bases. Oxygen saturations are 96% on room air. Pulse, blood pressure and temperature are normal.

Spirometry is arranged:

FEV1	2.2 L (predicted 3.8 L)
FVC	2.7 L (predicted 4.5 L)
FEV1/FVC	81% (normal > 75%)

A chest x-ray is arranged:



Which one of the following interventions is most likely to be beneficial?

A. Bosentan
B. Rotation of prophylactic antibiotic + postural drainage
C. Bronchodilator therapy
D. Prednisolone
E. Pirfenidone

E. Pirfenidone

The spirometry shows a restrictive picture consistent with pulmonary fibrosis. The chest x-ray is also consistent with this diagnosis, showing sub-pleural reticular opacities that increase from the apex to the bases of the lungs.

Pirfenidone is currently the only drug recommended by NICE for the treatment of idiopathic pulmonary fibrosis.

Question 68 of 231

A 45-year-old man presents to the emergency department with a two-week history of a dry cough, fever and retrosternal discomfort. He has a past medical history of HIV and is poorly compliant with anti-retroviral medications. He has recently returned from a holiday in Mississippi.

Observations:

- Heart rate 95 beats per minute
- Blood pressure 101/65 mmHg
- Respiratory rate 24/minute
- Spo2 93% on room air
- Temperature 37.3C

The examination is unremarkable.

A chest x-ray demonstrates multifocal consolidation that extends to the periphery of the lungs. Sputum microscopy reveals yeasts.

What organism is most likely responsible for this presentation?

A. Coccidioides posadasii
B. Histoplasma capsulatum
C. Legionella pneumophila
D. Pseudomonas aeruginosa
E. Streptococcus pneumoniae

B. Histoplasma capsulatum

Mississippi and Ohio River valleys → ?histoplasmosis

Histoplasma capsulatum is the correct answer. The patient presents with a dry cough, retrosternal discomfort, fever and chest x-ray evidence of multifocal pneumonia after travelling from a region where histoplasmosis is endemic. Yeasts identified on sputum microscopy are also uggestive of a fungal rather than bacterial cause. Severe histoplasmosis is more common in immunocompromised patients. His history of poor compliance with HIV medications suggests he is at further risk of developing severe fungal infections. Histoplasmosis is often a self-limiting illness in an immunocompetent individual.

Coccidioides posadasii is incorrect. This causes coccidioidomycosis, another endemic mycosis. While infection with this fungal organism can cause respiratory failure and multifocal consolidation in patients with HIV, it is not endemic to Mississippi. It is found in more arid regions including southern California, southern Nevada, Arizona, New Mexico, Utah and western Texas. it is also found in parts of South America and Central America.

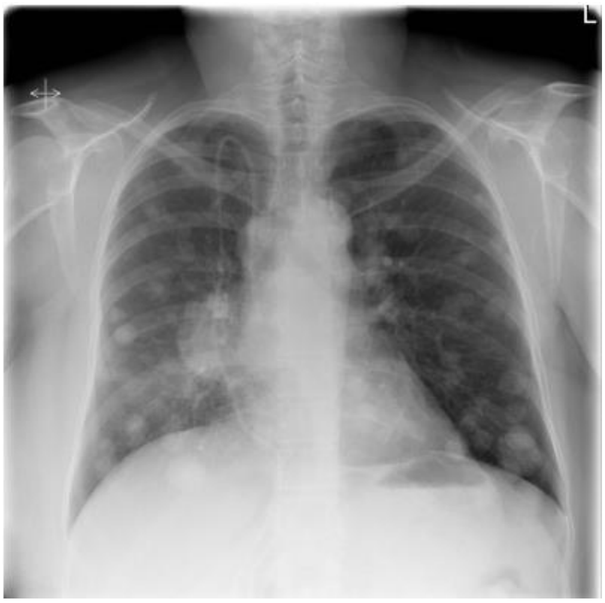
Legionella pneumophila is incorrect. This is a cause of a bacterial atypical pneumonia. It is typically transmitted by inhaling contaminated water droplets and so outbreaks have been linked to swimming pools and air conditioning systems. It is not necessarily endemic to Mississippi and sputum microscopy would not demonstrate a yeast, which implies a fungal infection.

Pseudomonas aeruginosa is incorrect. This is another potential cause of pneumonia in a patient with HIV and probable low CD4 count. However, yeasts would not be seen on sputum microscopy and this indicates a fungal infection. *Pseudomonas* infections are also more common in patients with pre-existing lung disease and indwelling vascular access.

Streptococcus pneumoniae is incorrect. This is one of the most common causes of pneumonia. However, this typically causes lobar rather than multifocal pneumonia. Additionally, the sputum sample may confirm that organism rather than grow a yeast.

Question 69 of 231

A 68-year-old woman is admitted to the Emergency Department with shortness of breath. A chest x-ray is taken as part of the initial investigations.



Based on the chest x-ray, what is the most likely diagnosis?

A. Multiple pulmonary emboli
B. Tuberculosis
C. Multiple lung abscesses
D. Bronchiectasis
E. Lung metastases

E. Lung metastases

The multiple rounded lesions are highly suggestive of lung metastases.

Question 70 of 231

A 50-year-old female patient presents to the respiratory outpatient clinic for her asthma review.

Unfortunately, she has been admitted to hospital three times in the last year with asthma exacerbations, requiring 2-3 days in hospital but never requiring intubation or intensive care admission. This is on a background of multiple admissions to hospitals in previous years.

On review, she reports wheeze associated with dyspnoea on most days and this is usually triggered by exertion. There is a non-productive cough most mornings which settles throughout the course of the day. There is no history of allergic rhinitis, eczema or other medical problems. She is a lifelong non-smoker.

Current asthma therapy is high dose inhaled fluticasone propionate plus salmeterol 2 puffs twice daily, prednisolone 10mg once daily and inhaled salbutamol as required. She has been taking regular prednisolone 10mg for the last eighteen months.

On examination, observations revealed a respiratory rate of 14/min, oxygen saturation 98% on room air, heart rate 80/min regular, blood pressure 130/70 mmHg and a temperature of 36.8ºC. There is no clubbing, cervical lymphadenopathy or elevation of the jugular venous pressure. Auscultation of the chest revealed dual heart sounds with no murmurs and some mild expiratory wheeze in the upper zones. The calves were soft and non-tender, with no pedal oedema.

You had reviewed this patient during her most recent exacerbation and had arranged some outpatient tests, the results of which are shown below:

Hb	140 g/l	Na +	138 mmol/l
Platelets	350 * 10 /l 9	K +	3.4 mmol/l
WBC	8 * 10 /l 9	Urea	5 mmol/l
Neuts	4.5 * 10 /l 9	Creatinine	70 µmol/l
Lymphs	1.0 * 10 /l 9	CRP	7 mg/l
Eosin	2.5 * 10 /l9		
Fraction of exhaled nitric oxide	65 parts per billion (upper limit of normal 50 ppb)		

Which of the following would be the most appropriate management for this patient?

A. Add in mepolizumab
B. Start a course of voriconazole
C. Increase dose of prednisolone to 20mg once daily
D. Start home nebulisers
E. High resolution computed tomography of the thorax (HRCT)

A. Add in mepolizumab

Mepolizumab and other anti-IL-5 therapies can be used in adults with eosinophilic asthma

This patient has inadequately controlled asthma as evidenced by the three admissions to hospital and ongoing cough, wheeze and dyspnoea. There is a serum eosinophilia and elevated fraction of exhaled nitric oxide (FENO), both suggesting eosinophilic inflammation as an important driver of this patient's asthma. Such patients are eligible for anti-interleukin-5 therapy such as mepolizumab.

Mepolizumab administered either intravenously or subcutaneously has been shown to significantly reduce asthma exacerbations and is particularly useful in patients on long-term steroid therapy.

There are several inflammatory phenotypes in asthma most commonly described as eosinophilic, neutrophilic, mixed, and paucigranulocytic. The presence of eosinophilic inflammation can be demonstrated by one or more of the following:

- Sputum Eosinophils 3% or more
- FENO of 50 ppb or more
- Eosinophil count of 0.3X109/L or higher
- Prompt deterioration of asthma control after a 25% or less reduction in inhaled corticosteroid dose

Studies have shown an association between higher levels of FENO and eosinophilic airway inflammation, although the mechanism by which this occurs is still unclear.

Option A - the correct answer

Option B - there is insufficient evidence to support a diagnosis of allergic bronchopulmonary aspergillosis (ABPA) and therefore a course of voriconazole is not indicated

Option C - Another advantage of mepolizumab if that is has been shown to improve asthma symptoms to such an extent that steroid-dependent patients can actually cease their oral corticosteroid therapy. Given the significant side effects long-term corticosteroid therapy can have, increasing the steroid dose further is not the most appropriate management step, especially when there is a treatment that specifically targets this patient's asthma phenotype

Option D - home nebulisers would not treat the underlying problem of eosinophilic asthma Option E - There is no indication for HRCT in this case.

Question 71 of 231

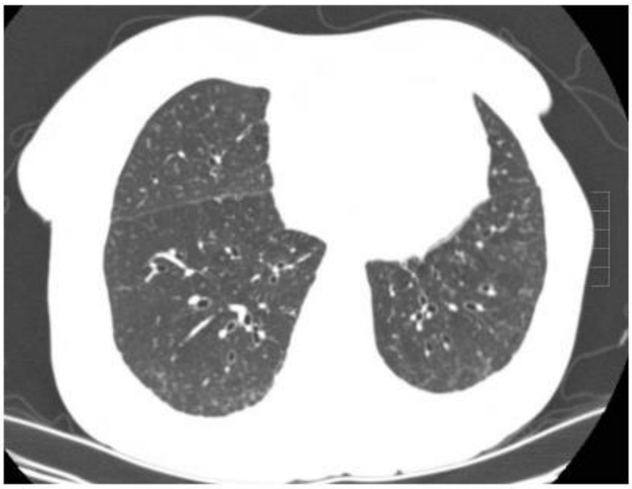
A 41-year-old woman is seen in the respiratory clinic with a 4-month history of a productive cough and shortness of breath on exertion. There is no history of fever or weight loss although she does describe feeling more fatigued. Her past medical history includes coeliac disease and she smokes 10 cigarettes/day.

Her observations are recorded as follows:

- Temperature 36.1ºC
- Heart rate 87bpm
- Blood pressure 114/67mmHg
- Respiratory rate 15 breaths/min
- Saturations 94% on room air

On examination, there is evidence of finger clubbing. On auscultation, bilateral coarse crackles are heard. Heart sounds are normal and her abdominal examination is unremarkable.

A high resolution computed tomography (HRCT) chest is requested:



What is the most likely diagnosis?

A. Mycobacterium tuberculosis
B. Bronchiectasis
C. Chronic obstructive pulmonary disease
D. Pneumocystis jiroveci pneumonia
E. Pulmonary fibrosis

B. Bronchiectasis

The diagnosis here is bronchiectasis. Bronchiectasis is the term given to a respiratory condition characterised by the permanent dilatation of the airways. This transverse slice of a CT chest shows multiple dilated bronchi, in keeping with the diagnosis. Causes of bronchiectasis include chronic infection and inflammation for example cystic fibrosis or following treatment for mycobacterium tuberculosis. This patient has had recurrent respiratory tract infections which may be involved in the pathogenesis of bronchiectasis in this patient. Symptoms include a persistent productive cough, shortness of breath and haemoptysis. Coarse crackles may be heard on auscultation and finger clubbing may be present.

Mycobacterium tuberculosis is a bacterial infection characterised by fever, lethargy and a productive cough. Constitutional symptoms such as weight loss and night sweats may also be seen. Whilst chronic inflammation secondary to *Mycobacterium tuberculosis* is a cause of bronchiectasis it is unlikely to be the current diagnosis as this patient has no history of fever or constitutional symptoms.

Chronic obstructive pulmonary disease (COPD) is most commonly secondary to tobacco use and a history of regular smoking can increase the likelihood of the disease. Examination findings tend to include wheeze rather than coarse crackles and COPD is not a cause of finger clubbing, suggesting an alternative diagnosis. Findings in keeping with COPD on a CT scan vary from person to person and include features such as bronchial wall thickening, air-space enlargement and bullae formation.

Pneumocystis jiroveci pneumonia is a serious fungal infection characterised by fever, cough, shortness of breath, chest pain and fatigue. It is most commonly seen in patients with immunosuppression. Autoimmune conditions are associated with coeliac disease, but coeliac disease itself should not give rise to significant immunosuppression.

Pulmonary fibrosis presents as progressive shortness of breath and a dry cough. It is also a cause of finger clubbing. Pulmonary fibrosis can be diagnosed on a CT scan by the presence of the characteristic honeycomb appearance which is not seen here.

Question 72 of 231

A 65-year-old man is seen in the respiratory clinic for a follow-up appointment of his chronic obstructive pulmonary disease (COPD). At his last appointment, his medications were escalated to regular inhaled Spiriva (tiotropium bromide), Symbicort (budesonide and formoterol), and salbutamol, as required. He reports ongoing shortness of breath at rest and on exertion that is limiting his activities of daily living. He has had 2 exacerbations in the last year and he has been an ex-smoker for 6 months.

On examination, he is tachypnoeic with saturations of 92% on air. On auscultation, there is an audible wheeze bilaterally and normal heart sounds. His calves are soft and non-tender with no evidence of oedema.

Arterial blood gas:

pH	7.35	(7.35 - 7.45)
PaO2	8.2 kPa	(11 - 13)
PaCO2	5.1 kPa	(4.7 - 6.0)
Haemoglobin	135 g/L	(135 - 180)
FEV1	< 50% predicted	

What is the most appropriate addition to the long-term management of this patient?

A. Long-term oxygen therapy
B. Montelukast
C. Nebulised salbutamol
D. Omalizumab
E. Roflumilast

E. Roflumilast

Roflumilast should be used in COPD for patients who are losing control on triple inhaled therapy

Important for me Less im

This patient has poorly controlled COPD, as seen by his persistent symptoms of shortness of breath despite increasing his regular medication regime. In patients who continue to have persistent symptoms despite a long-acting muscarinic antagonist, beta-agonist and inhaled corticosteroid, roflumilast can be tried. **Roflumilast** is a phosphodiesterase inhibitor recommended by NICE as an option for treating severe chronic obstructive pulmonary disease if the following criteria are met:

- Severe disease is defined as a forced expiratory volume in 1 second (FEV1) after a bronchodilator of less than 50% of predicted normal.

AND

- The person has had 2 or more exacerbations in the previous 12 months despite triple inhaled therapy with a long-acting muscarinic antagonist, a long-acting beta-2 agonist and an inhaled corticosteroid.

Long-term oxygen therapy is indicated for patients with COPD if the following criteria are met:

- Resting PaO2 ≤7.3-kPa

OR

- Resting PaO2 ≤8-kPa with evidence of peripheral oedema, polycythaemia (haematocrit ≥55%) or pulmonary hypertension.

This patient has a PaO2 of 8.2kPa, making long-term oxygen therapy currently inappropriate.

Montelukast is a leukotriene receptor antagonist that is used in the management of asthma. It is not routinely used in the management of COPD.

Nebulised salbutamol may help alleviate symptoms in patients with COPD. However, salbutamol is a short-acting beta-agonist and nebulised salbutamol will only provide short-term symptomatic relief and does not help with the long-term management of symptoms.

Omalizumab is a monoclonal antibody used in the treatment of persistent allergic asthma. It works by reducing the levels of IgE and subsequent inflammation. It is not used in the treatment of severe COPD.

Question 73 of 231

A 75-year-old man presents to the emergency department with hemoptysis. He has a past medical history of hepatitis C. He declined anti-viral therapy.

On examination, he has a saddle nose deformity. There is a non-blanching rash on his lower limbs. Blood tests:

Hb	88 g/L	Male: (135-180)Female: (115 - 160)
Platelets	489 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	18.2 mmol/L	(2.0 - 7.0)
Creatinine	155 µmol/L	(55 - 120)
CRP	151 mg/L	(< 5)

Urinalysis:

Blood	+
Protein	+++

Plain radiography of the chest demonstrates bilateral infiltrates.

Given the probable diagnosis, what test is most likely to be positive?

A. Anti glomerular basement membrane antibody (anti-GBM)
B. C-ANCA
C. Cryoglobulins
D. Double-stranded DNA (dsDNA)
E. P-ANCA

B. C-ANCA

Granulomatosis with polyangiitis - cANCA positive

C-ANCA is correct. The patient has a multisystem disease characterized by haemoptysis, saddle nose deformity, likely pulmonary haemorrhage (infiltrates, haemoptysis, anaemia) and an acute kidney injury with haematoproteinuria. The likely diagnosis is granulomatosis with polyangiitis (GPA). GPA is an ANCA-associated vasculitis that is most commonly associated with cANCA.

Anti glomerular basement membrane antibody (anti-GBM) is incorrect. This can also cause a pulmonary-renal syndrome with pulmonary haemorrhage and rapidly progressive glomerulonephritis. However, it is not associated with the ENT features that are seen in GPA i.e. saddle nose deformity, as seen in this case. Rarely, the two disorders can co-exist but the more likely scenario is that cANCA will be positive rather than an anti-GBM antibody.

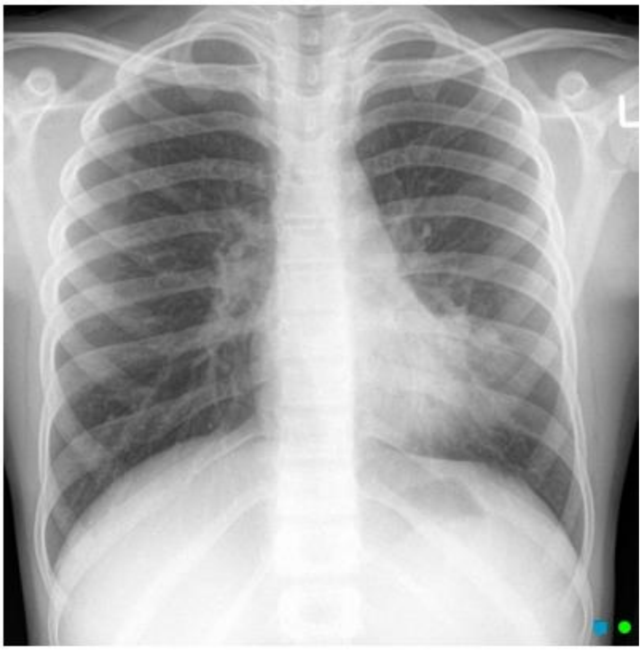
Cryoglobulins are incorrect. Hepatitis C infection would put the patient at risk of cryoglobulinaemia, which can cause rash and renal impairment. However, it is less likely to cause pulmonary haemorrhage and is not associated with ENT involvement, wich is present in this case.

Double-stranded DNA (dsDNA) is incorrect. This is a specific antibody associated with systemic lupus erythematosus. SLE is typically associated with younger women rather than older men. Additionally, ENT involvement is not typical and pulmonary haemorrhage is rarer than in ANCA vasculitis.

pANCA is incorrect. This is more commonly associated with microscopic polyangiitis. This typically caused pulmonary and renal vasculitis but is discriminated from GPA by lack of ENT involvement in most cases. It may also be positive in a variety of other conditions including inflammatory bowel disease and primary sclerosing cholangitis. In general, a positive pANCA with negative MPO/PR3 has a poor positive predictive value for vasculitis.

Question 74 of 231

An 11-year-old girl presents with a productive cough and fever. A chest x-ray is taken:



What is the main finding on the x-ray?

A. Bilateral pneumothoraces
B. Left lingual consolidation
C. Dilated cardiomyopathy with pulmonary oedema
D. Left humeral head fracture
E. Left middle lobe consolidation

B. Left lingual consolidation

The loss of the left heart border is a classic sign of left lingual consolidation. There is no left middle lobe

Question 75 of 231

A 56-year-old man presents to the Medical Admissions unit with a two-week history of a productive cough. His past medical history is significant for type 2 diabetes mellitus. He reports that he developed a cough productive of green sputum shortly after returning from a business trip to the United States. He also complains of persistent retrosternal pain for the last ten days. He has completed a course of doxycycline prescribed by his GP, to little symptomatic benefit.

Alongside routine blood tests, he provides a sputum sample for culture, with provisional results as follows:

Sputum culture	Fungal spores seen - full speciation awaited

Based on the likely diagnosis, what is the most appropriate management option?

A. Co-trimoxazole
B. Co-trimoxazole + prednisolone
C. Dapsone
D. Itraconazole
E. Voriconazole

D. Itraconazole

Amphotericin or itraconazole are the pharmacological agents of choice for histoplasmosis

The correct answer is **itraconazole**. This patient has a likely diagnosis of histoplasmosis. This is based on the presence of retrosternal pain alongside symptoms of a respiratory tract infection, combined with a history of recent travel to the United States, where the causative pathogen *Histoplasma capsulatum* is endemic, in parts. Further weight is given to the diagnosis of histoplasmosis by the presence of fungal spores in sputum culture. Of the options provided, only itraconazole is a typical first-line treatment of histoplasmosis.

Co-trimoxazole is incorrect. This would be an appropriate initial management option for *Pneumocystis jirovecii* pneumonia (PJP). This would tend to appear in question stems as a cause for hypoxia with exertional desaturation in immunosuppressed patients, rather than with a productive cough and retrosternal pain. Diagnosis tends to be confirmed on bronchoalveolar lavage rather than sputum culture.

Co-trimoxazole + prednisolone is incorrect as this would tend to be a regime used for PJP with severe hypoxia rather than histoplasmosis.

Dapsone is incorrect, as this tends to be used as a second-line agent for PJP if co-trimoxazole is ineffective or contraindicated, rather than treatment for histoplasmosis.

Voriconazole is incorrect. Although from the same class of drugs as itraconazole, voriconazole is more conventionally used for the treatment of invasive aspergillosis, or its prevention, for example in allogeneic stem cell transplant recipients. It is not typically used as a first-line treatment option for histoplasmosis.

Question 76 of 231

A 21-year-old man is admitted to the specialist burns unit with severe burns following a house fire. He is haemodynamically stable and receives IV fluids and oxygen, although does not require intubation. Three days after his admission, he develops acute-onset shortness of breath. The only past medical history reported was hay-fever as a child and his mother has relapsing-remitting multiple sclerosis. He smoked 1-2 roll-up cigarettes per week and did not drink any alcohol.

His observations include a respiratory rate of 28 breaths per minute, oxygen saturations of 91% on 12L of oxygen, a heart rate of 112 beats per minute and blood pressure of 114/78 mmHg. His temperature was 36.9ºC. Examination revealed widespread crackles over both lung fields.

Chest x-ray reveals bilateral infiltrates.

What is the most likely diagnosis?

A. Hospital-acquired pneumonia
B. Pneumonitis
C. Acute respiratory distress syndrome
D. Renal failure
E. Asthma attack

C. Acute respiratory distress syndrome

The correct answer is **Acute respiratory distress syndrome (ARDS)**. This patient presents with the classical features of ARDS following a major burn injury, which is a well-known precipitating factor. The diagnosis is supported by the acute onset of respiratory symptoms, bilateral infiltrates on chest x-ray, and hypoxaemia (requiring high-flow oxygen to maintain saturations above 90%) occurring within a week of the initial insult. The patient meets the Berlin criteria for ARDS, which includes timing within 7 days of a known clinical insult, bilateral opacities not fully explained by effusions or collapse, and respiratory failure not fully explained by cardiac failure or fluid overload.

Hospital-acquired pneumonia is incorrect because although this can occur in burns patients due to immunosuppression, the bilateral nature of the infiltrates and the timing (3 days) would be unusual. Hospital-acquired pneumonia typically presents after 48 hours of admission with unilateral changes initially, and often includes pyrexia and purulent sputum, which are not present here.

Pneumonitis is incorrect as this term typically refers to inflammation of lung tissue from noninfectious causes such as chemical injury or autoimmune conditions. While smoke inhalation can cause chemical pneumonitis, this would have been evident from admission rather than developing after three days.

Renal failure is incorrect as while this can occur in burns patients due to fluid loss and myoglobinuria, it would not explain the respiratory symptoms and chest x-ray findings. Whilst pulmonary oedema can occur in renal failure, the acute onset and bilateral infiltrates are more consistent with ARDS.

Asthma attack is incorrect because despite the patient's history of atopy (hay fever), the presentation is not consistent with acute asthma. Asthma typically presents with wheeze rather than crackles, and the chest x-ray would not show bilateral infiltrates. Additionally, asthma would be unlikely to develop acutely in this setting without a clear trigger.

Question 77 of 231

A 52-year-old gentleman presents to the respiratory clinic with shortness of breath and a dry cough. He has noticed his symptoms getting progressively worse over months. He has a past medical history of hypertension and depression. He takes only ramipril and has no allergies. On examination, he has bilateral inspiratory crackles at both lung bases. A chest X-ray demonstrates extensive pleural plaques. He has worked as an electrician 20 years ago and believes that he may have had asbestos exposure. A diagnosis of asbestosis with extensive pleural plaques is suspected.

What is his pulmonary function tests likely to show?

A. FEV1 to FVC ratio >0.7
B. FEV1 to FVC ratio <0.7
C. Normal ratio of FEV1 to FVC and normal FEV1
D. FEV1 to FVC ratio <0.7 but improves with inhaled steroids
E. FEV1 to FVC ratio <0.7 but improves with inhaled salbutamol

A. FEV1 to FVC ratio >0.7

The correct answer is FEV1 to FVC ratio >0.7, which would be in keeping with a restrictive pattern if the FEV1 compared to expected was also reduced. In asbestosis, there is restriction of lung expansion due to pleural disease, limiting expansion of lung volume as the plaques are not as expansile as pulmonary tissue. This stops the lungs from fully expanding leading to a restrictive picture on spirometry. Obstructive patterns, with a decreased ratio of FEV1 to FVC would be associated with COPD and asthma.

Question 78 of 231

A 24-year-old woman attends the respiratory clinic for a review of her asthma treatment. The patient reported that overall, her symptoms of asthma had been well controlled in the 6 months since her last review. She had not suffered any significant exacerbations of her asthma in that time and felt she was required to use her salbutamol inhaler only around once per week (which represented a significant improvement over her normal control). The patient also reported that she was now 3 months pregnant, and had just had an unremarkable 12-week ultrasound. While she had not been planning to have a baby, the patient reported being very happy about it, and she was keen to maximise her health during this time.

The patient had a long-standing diagnosis of asthma, with her first presentations during early childhood. While the illness had only caused mild symptoms between the ages of 10 and 15 years, the patient had suffered several severe exacerbations of asthma in her late teenage years, coinciding with the time when the patient had become a regular smoker. The patient did not report any other significant on-going health problems or past medical history. In particular, she denied a history of seizures, high blood pressure or mental health problems.

The patient's current asthma treatment was a salmeterol-fluticasone combination inhaler (Seretide Accuhaler 250), one puff twice daily. She was also prescribed a metered-dose salbutamol inhaler for use as required. The patient had no history of drug allergies.

The patient reported that she continued to be a regular cigarette smoker. Since finding out she was pregnant, she had managed to reduce her regular intake to 12 cigarettes per day, reduced from her previous typical intake of 20 cigarettes per day. The patient was motivated to use her pregnancy as a motivating factor to stop smoking permanently, and during the clinic asked about medication to assist her with quitting.

What is the appropriate drug treatment strategy to assist this patient to stop smoking?

A. Nicotine replacement patch with short-acting nicotine replacement
B. Varenicline
C. No drug treatment options available
D. Bupropion
E. Nicotine replacement patch only

Not answered in the file

Question 79 of 231

A 33-year-old woman with a three-year history of extremely difficult to control asthma and allergic rhinitis was admitted to the intensive

care unit having been deteriorating at home for several weeks Blood tests from a GP consultation last week were available:

Hb	121 g/l(115 - 165)
Platelets	135 * 10 /l(150 - 400)9
WBC	11.8 * 10 /l(4.0 - 11.0)9
Neuts	7.6 * 10 /l(1.5 - 7.0)9
Lymphs	0.9 * 10 /l(1.5 - 4.0)9
Eosin	3.03 * 10 /l(0.04 - 0.4)9
Serum CRP	103 mg/l(<10)
c-ANCA	negative
p-ANCA	positive
PR3	5U/ml(<10)
MPO	100U/ml(<10)

What is the most likely diagnosis?

A. Anti-glomerular basement antibody (anti-GBM) disease
B. Legionnaires' disease
C. Eosinophilic granulomatosis with polyangiitis
D. Microscopic polyangiitis
E. Granulomatosis with polyangiitis

C. Eosinophilic granulomatosis with polyangiitis

Eosinophilic granulomatosis with polyangiitis is a necrotizing small vessel vasculitis

The most likely diagnosis is eosinophilic granulomatosis with polyangiitis (EGPA), which tends to progress through three phases: atopy (asthma, rhinitis, sinusitis), eosinophilia >10% (often with pulmonary infiltrates), and necrotizing multi-system small vessel vasculitis. pANCA is positive in 40-70% of patients with eosinophilic granulomatosis with polyangiitis.

In contrast, patients with microscopic polyangiitis tend to have diffuse alveolar haemorrhage rather than nasal or asthma symptoms as the scenario depicted. Similarly, patients with granulomatosis with polyangiitis (Wegener's syndrome) tend not to have asthma as a feature and have predominantly positive cANCA. Patients with anti-glomerular basement antibody (anti-GBM) disease present with symptoms of pulmonary/renal involvement include haematuria, shortness of breath, cough, and expectoration of material that ranges from blood-streaked sputum to massive haemoptysis. The presence of anti-GBM antibodies is pathognomonic. Legionnaires disease is a form of pneumonia caused by *Legionella pneumophila* and negative to both cANCA and pANCA.

Question 80 of 231

A 60-year-old man is admitted with an infective exacerbation of COPD. He normally has a productive cough but has been bringing up large quantities of sputum and estimates about 1 cup of yellow sputum with streaks of blood being produced a day.

He takes steroid nose drops and had endoscopic surgery for recurrent sinusitis 5 years ago. He lives alone independently and drives a car. He can usually walk 50-100 metres on the flat.

He arrives to the emergency department in extremis. There is accessory muscle use and widespread coarse crepitations in both lungs. His heart sounds are normal with no signs of cardiac failure. He is started on antibiotics, steroids, aminophylline and back to back nebulisers. He continues to produce lots of phlegm and the nurses suction to clear a yellow mucoid substance from his mouth. He responds to commands, his eyes open to voice. and he is talking in normal words but his thoughts are incoherent. He is started on non invsaive ventilation and tolerates the mask. He continues to cough producing a 20ml plug of sputum with dried clot whilst given his first nebuliser. The respiratory registrar decides that NIV should be stopped.

Na +	139 mmol/l
K +	4.2 mmol/l
Urea	4.3 mmol/l
Creatinine	76 µmol/l
CRP	189 mmol mg/l
Hb	90 g/l
Platelets	178 * 10 /l9
WBC	23 * 10 /l9
ABG	(in air)
pH	7.39
pCO2	7.37 kPa
pO2	6.9 kPa
HCO3	25 mmol/l
Lactate	2.3 mmol/l
Chest x-ray	bilateral alveolar shadowing

Which contraindication to non invasive ventilation is present in this case?

A. Copious secretions
B. Not on maximal medical therapy
C. Endoscopic sinus surgery
D. Level of consciousness
E. Lack of consent

A. Copious secretions

Copious secretions are a contraindication to non-invasive ventilation

There are many contraindications to non invasive ventilation that must be carefully considered. Patients must be awake and able to protect their airway which this man although drowsy should be able to achieve with a Glasgow Coma Score of 13. The patient is on maximal medical therapy and there are few additional agents that would be helpful. His ENT surgery is important but some years ago and there is no head or neck trauma present which would be a contraindication. The gentleman is coughing up large volumes of sputum/secretions and this could pose a compromise to his airway. It is difficult to understand if he has capacity from the question but given his good premorbid function, active treatment would likely be in his best interests.

Question 81 of 231

A 52-year-old gentleman is admitted to hospital with a cough and fever. He has been unwell for a week with high temperatures, coughing rusty coloured sputum as well as small amounts of blood. He has no significant past medical history but smokes ten cigarettes per day. A chest X-ray shows right sided lower lobe consolidation with a pleural effusion. An aspirate demonstrates low pH raising the suspicion of empyema and a chest drain is requested under ultrasound guidance.

What factor may help predict drainage success or failure?

A. Protein level of pleural fluid
B. Echogenicity on US
C. pH of pleural fluid
D. Presence of associated consolidation
E. Septation density on ultrasound

E. Septation density on ultrasound

The correct answer is septation density on ultrasound. This is a patient with a possible empyema or parapneumonic effusion. The presence of low pH in the effusion makes the former more likely. The presence of septation density indicates various pockets within the effusion indicating that even if a drain accesses any pocket in particular, it may fail in draining all of the effusion. Protein level helps determine if an effusion is a transudate or an exudate, whilst a low pH is most useful in determining the risk of empyema. Consolidation may imply ongoing pneumonia and may suggest a cause of the effusion.

Question 82 of 231

You arrange a long term oxygen therapy (LTOT) assessment for a 69-year-old man. He has a past medical history of COPD. He has developed dyspnoea at rest.

Results of the LTOT assessment are as follows: ABG on air:

PaO2	7.1 kPa
PCO2	5.1 kPa
pH	7.41
HCO3	26 mmol/l

ABG after 1 litre of O2 via a nasal cannula:

PaO2	9.3 kPa
PCO2	6.5 kPa
pH	7.33
HCO3	26 mmol/l

The patient feels less short of breath at the end of the trial.

How will you manage this patient?

A. Provide LTOT
B. Decline LTOT
C. Further medical optimisation and reassess after 4 weeks
D. BiPAP
E. CPAP

C. Further medical optimisation and reassess after 4 weeks

Patients who develop a respiratory acidosis and/or a rise in PaCO2 of >1 kPa (7.5 mmHg) during an LTOT assessment may have clinically unstable disease. These patients should undergo further medical optimisation and be reassessed after 4 weeks

The ABG on room air meets the criteria for LTOT as the PaO2 is < 7.3 kPa. After a 1 hour trial of low flow oxygen, the patients symptoms have improved, and his PaO2 has significantly improved. However it is important to note that his PCO2 has significantly increased resulting in a respiratory acidosis.

Patients who develop a respiratory acidosis and/or a rise in PaCO2 of >1 kPa (7.5 mmHg) during an LTOT assessment may have clinically unstable disease. These patients should undergo further medical optimisation and be reassessed after 4 weeks.

Question 83 of 231

A 55-year-old male presents to the emergency department with worsening cough and breathlessness over the past three weeks. He reports a productive cough with haemoptysis and admits to fevers and weight loss over this time.

Past medical history is significant for type 2 diabetes mellitus. He currently smokes 20 cigarettes per day and drinks approximately 60 units per week.

Examination reveals on unkempt, cachectic man with bronchial breath sounds in the right upper zone.

Chest X-Ray is reported as having right upper lobe consolidation with a 'bulging fissure sign'

What is the most likely causative organism?

A. Klebsiella pneumonia
B. Mycobacterium tuberculosis
C. Aspergillus fumigatus
D. Staphylococcus aureus
E. Streptococcus pneumoniae

A. Klebsiella pneumonia

The bulging fissure sign is classical of Klebsiella pneumonia

The bulging fissure sign is an increasingly rare but classical feature of *Klebsiella pneumonia*. It is due to large volumes of consolidation (typically in the right upper lobe) causing displacement of the adjacent fissure.

Other features in the question to support a diagnosis of *Klebsiella pneumonia* include a history of alcohol excess and haemoptysis, often described as 'red currant jelly sputum'.

Whilst tuberculosis is an important differential to consider but seldom causes such dense consolidation to cause this sign. Radiologically, tuberculosis and aspergillosis usually appear as cavities. Klebsiella can also cause an isolated cavitating pneumonia.

Both *Streptococcal pneumoniae* and *Staphylococcus aureus* appear radiologically as the bulging fissure sign, other features in the question would be present to point you towards this diagnosis. Questions relating to *Streptococcal pneumoniae* will often describe a cough productive of rustycoloured sputum and often a proceeding herpes labialis. Questions relating to *Staphylococcus aureus* will commonly report a proceeding flu-like illness with subsequent rapid deterioration into a bacterial pneumonia.

Question 84 of 231

A 60-year-old gentleman is seen by his general practitioner 3 weeks after a recent infective exacerbation of COPD. He is currently well but concerned that this is his second exacerbation during this winter season.

He is currently managed on fostair, tiotropium and as required salbutamol. He currently has a mild cough but is well and has attended his recent COPD review.

Today, his chest is clear with no wheeze or crepitations. The JVP is not raised and there is no oedema. His oxygen saturations are 94% in air and he has a respiratory rate of 22 breaths per minute.

He is currently well and able to do his gardening and walks the dog up to half a mile each day. He does not get breathlessness at night and has been discharged from chest physio who are happy with his current performance.

FEV1 (% predicted)	40%
FVC (% predicted)	80%
Chest x-ray	several bullae noted, hyperexpanded chest with no consolidation
ECG	sinus rhythm, right bundle branch block

What intervention should be added to his current management?

A. Furosemide
B. Long term home oxygen
C. Home nebulisers
D. Roflumilast
E. Pulmonary rehabilitation

D. Roflumilast

Oral PDE-4 inhibitors such as roflumilast reduce the risk of COPD exacerbations in patients with severe COPD and a history of frequent COPD exacerbations

This is a gentleman with COPD and two recent exacerbations. He shows no signs of cor pulmonale or fluid overload and would therefore not benefit from a loop diuretic. Home nebulisers and pulmonary rehabilitation can be beneficial in severe symptomatic COPD but this patient is currently well and maintaining regular exertion without difficulty. Likewise, he is not hypoxic and there are no signs of cor pulmonale so he would not be a candidate for long term home oxygen. This leaves roflumilast as the answer, this is a phosphodiesterase-4 inhibitor that is recommended in COPD patients on maximal medical therapy with FEV1 <50% and had more than one exacerbation as per recent GOLD guidance.

Question 85 of 231

A 73-year-old gentleman presents to oncology clinic with a two-week history of shortness of breath. He has a background of mesothelioma diagnosed two years ago. He has noticed that he has been finding it more difficult to walk distances without developing shortness of breath, and today struggled to make it into the clinic from the car-park, 200 yards away. He denies having a cough or fever but has been feeling more tired lately. Saturations are 95% whilst breathing room and his blood pressure, temperature, heart rate and respiratory rate are all within normal parameters.

A chest X-ray is done which demonstrates a right-sided pleural effusion. He is admitted to hospital and a chest drain is inserted, draining three litres of blood-stained fluid in two hours. He becomes increasingly short of breath and starts to cough. He denies any chest pain. On examination, he is uncomfortable and breathing 4L of oxygen via a non-rebreather mask. There are bilateral crepitations in his chest.

25/11/16 16:31	25/11/16 14:18	
Saturations	91%	95%
Respiratory rate	22/min	18/min
Blood pressure	131/81mmHg	139/85mmHg
Heart rate	101/min	71/min
Temperature	37.0°C	37.1°C

What is the likely diagnosis?

A. Empyema
B. Iatrogenic chest infection
C. Re-expansion pulmonary oedema
D. Pneumothorax
E. PE

C. Re-expansion pulmonary oedema

The correct answer is re-expansion pulmonary oedema. This is a potentially life-threatening condition which can occur when a large volume of fluid or air is rapidly drained, as has happened with this patient. It is suggested by sudden onset of shortness of breath, cough and hypoxaemia following chest drain insertion. Empyema is unlikely given the absence of fever and no evidence of it on the original chest X-ray. Again, the absence of a fever makes iatrogenic infection less likely, and the timing is too early for infection. Pneumothorax is possible, but the examination demonstrates crepitations rather than any clinical evidence of pneumothorax. A PE is also possible given the history of malignancy and tachycardia and cannot be excluded clinically, but given the timing of the chest drain and the volume taken, re-expansion pulmonary oedema is more likely.

Question 86 of 231

A 26 year old asthmatic woman is admitted to hospital following a deliberate overdose of her usual theophylline tablets.

Which one of the following may be a complication of theophylline toxicity?

A. Hypoglycaemia
B. Atrioventricular nodal blockade
C. Bronchoconstriction
D. Increased myocardial contractility
E. Hyperkalaemia

D. Increased myocardial contractility

Theophylline poisoning presents with hypokalaemia, hyperglycaemia, tachycardia and increased myocardial contractility

Theophylline is a methylxanthine derivative drug which is structurally and clinically similar to caffeine. Aminophylline is the name given to theophylline when it is ligand bound to the chemical ethylenediamine which increases water solubility and hence aminophylline tends to be the intravenous form. Methylxanthine derivatives are used clinically for the treatment of bronchoconstriction in asthma, chronic obstructive pulmonary disease and in neonatal apnoea. They work in a two-fold fashion; firstly they inhibit the family of metabolic enzymes, the phosphodiesterases which increase levels of cyclic adenosine monophosphate and dampens the inflammatory cytokine cascade, and secondly they are competitive antagonists at the endogenous adenosine receptors located in the central nervous system, heart and lungs.

Inhibition of various phosphodiesterases causes a reduction in the circulating population of inflammatory cytokines and also increases cardiovascular and peripheral blood flow. Due to increased metabolism, hypokalaemia is common and gluconeogenesis and glycogenolysis is stimulated causing a rise in the plasma glucose load.

Competitive antagonism at the adenosine receptor causes roughly the opposite effects of adenosine. Whereas this drug is used clinically to slow the heart rate and block transmission at the AV node, theophyllines cause tachycardia and an increase in AV conduction, cardiac automaticity and an increase in myocardial contractility, ultimately leading to an increased cardiac output with hypertension and flushing. Inhibition of adenosine receptors in bronchioles causes relaxation and improved airflow, and in the central nervous system leads to agitation, headache, anxiety, tremor and insomnia.

Other symptoms of methylxanthine toxicity include extreme nausea and vomiting, pancreatitis, gastroesophageal irritation, psychiatric symptoms and seizures. Tachyarrhythmias may deteriorate into ventricular rhythms quickly which may be fatal. Competing metabolic acidosis and respiratory alkalosis may cause a mixed arterial blood gas picture and many electrolyte disturbances can occur but an unexplained hyperglycaemia with a hypokalaemia is very suggestive of theophylline toxicity. Theophylline has a narrow window of therapeutic efficacy and patients may become toxic rapidly if drugs which inhibit their metabolism are given concurrently, particularly antibiotics such as macrolides or fluoroquinolones.

Management of theophylline toxicity is largely supportive with seizures controlled by benzodiazepines or intubation. Phenytoin is best avoided as it can worsen arrhythmia. Electrolyte abnormalities must be corrected, particularly hypokalaemia and hypomagnesaemia. Hypertension and tachycardia may respond to beta-blockers but beware of making the situation worse in an asthmatic patient. Verapamil is an alternative. Ventricular rhythms should be electrically cardioverted.

Theophyllines are one of the few drugs which are highly adsorbed by activated charcoal and this should be considered even beyond an hour after ingestion due to the extended release nature of most preparations and the drugs slowing of gastric emptying

Question 87 of 231

A 53-year-old man with known interstitial lung disease presents with worsening of his shortness of breath, fevers and night sweats. He is an immigrant from Pakistan and has previously worked on quarry sites extracting silica from sand. He stopped due to shortness of breath and moved to the UK five years ago.

He does not work and can usually walk 100 metres before he becomes breathless but this has reduced to 10 metres over the past two weeks. He has a cough with phlegm but no haemoptysis and feels weak. He was well 1-2 months prior when he visited his home town in Pakistan and he does not recall meeting any ill contacts but reports that he took a number of long train journeys on public trains there.

On examination, he has crepitations in both lungs which are best heard at the apices. He is saturating at 92% on 2 litres of nasal cannulae. He is thin with a body mass index of 21. His JVP is not visible and there is no oedema in the calves.

Na +	139 mmol/l
K +	3.9 mmol/l
Urea	7.6 mmol/l
Creatinine	132 mmol/l
Hb	115 g/l
Platelets	378 * 10 /l9
WBC	11.9 * 10 /l9
Neuts	9.8 * 10 /l9
Eosin	0.1 * 10 /l9
D-dimer	elevated
Interferon-gamma release assay	positive
Sputum	gram stain negative, cultures awaited
ECG	sinus, p-pulmonale
Blood cultures	awaited
CXR	cavitating disease with reticulonodular pattern predominantly upper lobe

High-resolution CT chest	ground glass changes and honeycomb lung appearance, 2cm cavity seen in the left upper lobe with background emphysematous change

What is the likely diagnosis?

A. Cor pulmonale
B. Influenza
C. Pulmonary embolism
D. Tuberculosis
E. Lower respiratory tract infection

D. Tuberculosis

Silicosis increases susceptibility to tuberculosis

This gentleman with previous silica exposure likely has silicosis. He has recent travel on long distance train journeys and pulmonary embolism is possible. However, he has more systemic symptoms with weight loss and night sweats and has been to the Indian subcontinent where tuberculosis is prevalent. His IGRA test is positive suggesting exposure and he has cavitating disease on his CXR/CT scan. He could have a lower respiratory tract infection or influenza but the presentation is usually more acute. Cor pulmonale is the development of right-sided heart failure on the background of chronic respiratory distress and this is usually more gradual. Patients with silicosis are at higher risk of tuberculosis infection that is more severe and extensive than for other people and is termed silicotuberculosis.

Question 88 of 231

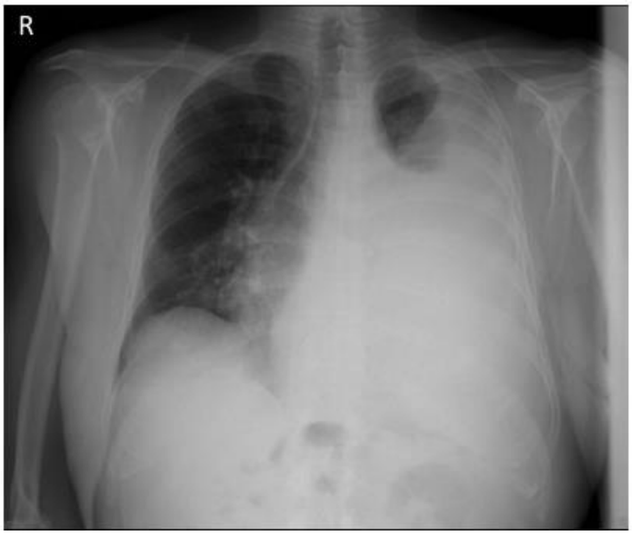
A 74-year-old man is admitted to the hospital with a 2-month history of progressive dyspnoea and weight loss. He has also noted a cough productive of purulent phlegm, with occasional flecks of dark red blood. His only medical history is of type 2 diabetes for which he takes oral therapies. He is an ex-smoker of 40 pack years.

His observations reveal a heart rate of 80/min, blood pressure of 130/85 mmHg, temperature 37.4ºC, respiratory rate of 24 breaths per minute and oxygen saturation of 94% whilst breathing 4 litres/min via nasal cannula.

Laboratory results are shown below:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	410 * 10 /L 9	(150 - 400)
WBC	12.5 * 10 /L 9	(4.0 - 11.0)
Na +	130 mmol/L	(135 - 145)
K +	3.9 mmol/L	(3.5 - 5.0)
Urea	6.7 mmol/L	(2.0 - 7.0)
Creatinine	78 µmol/L	(55 - 120)
Calcium	2.75 mmol/L	(2.1-2.6)
Phosphate	0.81 mmol/L	(0.8-1.4)
Parathyroid hormone	1.0 pmol/L	(1.6 - 7.2)
CRP	90 mg/L	(< 5)

His chest radiograph is shown below:



What is the next most appropriate test for this patient?

A. Bronchoscopy
B. CT chest
C. Ultrasound-guided pleural aspiration
D. Sputum microscopy, sensitivity and culture (MC&S)
E. Technetium sesta-methoxyisobutylisonitrile (sestamibi) imaging

C. Ultrasound-guided pleural aspiration

This man's chest x-ray shows a unilateral left-sided pleural effusion. The history of weight loss and haemoptysis in a smoker raises concern for an underlying malignancy. Infection is a possibility given his elevated CRP and borderline pyrexia however the hypercalcemia makes malignancy more likely. The most appropriate next test for this man is an ultrasound-guided aspiration of the pleural fluid to both ascertain a diagnosis and to alleviate his symptoms of dyspnoea. The pleural fluid should be tested for biochemistry (including pH, protein, glucose and LDH), microbiology and cytology.

A CT chest will form part of this man's diagnostic tests however a pleural aspiration will both add diagnostic value and alleviate his symptoms in the first instance.

If the cytology yielded from a pleural aspiration is non-diagnostic or insufficient, then a bronchoscopy could be considered.

A CT scan of the chest would be required in advance of pursuing a bronchoscopy.

Technetium sestamibi scan is a nuclear medicine imaging technique that helps to localise parathyroid adenomas. Although this man is hypercalcemic, his parathyroid hormone levels are appropriately suppressed thus there is no evidence of hyperparathyroidism.

Sputum microscopy, culture and sensitivity (MC&S) would be a reasonable test to perform however the concern based on the imaging and clinical syndrome is of malignancy. Sputum MC&S is an essential test when diagnosing respiratory infection but will not diagnose the pleural effusion found on this man's chest radiograph.

Question 89 of 231

A 58-year-old man presents to the emergency department with a three-day history of sharp chest pain. He denies any shortness of breath. His pain is worse on deep inspiration and has not improved with paracetamol. He has no other symptoms. He has a past medical history of COPD and uses regular combination inhalers with salbutamol inhalers when he becomes short of breath. He has not recently had an exacerbation and he has never been admitted to ITU or had invasive ventilation. Examination demonstrates no abnormalities; the chest is clear on auscultation and vital parameters are within normal range. A chest X-ray demonstrates a <1cm right-sided pneumothorax. He is treated with high flow oxygen.

What is the benefit of oxygen In the treatment of a pneumothorax?

A. Maintaining pressure inside alveoli to prevent further expansion of pneumothorax
B. Exchange of nitrogen for oxygen allowing quicker resorption of the pneumothorax
C. Prophylactic treatment if suddenly becomes hypoxic
D. There is no indication for oxygen
E. Symptomatic relief

B. Exchange of nitrogen for oxygen allowing quicker resorption of the pneumothorax

The correct answer is the exchange of nitrogen for oxygen allowing quicker resorption. Patients who are diagnosed with a pneumothorax should be given high-flow oxygen as it allows the exchange of nitrogen from the air trapped forming the pneumothorax with the additionally inspired oxygen from given to the patient. This exchange increases the oxygen content of the pneumothorax whilst decreasing the nitrogen concentration. Oxygen is more readily absorbed, and therefore the pneumothorax resolves more quickly.

Question 90 of 231

A 35-year-old man presents with a chronic productive cough which has been affecting him for several years. He has no other past medical history apart from recurrent otitis media as a child. He takes no regular medications. He has never smoked and has no history of passive smoking and works as a solicitor. He has no pets at home and has no mould that he is aware of. On examination there is finger clubbing, he appears underweight, there are coarse late-inspiratory crepitations and a mild wheeze. Also, his heart sounds are louder on the right side, and his apex beat is also only present on the right.

What further investigation would most likely confirm the diagnosis?

A. Immunological testing for Aspergillus fumigatus specific IgE
B. CFTR gene testing
C. Sputum MCS
D. Sputum Zeil-Neilsen staining and microscopy.
E. Ciliary function tests

E. Ciliary function tests

The correct answer is ciliary function tests. This would confirm a diagnosis of primary ciliary dyskinesia. Ciliary function is commonly tested by the use of saccharin. Saccharin is placed 1cm behind the inferior turbinate and the test is positive if the patient does not taste sweetness within 20min. This is because if cilia work normally they will sweep the sweet saccharin inwards, allowing the patient to taste it.

Cilia line the upper respiratory tract, including the eustachian tubes, and moves normally in a coordinated fashion to help clear mucous, secretions and debris. In ciliary dyskinesis there is less movement or it is less coordinated. For this patient there is first a clear history and signs of bronchiectasis with chronic productive cough, bilateral late inspiratory crepitations and clubbing. But the history of otitis media, young patient and indications dextrocardia are all suggestive of primary ciliary dyskinesis. Cystic fibrosis is less likely due to the absence of gastrointestinal symptoms and signs, there is no travel history, heamoptysis or other factors to suggest TB, and there is no history of asthma making fungal infection and immunological response unlikely.

Question 91 of 231

A 32-year-old woman is reviewed in the respiratory clinic. She was admitted some 6 weeks earlier with acute severe asthma which required a period of ventilation. She is already treated with maximum dose salmeterol / fluticasone combination inhaler, montelukast and low dose oral corticosteroids, and a decision is made to start her on omalizumab.

Which of the following reflects the mode of action of omalizumab?

A. Anti-IgE
B. Anti-TNF
C. Anti-IL6
D. Anti-IL13
E. Anti-IL22

A. Anti-IgE

Omalizumab is an anti-IgE monoclonal antibody recommended by NICE for patients with severe allergic asthma which is refractory to other treatments including multiple courses of oral corticosteroids per year. The manufacturer recommends that the drug is only used in patients who have a positive skin test to a recognised respiratory allergen.

Anti-TNF antibodies such as etanercept are used in the treatment of rheumatoid arthritis. Anti-IL6 antibodies such as tocilizumab are also used in the treatment of arthritis. Anti-IL13 and anti IL22 antibodies are both thought to target cytokines responsible for the development of asthma, and may play a role in combination therapy for the disease.

Question 92 of 231

A 51-year-old lady is admitted to the Medical Admissions Unit with a 2-week history of fever, breathlessness, lethargy and fatigue.

She has a history of poorly controlled asthma which has caused her to attend the Emergency Department five times over the past 2 years. She was reviewed by the respiratory team during her last admission and started on reducing dose oral prednisolone. However, she was unable to reduce her dose below 10mg per day due to recurrent breathlessness and wheeze.

She was reviewed again in the Respiratory Clinic 4 months ago and started on montelukast 10mg per day as a steroid-sparing therapy. Her prednisolone was subsequently reduced to 5mg per day and she reports that she had been well since then.

Her past medical history is otherwise remarkable for sinusitis and nasal polyposis. She has had several surgeries for the latter. Her current medications include Seretide 500/50 1 puff twice daily, montelukast 10mg once daily, prednisolone 5mg once daily and salbutamol via MDI as required. She is allergic to aspirin.

On examination, her temperature is 37.6ºC, her pulse is 98bpm and her blood pressure is 164/91mmHg. Her respiratory rate is 22/min and her oxygen saturations are 93% breathing room air. Her JVP is elevated at 5cm. Auscultation of the chest reveals diffuse polyphonic wheeze and bibasal crackles extending to the mid-zones. There is mild ankle oedema. Her abdomen is soft and non-tender.

Her initial investigations are as follows:

Hb	112 g/l	Na +	136 mmol/l
Platelets	215 * 10 /l 9	K +	5.9 mmol/l
WBC	14.2 * 10 /l 9	Urea	22.3 mmol/l
Neuts	8.4 * 10 /l 9	Creatinine	484 µmol/l
Lymphs	2.1 * 10 /l 9	CRP	107 mg/l
Eosin	3.4 * 10 /l9		
Urine dipstick	Blood +++ protein ++		

What would be the most likely finding on renal biopsy?

A. Mesangial hypercellularity
B. Pauci-immune crescentic glomerulonephritis

C. Podocyte fusion
D. Thickened capillary walls with subepithelial deposits
E. Diffuse proliferative glomerulonephritis

B. Pauci-immune crescentic glomerulonephritis

The patient has presented with worsening asthma, prominent peripheral blood eosinophilia, and acute kidney injury. This, in combination with the history of paranasal sinusitis, points towards a diagnosis of eosinophilic granulomatosis with polyangiitis (EGPA) or Churg-Strauss syndrome.

EGPA is a rare systemic necrotising vasculitis that affects small to medium-sized blood vessels. The natural history of the disease progresses through three distinct phases: a prodromal phase, characterised by asthma and paranasal sinusitis; an eosinophilic phase, with prominent peripheral blood eosinophilia and eosinophilic infiltration of various bodily tissues, and a final vasculitic phase. Vasculitic phenomena include skin rashes, peripheral neuropathy, and renal involvement; the latter is most commonly due to rapidly progressive glomerulonephritis (RPGN). RPGN is characterised histologically by the formation of epithelial crescents in the majority of glomeruli.

There is an association between the introduction of leukotriene receptor antagonists (LTRAs) and the onset of EGPA. The reason for this is unclear and various theories have been proposed. It has been suggested that some patients with difficult-to-control asthma may actually have a subclinical form of EGPA that is suppressed by repeated courses of corticosteroids. Instituting therapy with LTRAs allows tapering of corticosteroids and precipitates clinical disease.

The patient in the vignette may have had aspirin-sensitive asthma, in the which LTRAs have a prominent therapeutic role. There may also be a direct link between aspirin-sensitive asthma and EGPA.

Question 93 of 231

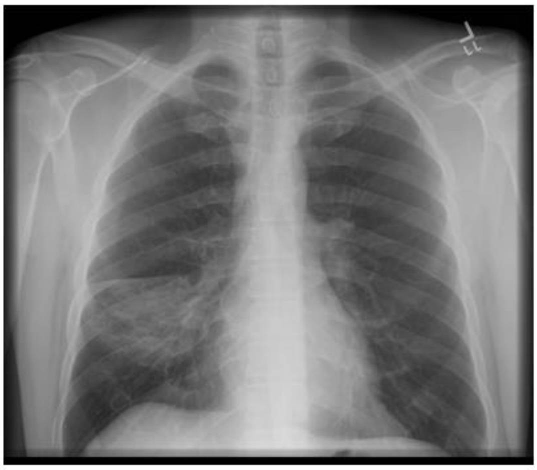
A 25-year-old man presents to the emergency department with a one-week history of cough, fever and shortness of breath. He has no past medical history and has never previously attended the hospital. He is orientated and responds to questioning appropriately. His respiratory rate is 14 breaths per minute, oxygen saturations are 98% on room air and his blood pressure is 115/65 mmHg.

He reports that he had a previous reaction to pivmecillinam aged 20, with the development of a widespread raised itchy rash.

Blood tests are taken with the following results:

Hb	123 g/L	(135-180)
Platelets	478 * 10 /L 9	(150 - 400)
WBC	17 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.5 mmol/L	(2.0 - 7.0)
Creatinine	85 µmol/L	(55 - 120)

A chest x-ray is taken, as shown below:



What is the most appropriate management for this patient?

A. Admit for IV amoxicillin and clarithromycin
B. Admit for IV co-trimoxazole
C. Admit for respiratory review
D. Discharge with oral doxycycline
E. Discharge with oral doxycycline and clarithromycin

D. Discharge with oral doxycycline

The chest x-ray shows an area of dense consolidation in the right mid-zone, typical of pneumonia, which is community-acquired in this case. The patient scores 0 on the CURB-65 score, which means that he is in a low-risk group with a 0.6% 30-day mortality, and can be managed as an outpatient with oral antibiotics given that there are no other concerning features.

The patient has had a previous urticarial reaction to pivmecillinam (which is a type of penicillin usually given for urinary tract infections), suggesting he is likely to have a type 1 allergic reaction to penicillin, and should not receive penicillin in the future.

Discharge with oral doxycycline is correct. NICE recommends that patients with penicillin allergies should be treated with either a macrolide (clarithromycin or azithromycin) or doxycycline.

Admit for IV amoxicillin and clarithromycin is incorrect. A patient might be admitted if they scored 2 or more on the CURB-65 score, or if there were other features giving cause for concern, which is not the case in this scenario. The patient should also not be given amoxicillin, which is a type of penicillin.

Admit for IV co-trimoxazole is incorrect. This antibiotic choice would be safe for this patient as it is not penicillin based but, as above, the patient does not require hospital admission. Cotrimoxazole is sometimes used for hospital-acquired pneumonia as it has a broader spectrum of activity but is not routinely used for community-acquired pneumonia.

Admit for respiratory review is incorrect. Although there is a significant area of consolidation on the chest x-ray, the patient is not compromised and does not require specialist respiratory input at this point. He would require a follow-up chest x-ray at 4-6 weeks to ensure that the consolidation has resolved.

Discharge with oral doxycycline and clarithromycin is incorrect. It would be reasonable to give the patient doxycycline alone, as per NICE guidelines for patients with penicillin allergies.

Clarithromycin is often added to provide cover for atypical organisms, such as *Legionella pneumophila* and *Mycoplasma pneumoniae* which are not treated by penicillin-based antibiotics. However, NICE recommends that atypical cover should only be prescribed for patients with moderate or severe community-acquired pneumonia, so it is not required in this patient.

Question 94 of 231

You are the admitting medical registrar and receive the following referral from your emergency department colleague.

A 30-year-old woman with asthma has presented with three days of increasing wheeze, dyspnea, productive cough and fevers. You are informed there is a leukocytosis and consolidation on the chest x-ray. The emergency department team have commenced antibiotics and referred for inpatient admission.

You obtain a further history. This patient was diagnosed with asthma in childhood but as an adult, she rarely required any use of her salbutamol inhaler and did not require follow up with a respiratory physician or general practitioner. However, over the last 18 months, she has been experiencing increasing wheezing and cough. Initially, this was a dry cough but has now become productive of brown sputum. There is no history of haemoptysis. This has been associated with malaise and weight loss. She was admitted to hospital with an asthma exacerbation two weeks ago and was discharged on a short course of prednisolone and started on a salmeterol-fluticasone combination inhaler. Following discharge, she initially felt improved but feels her symptoms have returned over the last few days. She denies missing any doses of her inhaled medication and uses a spacer. There is no history of chest pain or travel. She is a lifelong non-smoker and works full time as a computer programmer.

Past medical history includes allergic rhinitis, eczema and endometriosis.

Examination revealed a thin woman, with respiratory rate of 22/min, oxygen saturation 95% on air, blood pressure 100/60 mmHg, heart 90/min and temperature of 37.8ºC. There was diffuse expiratory wheeze and reduced breath sounds in the right upper zone of the anterior chest. Heart sounds were dual with no murmurs. The jugular venous pressure was not elevated. There was palpable cervical lymphadenopathy and no clubbing. Calves were soft, non-tender and there was no pedal oedema.

Hb	140 g/l	Na +	138 mmol/l
Platelets	380 * 10 /1 9	K +	3.6 mmol/l
WBC	11 * 10 /1 9	Urea	5 mmol/l
Neuts	9 * 10 /1 9	Creatinine	70 µmol/l
Lymphs	1 * 10 /1 9	CRP	20 mg/l
Eosin	1 * 10 /l9		

A chest x-ray shows a homogeneous triangular shaped opacity extending from the mediastinum towards the right upper zone.

Which of the following are you most likely to find this patient?

A. Elevated serum IgE levels
B. Upper lobe bronchiectasis on high resolution computed tomography of the thorax
C. A positive urinary Streptococcus pneumoniae antigen
D. Sputum analysis staining positive for acid-fast bacilli
E. No change in symptoms with a repeat course of prednisolone

A. Elevated serum IgE levels

Consider allergic bronchopulmonary aspergillosis in asthma patients who have developed difficult to control symptoms and/or have become dependent on oral steroids

This patient has allergic bronchopulmonary Aspergillosis (ABPA) as evidenced by the development of inadequately controlled asthma, cough productive of brown sputum, malaise, weight loss and a homogeneous opacity on chest x-ray. Typically there is a serum eosinophilia but given the recent course of prednisolone, the eosinophil count may still be suppressed.

ABPA is a chronic hypersensitivity reaction that occurs in response to colonization of the lower airways with Aspergillus species. It occurs most commonly in patients with atopic asthma or cystic fibrosis (CF). The resulting inflammation can lead to the destruction of pulmonary parenchyma and bronchiectasis.

A diagnosis of ABPA is supported by:

- Symptoms as described above
- Serum eosinophilia in steroid naÃ¯ve patients and/or no history of recent steroid use
- Elevated total serum IgE level (>1000 iU/ml), positive serum Aspergillus precipitins (IgM, IgG and IgE antibodies to Aspergillus species)
- Sputum showing elevated eosinophil count and/or fungal mycelia with healthy cytoplasm (cf. dead mycelia devoid of cytoplasm seen in patients with Aspergilloma)
- Immediate skin test reactivity to Aspergillus antigens
- A massive homogeneous shadow without fissure displacement is the most common abnormality seen on a chest radiograph with ABPA
- The bronchiectasis seen in ABPA is typically central

Management is usually with prednisolone +/- azole class antifungals (e.g. Itra or Voriconazole)

Option A - the correct answer

Option B - central bronchiectasis is typically seen, rather than lobe specific

Option C - community acquired pneumonia is a valid differential but the history and investigations are in favour of ABPA. If there was a pneumonic process that has such a dense consolidation to give homogeneous opacity on chest x-ray, you would expect worse hypoxia and respiratory distress as seen in this patient.

Option D - *Mycobacterium tuberculosis* infection is unlikely given the absence of risk factors and the history/investigations makes the pre-test probability of ABPA much higher than

Mycobacterium tuberculosis

Option E - prednisolone is the first line treatment for ABPA and patients may require multiple and/or prolonged courses. Azole anti-fungal therapy may also be added in order to decrease steroid burden and/or if there is a poor response to corticosteroid therapy.

Question 95 of 231

A 67-year-old gentleman presents with a three-day history of a productive cough. He complains that over the last two days he has been progressively more short of breath, He complains of feeling very weak and lethargic and on further questioning reports fevers and rigors. His wife brought him to the emergency department as she was concerned as he appeared to be deteriorating rapidly.

Observations are: heart rate 125 beats per minute, respiratory rate 32 breaths per minute, S 0 90% on room air, temperature 38.9º, blood pressure is 130/84 mmHg.

He appears distressed but is not confused. Initial investigations show:

Hb	134 g/l
Platelets	550 * 10 /l9
WBC	18 * 10 /l9
Na +	141 mmol/l
K +	3.7 mmol/l
Urea	9.2 mmol/l
Creatinine	130 µmol/l

Chest x-ray shows left lower zone consolidation.

From the above information, what is his CURB-65 score?

A. 1
B. 2
C. 3
D. 4
E. 5

C. 3

This patient has a community-acquired pneumonia which is a common presentation on the acute medical take (Incidence: 5-11/1000). Patients typically present with a productive cough, fevers, shortness of breath, anorexia, rigors and may report pleuritic chest pain and haemoptysis. Community-acquired pneumonia may be primary or secondary to underlying disease.

Question 96 of 231

A 49-year-old woman presents with a one-year history of joint pain and an intermittent purpuric rash. For the last 3 months, she feels more fatigued than usual with malaise, fever and intermittent abdominal pain. She had an appendectomy 10 years ago. Besides that, there is no past medical history of significance.

On clinical examination, the only abnormality is a purpuric rash involving her calves and thighs.

The results of initial investigations showed a normal full blood count, but impaired renal function with a plasma creatinine of 160 µmol/l.

Another set of investigations were ordered to reach a diagnosis:

Na+	135 mmol/l
K+	4 mmol/l
Creatinine	165 µmol/l
Urea	11 mmol/l
CRP	50 mg/l
ESR	70 mm/hr
Urine analysis	Protein +,RBCs ++
Rheumatoid factor	negative
C3 and C4 levels	normal
cANCA	positive
pANCA	positive
ANA	negative

Renal biopsy showed focal necrosis, crescent formation, and absence of immunoglobulin deposits on immunofluorescence.

What is the most likely diagnosis?

A. Rheumatoid vasculitis
B. Mixed cryoglobulinaemia
C. Wegener's granulomatosis (WG)
D. Microscopic polyangiitis (MPA)
E. Systemic lupus erythematosus (SLE)

D. Microscopic polyangiitis (MPA)

MPA is a systemic vasculitis affecting the small vessels including arterioles, capillaries, and venules. It usually presents with a long history of constitutional symptoms with multisystem involvement. Note that cANCA and pANCA could be useful in differentiating WG from MPA but not always.

SLE would be unlikely with a negative ANA, and pauci-immune glomerulonephritis.

WG is unlikely with the absence of upper and lower airway involvement. Also, the absence of granuloma formation in the kidneys would not favour it.

Usually, rheumatoid vasculitis would be clinically apparent because it develops on a background of severe rheumatoid disease. Also, the rheumatoid factor would be very high, with low C3 and C4.

Mixed cryoglobulinaemia characteristically would have a positive rheumatoid factor. Glomerulonephritis has distinctive features, being characterized by marked deposition of immunoglobulin and complement. C4 would be markedly low in 90% of patients due to classical pathway activation by cryoglobulins. This is in contrast to MPA where the complement levels would be normal or even elevated as an acute phase response.

Question 97 of 231

A 40-year-old man attends the emergency department with a 3-day history of worsening respiratory symptoms. The patient reported that his initial symptoms had included a runny nose, sore throat and myalgia. Subsequently, he developed a persistent dry cough and had experienced mild shortness of breath on exertion, for example after climbing a flight of stairs. The patient had not measured his temperature at home but recalled that, at times, he had felt extremely hot and sweaty. The patient denied any other symptoms, including a cough productive of sputum or blood, abdominal symptoms or chest pain.

The patient reported having just returned from a 2 week holiday in Egypt. The majority of the patient's trip had been based in large towns and cities; however, the patient had also participated in a 4-day 'camel trek' through the desert. On direct questioning, the patient reported having drunk camel milk offered to him by his guides, which he did not think had been pasteurised or otherwise processed prior to consumption. The patient had not knowingly spent time around any unwell individuals and had not sought medical advice while overseas. Prior to this holiday, the patient had not travelled outside of the UK for several years.

The patient was in generally good health, with no active chronic medical problems. The patient's only previous attendance at the emergency department was 5 years previously when he had treated for a broken ankle sustained when playing football. The patient took no regular medications and had no known allergies to medications. The patient did not regularly consume alcohol or recreational drugs but did smoke 5-10 cigarettes per day.

General examination of the patient showed a middle-aged man who appeared flushed in the face and unwell. Examination of the respiratory system demonstrated normal air entry and resonance to both lung fields, with no significant added sounds on auscultation. With the patient at rest, there were no signs of respiratory distress. Examination of the cardiovascular and abdominal systems demonstrated no significant abnormality. There was no notable rashes and no signs of peripheral deep vein thrombosis.

Heart rate	92 beats / minute
Respiratory rate	18 respirations / minute
Blood pressure	125 / 76 mmHg
Oxygen saturations	95 %
Glasgow coma scale score	15
Temperature	38.2 Co

Haemoglobin	135 g / dL
White cell count	3.7 x 10>3 / microlitre
Neutrophils	2.5 x 10>3 / microlitre (reference 1.8-7.8)
Lymphocytes	1.0 x 10>3 / microlitre (reference 1.5-4.0)
Platelets	123 x 10>3 / microlitre
Urea	6.1 mmol / L
Creatinine	82 micromol / L
Alkaline phosphatase	154 U / L (reference 35-100)
ALT	72 U / L (reference 3-36)
Bilirubin	23 micromol / L (reference < 26)
Chest x-ray	clear lung fields, no pneumothorax

What is the likely pathogen responsible for the patient's illness?

A. MERS coronavirus
B. Dengue virus
C. West Nile virus
D. Junin virus
E. Ebola virus

A. MERS coronavirus

The patient's presentation is consistent with Middle East respiratory syndrome (MERS), caused by the betacoronavirus MERS-CoV. Dromedary camels are the primary animal host for MERS-CoV, with human transmission occurring secondary to close contact with camels, or the consumption of unpasteurised camel milk or undercooked camel meat. However, human-to-human transition via respiratory droplets is responsible for the majority of cases of MERS, particularly in the healthcare setting. At the present time, MERS-CoV is limited to the Arabian Peninsula and its surrounding countries, although due to an incubation period of 2-14 days travellers returning from this region may present with MERS in other parts of the world.

The clinical syndrome of MERS is varied, ranging from very only mild symptoms through to lifethreatening multi-organ failure. The patient in the question has typical blood results for MERS, including lymphocytopenia, thrombocytopenia and deranged liver function tests. The diagnosis of MERS can be confirmed by reverse transcriptase polymerase chain reaction analysis of respiratory tract secretions to identify MERS-CoV RNA. No specific treatment for MERS-CoV infection is available. Individuals developing significant complications (or those at high-risk of doing so) require admission to hospital for supportive care.

The pathogens included as incorrect answers to the question either are not endemic in the region the patient had travelled or have clinical presentations dissimilar to that described in the question.

Question 98 of 231

A 73-year-old is referred to the pulmonary hypertension team after undergoing an echocardiogram. She had initially been admitted after a 4-day history of exertional dyspnoea. A chest x-ray revealed bilateral pulmonary oedema. She demonstrated acute ischaemic changes on her ECG. Her past medical history includes type 2 diabetes mellitus, hypertension, hypercholesterolaemia and a previous NSTEMI in 2010. An echocardiogram demonstrated moderate to severe LV dysfunction, with a pulmonary arterial pressure of 83 mmHg (normal <25 mmHg).

What is the most appropriate next diagnostic investigation?

A. No further investigations for pulmonary hypertension
B. V/Q scan
C. CTPA
D. Right and left heart catheterisation
E. Lung function tests

A. No further investigations for pulmonary hypertension

Pulmonary hypertension is divided according to the World Health Organisation (WHO) into five classes based on aetiology:

- I pulmonary arterial hypertension
- II pulmonary hypertension secondary to left heart disease
- III pulmonary hypertension secondary to lung disease
- IV pulmonary hypertension secondary to chronic thromboembolic disease
- V pulmonary hypertension with unclear causes

This patient has sufficient left-sided heart disease to explain her pulmonary hypertension and is hence a group 2 pulmonary hypertension patient. No further investigations are required. Treatment of pulmonary hypertension, in this case, is dependent on optimising left ventricular failure.

Question 99 of 231

A 67-year-old female patient presents to respiratory outpatients having been referred by her GP with increasing breathlessness. The referral letter mentions she has received 2 courses of antibiotics for chest infections in the last year and a 50 pack year smoking history. The patient complains of a productive cough with occasional streaks of blood but no history of weight loss. Her past medical history includes cardiac failure treated with enalapril, bisoprolol and furosemide, recurrent urinary tract infections treated with long-term nitrofurantoin and osteoarthritis treated with paracetamol and meptazinol. On examination, there is bilateral scattered coarse crepitations and finger clubbing.

Spirometry in clinic is as follows:

Forced vital capacity (FVC)	1.99L (72% predicted)
Forced expiratory volume in 1 second (FEV1)	1.20L (52% predicted)
FEV1/FVC ratio	0.60

What is the likely diagnosis?

A. Bronchiectasis
B. Chronic obstructive pulmonary disease
C. Pulmonary fibrosis
D. Squamous cell carcinoma
E. Congestive cardiac failure

A. Bronchiectasis

The spirometry results suggest an obstructive lung disease as FEV1/FVC ratio is < 0.7.

This patient is likely to have bronchiectasis given the obstructive spirometry, productive cough, coarse crepitations and history of recurrent chest infections.

Suspicion of pulmonary fibrosis is raised by long-term nitrofurantoin use but the history, examination and spirometry findings do not fit this diagnosis. Congestive cardiac failure may cause bilateral crepitations but does not cause finger clubbing. A malignant diagnosis is less likely given the absence of weight loss and bilateral signs. One would expect to find wheeze to support a diagnosis of chronic obstructive pulmonary disease.

Question 100 of 231

A 30-year-old man presents to the Emergency Department with severe shortness of breath, cough and ongoing weight loss. He has a past medical history of asthma and nasal polyps.

He has seen his general practitioner (GP) 3 times in the last 6 months for chest infections and been given antibiotics.

Given the likely underlying diagnosis, what would you expect to see on his blood results?

A. Low lymphocyte count
B. Iron deficiency anaemia
C. Raised neutrophil count
D. Raised eosinophil count
E. Low platelet count

D. Raised eosinophil count

Churg-Strauss syndrome - eosinophilia

Although a raised neutrophil count is a potential here, a raised eosinophil count is classical of Churg-Strauss, and is required for diagnosis. Nasal involvement is more commonly associated with Wegener's granulomatosis, but it is also seen in a variety of other vasculitides.

Churg-Strauss syndrome (also known as eosinophilic granulomatosis with polyangiitis) is a vasculitis that affects small and medium-sized blood vessels.

It is commonly seen in patients with a history of atopy. It is often described to occur in three stages - the allergic 'prodromal' stage, the eosinophilic stage and the final vasculitic stage.

The mainstay of treatment includes steroids and other immunosuppressant drugs.

Question 1 of 133

A 22-year-old man presents to the emergency department with a worsening cough and shortness of breath over the past few days. He has no significant past medical history except for a known allergy to wasp stings and is not on any regular medication. Although he does not smoke himself, he works in an environment where others are often smoking around him.

On examination, he looks to be in respiratory distress, with tachypnoea, tachycardia and low-grade pyrexia. Peripheral oxygen saturations are 87% on air. Blood tests are performed:

Hb	112 g/L	Male: (135-180)Female: (115 - 160)
Platelets	185 * 10 /L 9	(150 - 400)
WBC	13.3 * 10 /L (22% eosinophils) 9	(4.0 - 11.0)
Urea	6.9 mmol/L	(2.0 - 7.0)
Creatinine	87 µmol/L	(55 - 120)

A chest X-ray is also performed, which demonstrates patchy mixed alveolar-interstitial infiltrates. The medical team are asked to review the patient and a bronchoalveolar lavage is conducted which demonstrates no signs of infection, but 56% eosinophils.

Given the likely diagnosis, which intervention is most appropriate initially?

A. Albendazole
B. Cyclophosphamide
C. Itraconazole
D. Methylprednisolone
E. Plasma exchange

D. Methylprednisolone

Acute eosinophilic pneumonia is highly responsive to steroids

The diagnosis here is the rare condition acute eosinophilic pneumonia. It is one of several conditions that cause pulmonary eosinophilia and is characterised by a cough, shortness of breath and sometimes a history of allergy. Being a smoker, or being exposed to second-hand smoke, is also thought to be a trigger. The key to diagnosis here is the patient's chest x-ray demonstrating patchy infiltrates, but crucially the bronchiolar lavage which shows a high eosinophil count. This condition is highly responsive to steroids and so methylprednisolone is the correct answer.

Albendazole is an antiparasitic medication. This may be indicated in Loeffler's syndrome - chest xray shadowing and blood eosinophilia sometimes due to parasites such as *Strongyloides stercoralis*. The history would have included more focus on a fever and night sweats, and parasites would have been identified during diagnosis.

Cyclophosphamide is an immunosuppressant, used in the management of cancers and autoimmune conditions. This would be indicated if the diagnosis were a rheumatological condition such as eosinophilic granulomatosis with polyangiitis. Similar features would be seen, but a history of asthma would be noted, as well as renal failure; this patient's renal function bloods were normal.

Itraconazole is an antifungal medication and may be used in the management of a differential, allergic bronchopulmonary aspergillosis (ABPA), characterised by asthma-like symptoms that do not respond to initial treatment. Eosinophilia is also seen, but a positive radioallergosorbent (RAST) test to *Aspergillus* should be demonstrated, which is not seen here. Oral steroids are actually used first-line, with itraconazole sometimes being used as an adjunct.

Plasma exchange does not play a role here. It may be used in the management of severe granulomatosis with polyangiitis, as well as a number of other conditions.

Question 2 of 133

A 62-year-old gentleman comes to the respiratory clinic for review. He was seen by his GP after presenting with pleuritic chest pain and slight breathlessness. The GP was concerned and arranged for a chest X-ray which shows pleural plaques and a slight right-sided pleural effusion. He has a past medical history of type 2 diabetes, hypertension and angina. He takes ramipril, amlodipine, metformin and has a GTN spray for when he needs it. He worked as a plumber over 30 years ago. On examination he has clubbing and slightly reduced air entry in the right base of his lungs, with some dullness on percussion. A diagnosis of asbestosis is suspected.

What feature of his history or examination is evidence towards poor prognosis?

A. Comorbidity with ischaemic heart disease
B. Shortness of breath
C. Pleuritic pain
D. Clubbing
E. Male sex

D. Clubbing

The correct answer is clubbing. This is a patient who presents with pleuritic chest pain and shortness of breath with a history of possible asbestos exposure (plumbing). These are common findings on diagnosis and are not associated with a difference in prognosis. Clubbing, however, has been shown to be a poor prognostic indicator as it has been associated with progression to mesothelioma.

Question 3 of 133

A 24-year-old woman attends the respiratory clinic for a review of her asthma treatment. The patient reported that overall, her symptoms of asthma had been well controlled in the 6 months since her last review. She had not suffered any significant exacerbations of her asthma in that time and felt she was required to use her salbutamol inhaler only around once per week (which represented a significant improvement over her normal control). The patient also reported that she was now 3 months pregnant, and had just had an unremarkable 12-week ultrasound. While she had not been planning to have a baby, the patient reported being very happy about it, and she was keen to maximise her health during this time.

The patient had a long-standing diagnosis of asthma, with her first presentations during early childhood. While the illness had only caused mild symptoms between the ages of 10 and 15 years, the patient had suffered several severe exacerbations of asthma in her late teenage years, coinciding with the time when the patient had become a regular smoker. The patient did not report any other significant on-going health problems or past medical history. In particular, she denied a history of seizures, high blood pressure or mental health problems.

The patient's current asthma treatment was a salmeterol-fluticasone combination inhaler (Seretide Accuhaler 250), one puff twice daily. She was also prescribed a metered-dose salbutamol inhaler for use as required. The patient had no history of drug allergies.

The patient reported that she continued to be a regular cigarette smoker. Since finding out she was pregnant, she had managed to reduce her regular intake to 12 cigarettes per day, reduced from her previous typical intake of 20 cigarettes per day. The patient was motivated to use her pregnancy as a motivating factor to stop smoking permanently, and during the clinic asked about medication to assist her with quitting.

What is the appropriate drug treatment strategy to assist this patient to stop smoking?

A. Nicotine replacement patch with short-acting nicotine replacement
B. Varenicline
C. No drug treatment options available
D. Bupropion
E. Nicotine replacement patch only

A. Nicotine replacement patch with short-acting nicotine replacement

The patient is motivated to stop smoking and this can be expected to have significant benefits, both for her own long-term health and for the health of her unborn fetus. The best drug treatment option available to her in pregnancy is combination nicotine replacement therapy, consisting of a long-acting nicotine replacement patch with a short-acting nicotine formulation (either oral or nasal spray) to help manage acute cravings. When used in individuals attempting to quit smoking, combination nicotine therapy has an absolute abstinence rate of 32 %, compared to 25 % for noncombination nicotine replacement.

Nicotine replacement therapy can be prescribed in pregnancy as systematic reviews do not show significant differences in serious adverse events between treatment and control groups in pregnancy. It is also clearly safer than tobacco smoke, which contains many toxins. The expert recommendation is for use of 16-hour nicotine patches in pregnancy, rather than 24-hour patches, to reduce unnecessary exposure to nicotine.

Varenicline is an oral nicotinic receptor partial agonist that binds less effectively than nicotine. The most significant unwanted effects of

varenicline are nausea and a possible increased risk of suicidal thoughts, especially in individuals with mental health problems. Bupropion is an oral nicotinic receptor antagonist with dopaminergic and adrenergic actions. It is contraindicated in individuals with a history of seizures. The absolute abstinence rates of varenicline and bupropion are 34 % and 25 % respectively. Unwanted effects include increased blood pressure and psychological effects. The safety of both varenicline and bupropion in pregnancy is unknown; therefore, the use of these medications in pregnancy should be avoided.

Question 4 of 133

A 45-year-old male with long standing asthma presents to his specialist doctor complaining of recurrent chest infections over the last year. He has a productive cough most mornings of thick, brownish sputum for most days of the last year and he feels it is getting worse. He has been to his general practitioner on a number of occasions and been treated with oral antibiotics and steroids but with no significant impact on symptoms. His general practitioner has also stepped up his asthma treatment to regular use of a long-acting beta-2 adrenergic agonist and an inhaled steroid, which he feels may have made a slight difference. He denies any fevers or night sweats but has lost approximately two kilograms in weight over the last year. He was diagnosed with asthma as a teenager, takes his inhalers regularly and has never had any hospital admissions. He has no other medical conditions and takes no other medications other than over the counter vitamin supplements. He drinks a moderate amount of alcohol and does not smoke. He works as an economist and travels regularly to the middle east and china.

On examination, he is comfortable at rest. His respiratory rate is 16 breaths/min, his oxygen saturation 95% breathing room air and his chest is clear to auscultation. His heart rate is 65 beats/min and his heart sounds are normal. There is no palpable lymphadenopathy in the axillae or groin.

What is the most likely diagnosis?

A. Cystic fibrosis
B. Allergic broncho-pulmonary aspergillosis
C. Tuberculosis
D. Lung cancer
E. Pseudomonas infection

B. Allergic broncho-pulmonary aspergillosis

This man's symptoms are suggestive of the development of bronchiectasis - thick sputum over a long period of time. There are many causes of bronchiectasis, most of which are unlikely in this case. The lack of risk factors or constitutional symptoms makes tuberculosis less likely. The worsening in asthma control (he has had to step up on his treatment) raises the possibility of ABPA (allergic bronchopulmonary aspergillosis), a diagnosis not often found in non-asthmatics. Investigation is with chest imaging and serum aspergillus precipitins levels. Treatment is with steroids and antifungals.

Question 5 of 133

A 53 year-old businessman presents to the neurology clinic complaining of weakness and numbness affecting his left hand. One month ago he was irritated when he noticed that the little finger of his left hand was often getting caught when he tried to put his hand in his pocket. Since then he has noticed progressive difficulty using the left hand, associated with an unpleasant tingling sensation.

In the last two weeks he has also noticed difficulty walking, and has tripped over on several occasions. When driving he finds that his right foot often becomes stuck behind the accelerator pedal and he struggles to lift it out.

On examination, in the left hand sensation to pin-prick is diminished over the little finger and medial side of the ring finger, as well as the medial side of the palm. There is weakness of finger abduction and adduction, but thumb abduction is normal. On examination of the legs, you note diminished sensation over the lateral aspect of the right calf, as well as the dorsum of the right foot. When asked to walk on his heels, he finds it difficult to do so, and trips over the right foot.

Investigations are as follows:

Haemoglobin	14.2 g/dl
WCC	7.1 x10^9/l
Platelets	420 x10^9/l
ESR	65 mm/hr
Na +	139 mmol/l
K +	4.3 mmol/l
Urea	13.2 mmol/l
Creatinine	171 µmol/l
Corrected calcium	2.26 mmol/l
ANCA	Positive, with perinuclear staining pattern
PR3 antibodies	Negative
MPO antibodies	Positive
Urine dipstick	+++ blood, +++ protein

Urine microscopy	Red cell casts
Chest radiograph	Clear

What is the most likely diagnosis?

A. Microscopic polyangiitis
B. Polyarteritis nodosa
C. Wegener's granulomatosis
D. Diabetes mellitus
E. Entrapment neuropathy

A. Microscopic polyangiitis

This is mononeuritis multiplex with ulnar and common peroneal neuropathy. The causes of mononeuritis multiplex include vasculitis, diabetes, AIDS, amyloidosis, and rheumatoid arthritis.

The elevated urea and creatinine, haematuria with red cell casts, and proteinuria, all suggest glomerulonephritis. The combination of mononeuritis multiplex with glomerulonephritis strongly suggests systemic vasculitis. This is supported by the raised ESR.

Microscopic polyangiitis is a small-vessel vasculitis which is typically positive for p-ANCA, with antibodies against MPO (myeloperoxidase). Other features may include systemic symptoms such as fever, weight loss, and fatigue, as well as rash.

ANCA is negative in classic polyarteritis nodosa.

Wegeners granulomatosis often features upper airway disease, and is typically positive for cANCA, with antibodies against PR3.

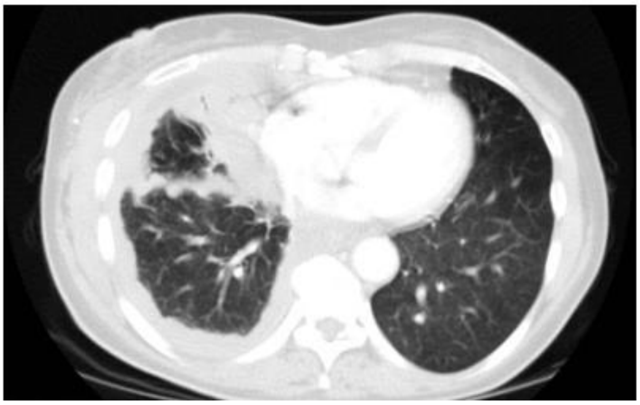
Diabetes mellitus is a common cause of many peripheral neuropathies including mononeuritis multiplex, however there is nothing in the history to suggest this. Haematuria and red cell casts are not a typical feature of diabetic nephropathy, and neither is ANCA positivity.

Entrapment is a common cause of both ulnar and common peroneal neuropathy, but for both to occur simultaneously would be unusual.

Question 6 of 133

A 75-year-old retired electrician presents with a 3-month history of progressive exertional dyspnoea, with associated chest pain. The chest pain is right-sided and is not worse on deep inspiration. He also describes intermittent haemoptysis and has noted 7kg of weight loss since the chest pain started.

A CT scan of his thorax is carried out, the images for which are given below:



What is the most likely cause of this imaging appearance?

A. Large cell carcinoma
B. Mesothelioma
C. Sarcoidosis
D. Small cell lung cancer
E. Tuberculosis

B. Mesothelioma

The CT shows concentric, nodular, pleural thickening. There also appears to be interlobular fissure pleural involvement. Pleural thickening can be due to a number of causes, one of which is **mesothelioma**. Other causes include pleural metastases, pleural lymphoma, chronic inflammation following empyema or recurrent pneumonia, and asbestos or silicosis-related lung disease. Pleural thickening can be differentiated from the appearance of a pleural effusion which is usually gravity dependent and crescent shaped.]

Mesothelioma is a cancer of the mesothelial layer of the pleural cavity that is strongly associated with asbestos exposure, which may have occurred due to this man's previous occupation as an electrician.

Small cell lung cancer is typically seen as a solid nodule within the lung, often located centrally in the hilar or peri-hilar region. They readily metastasise but do not generally involve the pleura.

Large cell lung carcinoma would usually manifest as a large peripheral mass of solid attenuation and irregular margin. There is not usually pleural involvement.

Sarcoidosis may show peri-lymphatic nodular thickening primarily affecting the upper/mid zones, ground glass opacities, cysts, or evidence of pulmonary fibrosis. It would not cause pleural thickening.

CT findings in pulmonary **tuberculosis** often show similar patterns of disease as seen with chest xrays, which would include fibronodular opacities in upper lobes with or without cavitation. Tuberculosis can involve the pleura but would present with a pleural effusion rather than pleural thickening as seen here.

Question 7 of 133

A 43-year-old Afro-Caribbean male presents with sudden onset palpitations and feeling generally unwell for 2 hours. An admission ECG in the emergency department demonstrates ventricular tachycardia. His heart rate is 80 beats/ minute with a blood pressure of 140/75mmHg. The patient is chemically cardioverted back to sinus rhythm with a single intravenous bolus of amiodarone. The patient was commenced on haemodialysis 9 months ago after developing end-stage renal failure over a course of 16 months with no conclusive underlying cause found for the deteriorating renal function. He also complains of a new dry cough over the past 18 months, weight loss of at least one and a half stone and general malaise, which he attributes to his deteriorating kidneys.

On examination, the patient has normal heart sounds with no additional murmurs. Auscultation of his chest demonstrates biapical find inspiratory crackles with no wheeze. Abdominal examination reveals a mild 2cm hepatomegaly with no splenomegaly. An arteriovenous fistula is noted in the left brachiocephalic region. No skin rashes are noted. An admission chest X-ray demonstrates no clear consolidation, reticular opacities in both apices and prominent bilateral hilar, with no cardiomegaly or tramlining.

Blood tests are as follows:

Hb	134 g/l
Platelets	292 * 10 /l9
WBC	12.5 * 10 /l9
Na +	131 mmol/l
K +	5.9 mmol/l
Urea	22.6 mmol/l
Creatinine	540 µmol/l
Bilirubin	17 µmol/l
ALP	55 u/l
ALT	70 u/l
CRP	12 mg/l
ACE (angiotensin converting enzyme)	negative

Pulmonary function tests: FVC 60% predicted FEV1 92% predicted

A bronchoalveolar lavage is performed, demonstrating lymphocytosis of 25%, CD4:CD8 ratio of 5:1, a transbronchial biopsy demonstrates non-caseating granulomas.

What is the underlying diagnosis?

A. Human immunodeficiency virus (HIV)
B. Miliary tuberculosis

C. Amyloidosis
D. Sarcoidosis
E. Lymphoma

D. Sarcoidosis

The patient has presented with multi-system disease with renal, cardiac, hepatic manifestations. In addition, the bihilar changes with apical interstitial changes, lymphocytosis, increased CD4:CD8 ratio and non-caseating granulomas on histopathology are strongly suggestive of sarcoidosis. A negative ACE is present in 25% of all patients with sarcoidosis, it has a poor negative predictive value. The most diagnostic test in differentiating against other multisystem disorders is histopathology in this case: Tb would produce caseating granulomas, lymphomas atypical lymphocytes and amyloid crossed beta sheets.

Question 8 of 133

A 78-year-old man presents to the acute medical unit with severe back pain. He described the pain as sudden onset sharp pain which reached maximum severity within seconds.

Investigation results are as follows:

Chest x-ray	Blunting of the left costophrenic angle
Pleural sample	Bloody in appearance

What is the most useful pleural fluid marker to make a diagnosis of a haemothorax?

A. pH
B. Lactate
C. Haematocrit
D. Lactate dehydrogenase
E. Triglyceride

C. Haematocrit

If the pleural fluid appears bloody, a haematocrit can be obtained if there is doubt as to whether it is a haemothorax. If the haematocrit of the pleural fluid is more than half of the patient's peripheral blood haematocrit, the patient has a haemothorax

The clinical features are suggestive of an aortic dissection which is a well known cause of a haemothorax. If the pleural fluid appears bloody, a haematocrit can be obtained if there is doubt as to whether it is a haemothorax. If the haematocrit of the pleural fluid is more than half of the patient's peripheral blood haematocrit, the patient has a haemothorax.

Question 9 of 133

A 72-year-old man presented with shortness of breath and haemoptysis. His past medical history includes polymyalgia rheumatica and Paget's disease. He is very fit and active and is independent of activities of daily living. He drives and does his own shopping, and attends the gym twice a week alongside tai chi lessons.

A chest x-ray revealed a left-sided mass.

CT thorax, abdomen, pelvis: There is a 4cm solid mass left-sided left upper lobe lung mass causing airway compression and partial lobe collapse. There is no evidence of distant metastases.

A biopsy of the lesion confirms adenocarcinoma.

What would be the most appropriate management option for this patient?

A. Chemotherapy
B. Complete resection with lobectomy and adjuvant chemotherapy
C. Complete resection with lobectomy and adjuvant radiotherapy
D. Pneumonectomy with adjuvant chemo-radiotherapy
E. Radiotherapy

C. Complete resection with lobectomy and adjuvant radiotherapy

Patients with stage I or II non-small cell lung cancer should be offered surgical resection if they are fit for surgery

Complete resection with lobectomy and adjuvant chemotherapy is the correct answer. This patient has stage II lung cancer (i.e. it is between 4-5cm, there is no distant spread, but there is blockage of the airway causing partial lobe collapse). All patients with stage I or II lung cancers should be offered surgical resection and adjuvant chemotherapy. This is done with curative intent.

Complete resection with lobectomy and adjuvant radiotherapy is incorrect. Radiotherapy can be offered as a sole treatment for patients with stage I or II NSLC who are not fit for surgery, and this is offered with curative intent. It is generally not used as an adjuvant treatment alongside surgical resection unless the resection is incomplete.

Pneumonectomy with adjuvant chemo-radiotherapy is incorrect. A pneumonectomy would not be the best option here as the mass is confined to the left upper lobe, a lobectomy would be preferable to preserve as much lung tissue as possible for the patient.

Radiotherapy is incorrect. This could be offered with curative intent if the patient was not fit for surgery, but here we have an active and well patient who should be given the opportunity to discuss surgical resection.

Chemotherapy is incorrect. Chemotherapy could be offered to patients with stage III or IV disease. Our patient here has stage II disease and so should be offered surgery. Stage III disease may include spread to mediastinal lymph nodes, spread to another lobe in the same lung, and invasion of the oesophagus, aorta, and mediastinum, for example.

Question 10 of 133

A 52-year-old man presents to the emergency department with shortness of breath. This started recently following a flight from Australia. He is morbidly obese and has a past medical history of type two diabetes mellitus, high cholesterol, hypertension and a previous cholecystectomy. He denies any leg pain or swelling and denies any chest pain. Observations are stable, and an ECG demonstrates sinus rhythm. A chest X-ray is clear. He undergoes a CT pulmonary angiogram (CTPA) to exclude a pulmonary embolus (PE). The CTPA is reported as finding no evidence of PE but notes a 7mm pulmonary nodule in the left lower lobe.

How should the pulmonary nodule be investigated or monitored?

A. Urgent CT-PET
B. Urgent image-guided biopsy
C. CT chest in three months
D. CT chest in one year
E. No further investigations needed

C. CT chest in three months

The correct answer is CT chest in three months. This is a pulmonary nodule which is larger than 5mm in size, and therefore has a significant potential of growing. Based on this, the British Thoracic Society (BTS) recommends surveillance. Only nodules which are greater than 8mm in diameter and have a greater than 10% risk of malignancy, as assessed by the Brock model (this can be accessed on the BTS website) should undergo PET-CT and then, based on outcomes, be assessed for obtaining a histological sample.

The timing of the follow-up CT is based on the nodule's size. A nodule of 5-6mm should be scanned at one year, whilst larger nodules should be scanned at three months (unless being otherwise investigated)

Question 11 of 133

A 60-year-old caucasian female attends the respiratory clinic for review, She has been referred by her GP after presenting complaining of a chronic cough which has persisted for 6 months. The cough is productive, however she denies any haemoptysis. The patient's husband has commented that she appears to have lost weight during this time period, and she admits to unintentionally going down a dress size.

Before the onset of her cough, the patient reports that she had been reasonably fit and well, walking half an hour every day. She has never smoked and does not have any underlying respiratory pathology. She denies any history of fever or night sweats and has recently traveled to Italy for a summer holiday where she visited a famous bird sanctuary.

You review her chest radiograph which was performed prior to the clinic. There is an increased opacity in the right upper lung field. You perform a number of further investigations detailed below:

Hb	140g/l	Na +	138 mmol/l
Platelets	400 * 10 /l 9	K +	5.0 mmol/l
WBC	11.0 * 10 /l 9	Urea	3.0 mmol/l
Neuts	6.6 * 10 /l 9	Creatinine	89 µmol/l
Lymphs	2.0 * 10 /l 9	CRP	18 mg/l
Eosin	0.01 * 10 /l 9	IFNγ-release assay	Negative
Sputum MC&S	Normal Flora	Sputum Acid Fast Bacilli (AFB)	Positive x 3

You also send the patient for a high resolution CT (HRCT) scan, which demonstrates a cavity in the right upper lobe with associated tree-in-bud appearances in the surrounding lung. There is no associated lymphadenopathy.

What is the most likely causative organism for this presentation?

A. Klebsiella species
B. Mycobacterium tuberculosis
C. Mycobacterium kansasii
D. Allergic bronco-pulmonary aspergillosis (ABPA)
E. Staphylococcal aureus

C. Mycobacterium kansasii

Non-tuberculous mycobacteria (NTM) pulmonary infection is increasing in prevalence within the non-HIV population. There are over 100 different species on NTM, the geographical distribution of which varies between region and country.

Diagnosis of pulmonary NTM infection can be challenging given the environmental nature of the organisms.

This question tests your understanding of the common presentations of pulmonary nontuberculous mycobacterium (NTM) infection in immunocompetent individuals. NTM infection in the non-HIV population is challenging diagnosis to make due to the environmental nature of NTM.

NTM can present in a variety of patterns commonly described based on the radiological characteristics demonstrated. The main types are:

- Hypersensitive-like disease
- Cavitating disease
- Bronchiectasis with or without nodules

Diagnosis can be made by following the joint American Thoracic Society / Infectious Diseases Society of America (ATS/IDSA) guidelines which were published in 2007. Diagnosis requires a range of clinical, radiological and microbiological characteristics to be fulfilled as described below:

Clinical: Pulmonary symptoms (e.g. cough, sputum, or constitutional) and exclusion of alternative diagnosis

Radiological: Chest X-ray or HRCT demonstrating cavities, bronchiectasis and or nodules Microbiological: Two or more positive sputum samples for an NTM species taken on separate days (or one of more positive sample from bronchoalveolar lavage or tissue biopsy)

In this question, although several of the alternative answers have the ability to cause cavitating disease of the lungs, the multiple positive AFB sputum samples point towards a mycobacterial cause. The negative IFNγ-release assay points away from the patient having tuberculosis, leaving Mycobacterium kansasii as the leading answer. However, it is worth noting that there are reports of cross reactivity between certain NTM species and IFNγ-release assay's.

Question 12 of 133

A 53-year-old man is reviewed in the respiratory outpatient clinic with progressive shortness of breath. He has a past medical history of chronic obstructive pulmonary disease and hypercholesterolaemia. He is on regular atorvastatin, salbutamol and symbicort. He still smokes 5 cigarettes daily and has a 40 pack-year history. He lives with his wife and his exercise tolerance is approximately 30 yards.

Clinical examination reveals hyper-resonance to percussion bilaterally and a barrel-shaped chest. There is moderate harsh-sounding wheeze on auscultation. The jugular venous pulse is not raised and there is no peripheral oedema. The heart sounds are normal and the pulse is regular. His fingertips are stained with nicotine. There is no clubbing.

Lung function tests:

FEV1	35% (predicted)
FVC	68% (predicted)
FEV1/FVC	51.4%

Blood tests:

Hb	154 g/L	Male: (135-180)Female: (115 - 160)
Platelets	211 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Na +	133 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Urea	5.3 mmol/L	(2.0 - 7.0)
Creatinine	99 µmol/L	(55 - 120)
Bilirubin	14 µmol/L	(3 - 17)
ALP	91 u/L	(30 - 100)
ALT	34 u/L	(3 - 40)
Î³GT	66 u/L	(8 - 60)
D-dimer	333 ng/ml	(<500)
Albumin	36 g/L	(35 - 50)
CRP	4mg/L	(<5)
BNP	88 pg/ml	(<100)

Plain radiography of the chest demonstrates generalized increased lucency bilaterally but clear lung fields.

Given the clinical history, what is the appropriate next step in management?

A. Add a long-acting beta antagonist
B. Add furosemide and switch salbutamol to ipratropium bromide
C. Add theophylline
D. Switch salbutamol to ipratropium bromide
E. Add a long acting muscarinic antagonist (LAMA)

E. Add a long acting muscarinic antagonist (LAMA)

COPD - still breathless despite using SABA/SAMA and a LABA + ICS → add a LAMA

Add a long-acting muscarinic antagonist (LAMA) is correct. This patient has worsening shortness of breath on a background of COPD. Common differential diagnoses have been excluded such as pulmonary embolism (normal d-dimer), heart failure (clinical examination and normal BNP) and infection (normal WCC, CRP and chest x-ray). The explanation for his symptoms is therefore worsening COPD. If patients are still breathless despite using a SABA and LABA + ICS (i.e. symbicort), then a LAMA should be added.

Add a long-acting beta antagonist is incorrect. The patient is already taking a combined LABA + inhaled corticosteroids (i.e. symbicort).

Add theophylline is incorrect. This should only be trialled once inhaled options have been exhausted.

Switch salbutamol to ipratropium bromide is incorrect. This will not be sufficiently effective.

Add furosemide and switch salbutamol to ipratropium bromide is incorrect. The patient has no clinical evidence of heart failure or fluid overload and has a normal BNP. Therefore furosemide is not indicated.

Question 13 of 133

A 67-year-old gentleman presents to the respiratory clinic via the 2-week rule. He presented to his general practitioner with haemoptysis and a persistent cough. On examination in the clinic, you observe that his clothes are loosely fitted. Chest percussion reveals left upper zone dullness. Chest X-ray confirms the presence of a left upper zone mass. After discussion with your consultant an urgent staging Computerised Tomography (CT) is arranged which unfortunately confirms a large left upper zone mass, mediastinal lymph node involvement and hepatocellular metastases. His performance status is 1. Hyponatraemia is noted on the bloods you requested in the clinic.

Na +	126 mmol/l
K +	4.1 mmol/l
Urea	7.5 mmol/l
Creatinine	91 µmol/l

In the context of the most likely diagnosis and staging , what would be the most appropriate treatment option?

A. Lobectomy
B. Partial pneumonectomy
C. Palliation
D. Chemotherapy
E. Radiotherapy

D. Chemotherapy

From the clinical details given the candidate would be expected to understand that the most likely underlying diagnosis is small cell lung carcinoma. Hyponatraemia secondary to syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a classic MRCP association.

Small cell lung carcinoma has a poor prognosis. National Institute for Clinical Excellence (NICE) guidelines state that in the context of small cell carcinoma with extensive disease chemotherapy should be offered as a treatment option provided after multidisciplinary team discussion the patient is deemed fit enough.

There is no role for surgical resection in small cell carcinoma, however, radiotherapy is an option in those with limited disease.

Question 14 of 133

A 60-year-old woman is referred to the general respiratory clinic with increasing shortness of breath over the last nine month months. This has been associated with pedal oedema. There is no orthopnoea, paroxysmal nocturnal dyspnea or cough. Her past medical history includes bilateral extensive pulmonary emboli and she is currently taking warfarin. She has no other lung disease and she does not smoke.

On examination her chest is clear but auscultation demonstrates a loud second heart sound. There is also a right ventricular heave with visible V-waves on jugular venous pressure.

A recent CT pulmonary angiogram showed resolution of the thrombus. Echocardiogram demonstrates severe right heart dilatation and impaired function with moderate tricuspid regurgitation.

What test will most likely provide a formal diagnosis?

A. Cardiac MR imaging
B. Right heart catheterisation
C. Left heart catheterisation
D. Brain natriuretic peptide (BNP) measurement
E. 6-minute walk test

B. Right heart catheterisation

This lady has right sided heart failure. The most likely diagnosis is chronic thromboembolic pulmonary hypertension and she requires a right heart catheterization to assess the pulmonary pressures (pulmonary hypertension = pulmonary arterial pressure 25 mmHg). Note these can be estimated on echocardiogram and cardiac MR imaging but should not be used to formally diagnose the condition. A cardiac MR can be used to further assess the right ventricular volumes, mass and function or for longitudinal follow up of patients treated for pulmonary hypertension.

A left heart catheterization is used to assess the coronary arteries and left side of the heart which should be relatively normal in this lady.

The BNP will invariably be raised given the severe right ventricular impairment and dilatation.

The 6-minute walk test is used as a prognostic measurement in pulmonary hypertension.

Question 15 of 133

A 67-year-old man presents to the emergency department with severe shortness of breath. He has a past medical history of COPD, type 2 diabetes mellitus and hypertension. On examination he appears very breathless and looks drowsy, with bilateral crackles and wheeze audible on auscultation. Following treatment with nebulisers, steroids, antibiotics and fluids he remains in type 2 respiratory failure with acidosis.

Arterial blood gas on admission:

pH	7.32
pO 2	7.3kPa
pCO 2	8.1kPa
HCO - 3	25mmol/L

Arterial blood gas at two hours:

pH	7.30
pO 2	8.2kPa
pCO 2	9.6kPa
HCO - 3	26mmol/L

He is started on non-invasive ventilation with a bi-level positive airway pressure.

What initial settings would be most appropriate for IPAP and EPAP?

A. IPAP 3cmH2O and EPAP 15cmH2O
B. IPAP 10cmH2O and EPAP 10cmH2O
C. IPAP 15cmH2O and EPAP 3cmH2O
D. IPAP 20cmH2O and EPAP 7cmH2O
E. IPAP 20cmH2O and EPAP 3cmH2O

C. IPAP 15cmH2O and EPAP 3cmH2O

The correct answer is IPAP 15cmH O and EPAP 3cmH O.

BTS advises that BiPAP should started with IPAP of 15cmH O in COPD. If the pH <7.25 then start with IPAP at 20cmH O. For neuromuscular disease needing NIV then starting with IPAP at 10cmH O is appropriate.

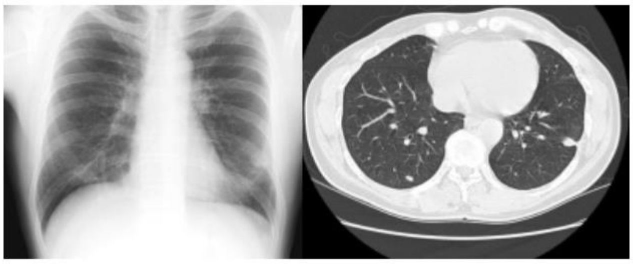
EPAP should be started at 3cmH O unless obstructive sleep apnoea is expected according to the British Thoracic Society, but it is common practice to start with an IPAP of 10cmH O and an EPAP of 4cmH2O. In either case, IPAP should be uptitrated with an aim of IPAP of 20cmH2O or as high as .the patient can tolerate

Question 16 of 133

A 48-year-old man presents to the respiratory clinic with a 2-month history of progressive shortness of breath and a dry cough. There is no history of fever or chest pain, although, he does complain of worsening lethargy. He works as a school teacher and visited India 6 months prior. He denies occupational exposure to hazardous chemicals and has never smoked. His past medical history includes childhood asthma, type 1 diabetes, and rheumatoid arthritis.

On examination, his observations are within normal limits. On auscultation, there are audible fine crackles at the bases with normal heart sounds. His calves are soft and non-tender with no visible oedema.

A chest x-ray and CT chest are organised, as shown below.



Which of the following conditions is the most likely diagnosis?

A. Allergic bronchopulmonary aspergillosis
B. Ankylosing spondylitis
C. Rheumatoid arthritis
D. Sarcoidosis
E. Tuberculosis

C. Rheumatoid arthritis

Causes of lower zone fibrosis: **MAID**

Most connective tissue diseases (e.g. rheumatoid arthritis)

Asbestosis

Idiopathic pulmonary fibrosis, infection

Drugs (e.g. methotrexate, amiodarone, bleomycin)

This patient's chest x-ray and CT scan show features of lower zone fibrosis with visible honeycombing on the CT scan. On closer inspection of the chest x-ray, there is a visible wellcircumscribed opacity in the left lower zone in keeping with a pulmonary nodule (e.g. rheumatoid nodule), and multiple smaller opacities can be seen throughout the slice of the CT scan. Of the conditions listed in the question, rheumatoid arthritis is the only disease that causes lower zone fibrosis, with the other conditions classically causing a pattern of fibrosis in the upper zones. Furthermore, the history of worsening lethargy and arthralgia are suggestive of rheumatoid arthritis, which commonly has an insidious onset over time.

Allergic bronchopulmonary aspergillosis (ABPA) causes a clinical picture similar to asthma and arises following exposure to *Aspergillus* spores. Symptoms include cough, wheeze, and shortness of breath. CT imaging shows dilated bronchioles (similar to bronchiectasis) and occasionally a 'finger-in-glove' appearance can be seen that represents the mucous filling of dilated bronchi. Lower zone pulmonary fibrosis is not a feature of ABPA.

Ankylosing spondylitis is a spondyloarthropathy that typically presents as a young man with lower back pain and stiffness that is worse in the morning. Ankylosing spondylitis causes apical fibrosis, unlike the changes seen on this CT chest that shows lower zone fibrosis.

Sarcoidosis is a multisystem disorder that causes respiratory symptoms such as shortness of breath and a dry cough, along with extra-pulmonary manifestations including fever, arthralgia, and erythema nodosum. Imaging findings in sarcoidosis include bilateral hilar lymphadenopathy, interstitial infiltrates, and fibrosis (typically in the upper lobes).

Tuberculosis is caused by the bacterium *Mycobacterium tuberculosis* with symptoms consisting of fever, productive cough, lethargy, night sweats, and weight loss. In contrast, the patient in this question describes progressive shortness of breath and a dry cough. Tuberculosis does not commonly cause fibrosis, but instead causes calcified lesions (typically apical in location).

Question 17 of 133

A 65-year-old woman slips on an icy road and has a neck of femur fracture. Her past medical history includes hypertension, type 2 diabetes and a pack-year history of 40 years. After six days in hospital, she becomes short of breath and develops haemoptysis. Her observations are:

- Blood pressure: 135/70 mmHg
- Pulse: 110 bpm
- Temperature: 36.4 deg C
- Respiratory rate: 24/min
- Oxygen saturation: 89% on air

A subsequent CTPA shows a right segmental pulmonary embolus and a 4mm solid nodule in her right upper lobe.

What is the most appropriate management of her nodule?

A. Antibiotics and repeat CT
B. Biopsy of lung nodule
C. No further follow-up required
D. PET-CT
E. Repeat CT in 3 months

C. No further follow-up required

Solitary, solid and non-calcified lung nodules of less than 5mm in size do not warrant further investigations or monitoring

Lung nodules are a common incidental finding in patients who have undergone CT scans. BTS guidelines recommend that solid nodules that are less than 5mm in size do not require any further follow-up, even in a smoker.

While chest infections are a common complication after surgery, there is no indication this patient has a chest infection and her CTPA did not show pneumonia. Antibiotics are therefore not indicated.

Larger (>8mm) nodules are more likely to be malignant, especially in patients who are smokers. Patients with such nodules should be ideally offered a PET-CT to help determine the risk of malignancy by combining nodule characteristics with patient characteristics. Patients with a higher risk of malignancy may be offered several options, including a biopsy to confirm malignancy or active surveillance such as a repeat CT in 3 months. This patient's nodule is too small.

Question 18 of 133

A 71-year-old man presents to his GP having suffered from daytime sleeping, which has become so interrupting that he has been placed on probation by his manager at work. He complains of having frequent morning headaches and often gets breathless on walking to the shops. He used to smoke 20 cigarettes per day for 20 years and drinks a pint of beer per evening at the pub. He is also clinically obese.

After being referred to the hospital, an evening arterial blood test is performed and reveals a PaO2 of 9.9 kPa and a PaCO2 of 4.4 kPa. The arterial blood gas is repeated the next morning and reveals a PaO2 of 10.0 kPa and a PaCO2 of 9.1 kPa.

What is the most likely diagnosis?

A. Pulmonary hypertension
B. Central sleep apnoea
C. Obesity hypoventilation syndrome
D. Benign intracranial hypertension
E. Multiple pulmonary emboli

C. Obesity hypoventilation syndrome

This patient most likely has obesity hypoventilation syndrome as characterised by his raised carbon dioxide levels in the morning, as opposed to the evening.

Question 19 of 133

A 67-year-old patient is reviewed in oncology clinic. He has recently been diagnosed with mesothelioma following a pleural biopsy. He has a past medical history of hypothyroidism, pseudogout and depression. He is concerned about the financial implications and is due to seek compensation. He has worked as a plumber for all of his professional life and wants to know when the asbestos exposure most likely occurred to cause him to develop mesothelioma.

How long ago would his asbestos exposure occurred?

A. >50 years ago
B. >30 years ago
C. >10 years ago
D. >5 years ago
E. >2 year ago

B. >30 years ago

The correct answer is >30 years ago. This is a gentleman with mesothelioma. It normally takes at least 10 years for pleural plaques to develop, 20 years for asbestosis and finally 30 years for mesothelioma. To develop mesothelioma a heavy exposure of asbestos will have occurred.

Question 20 of 133

A 71-year-old woman is referred by her out-of-hours GP service to the emergency department following her presentation with worsening shortness of breath and cough. The shortness of breath has been increasing in severity over the last 3 weeks and is associated by an occasional nonproductive cough.

She has an extensive cardiac past medical history including two myocardial infarctions which were treated with percutaneous coronary intervention, an aortic heart valve replacement and mild mitral regurgitation. Other history includes hypertension which is treated with amlodipine and ramipril, hypercholesterolaemia which is treated with atorvastatin and mild COPD for which he takes salbutamol and ipratropium bromide. She previously worked as a librarian, has smoked 10 cigarettes for the past 20 years and drinks on average 5 units of alcohol per week.

Examination reveals dull percussion and reduced breath sounds over the left mid and lower bases of the lung. Urgent chest x-ray reveals a left-sided pleural effusion. Pleural aspirate is taken and shows:

Protein content	45 g/L
Glucose	2.4mmol/L
pH	7.32

What is the most likely diagnosis?

A. Congestive cardiac failure
B. Bronchial carcinoma
C. Systemic lupus erythematosus
D. Mesothelioma
E. Boerhaave's syndrome

B. Bronchial carcinoma

The protein content of the pleural fluid is high (>30g/L) demonstrating that the fluid is an exudate. The low glucose and pH of the fluid, when coupled with the clinical symptoms of shortness of breath and cough indicates that the most likely diagnosis is bronchial carcinoma. There is no history of asbestos exposure and no clinical feature of systemic lupus erythematosus or Boerhaave's syndrome present.

Question 21 of 133

A 56-year-old woman with a diagnosis of asthma attends her respiratory outpatient appointment. She has had two exacerbations requiring hospitalisation over the past year and also has hypothyroidism and angina. She takes tiotropium, fluticasone, levothyroxine, simvastatin, aspirin and GTN spray. She was started on theophylline at a standard regime in the previous clinic appointment and has completed a course of ciprofloxacin the last week for a mild exacerbation. She is otherwise well and smokes 20 cigarettes a day. She has allergies to pollen.

On examination, she has a dry cough but is able to speak in full sentences. Her chest has scattered wheeze throughout.

Na +	145 mmol/l
K +	3.9 mmol/l
Urea	4.2 mmol/l
Creatinine	56 µmol/l
Chest x-ray	hyperexpanded lung fields
Theophylline level	6 mcg/ml (normal range 10-20)
TSH	5.2 mU/l

What is the likely cause of her subtherapeutic theophylline level?

A. Ciprofloxacin
B. Simvastatin
C. Smoking
D. Alcohol binge
E. Hypothyroid state

C. Smoking

Current smokers -> liver enzyme induction -> higher doses aminophylline required

Theophylline/aminophylline requirements vary between individuals. They are metabolised by the liver and therefore concentration depends on the rate of metabolism. Statins, ciprofloxacin and an alcohol binge or inhibit the liver increasing sensitivity to theophylline and increasing the risk of toxicity at smaller doses. In contrast, smoking is an inducer of liver enzyme activity and therefore smokers often require higher starting doses. The TSH suggests she is slightly hypothyroid at present but this does not significantly affect the metabolism.

Question 22 of 133

A 71-year-old man is being treated in a medical ward for an empyema. Shortly after admission, a chest drain is inserted under ultrasound guidance and antibiotics are started. Over the past few days, there have been significant volumes drained and the patient has been improving clinically.

On the daily morning ward round, his chest drain is reviewed. It is on suction. There is minimal drain output over the past 24 hours and it is noted that the chest drain is bubbling. This bubbling is more significant when the patient is asked to cough.

What does this indicate?

A. Blocked chest drain
B. Bronchopleural fistula
C. Chest drain moved displaced outside of the chest
D. Normal
E. Unresolved empyema

B. Bronchopleural fistula

Bubbling of a chest drain inserted to drain an empyema may indicates that a bronchopleural fistula has occurred

Bubbling of a chest drain inserted into the pleural space is indicative of an air leak. Therefore, given the clinical history of an empyema, it is likely that a bronchopleural fistula has formed. This is therefore the correct answer.

As there is bubbling of the chest drain, it cannot be blocked. This is therefore an incorrect answer.

If the chest drain is displaced outside of the chest and on suction, bubbling can occur. Distinguishing between a bronchopleural fistula and a displaced chest drain can be difficult however one simple test is to ask the patient to cough. As the patient coughs and the intrathoracic pressure rises, this will cause an increase in the air flowing into the pleural space and therefore the bubbling of the drain. If the drain is outside of the pleural space, the bubbling will be constant and unrelated to coughing.

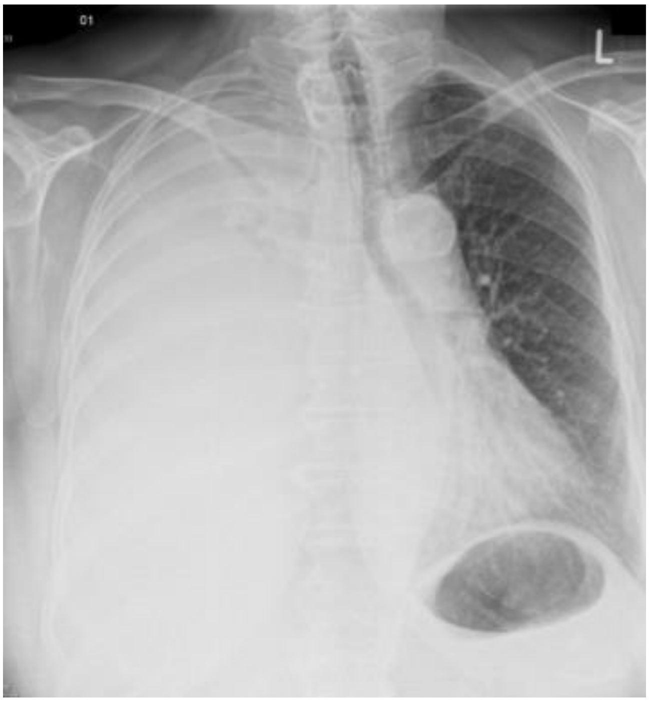
Bubbling from a chest drain is not a normal finding . Although swinging is normal with changes in intrathoracic pressure, bubbling is caused by air being entrained into the drain. The most common cause for this is the displacement of the drain outside of the thorax, however, a bronchopleural fistula is the diagnosis here as indicated by the changes on coughing.

An unresolved empyema is not necessarily indicated here by the drain activity as this would not cause bubbling of the chest drain. The drain is clearly patent, as indicated by the bubbling which is worse on coughing, and there is minimal drain output. It may be that the drain is not located within the empyema limiting its resolution, however further imaging would be required to determine this.

Question 23 of 133

A 69-year-old woman presents to the Emergency Department with a one month history of gradually worsening breathlessness. She is generally fit and well but last year was diagnosed with chronic obstructive pulmonary disease (COPD) after a 50-pack-year history of smoking. Around 10 years ago she retired from the local car production plant. On examination she is breathless at rest with a respiratory rate of 18/min and oxygen saturations of 93% on room air.

A chest x-ray is performed:

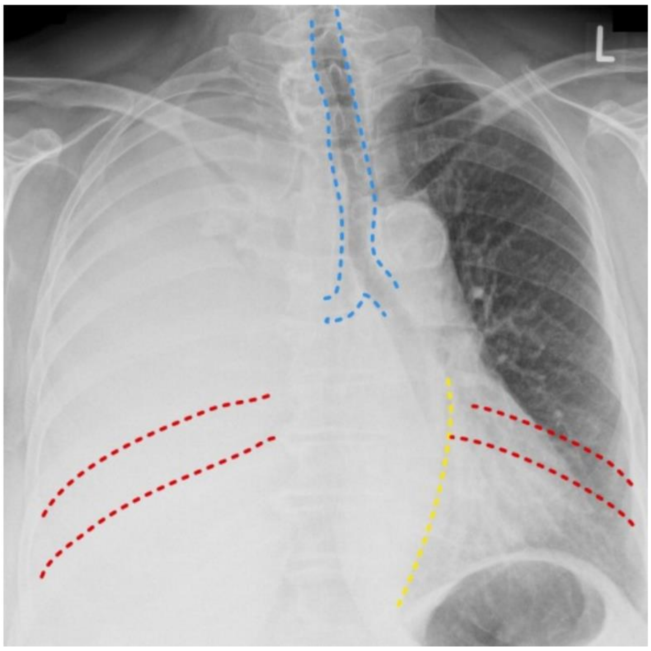


What is the most likely diagnosis?

A. Pneumonectomy
B. Mesothelioma
C. Lung collapse
D. Massive pleural effusion
E. Ewing sarcoma

D. Massive pleural effusion

The chest x-ray shows that the the trachea (blue) is pushed away the side of the white-out. The other signs of a positive mass effect include leftward bowing of the azygo-oesophageal recess (yellow) and splaying of the ribs on the right.



Question 24 of 133

A 39-year-old woman is seen in the respiratory clinic with a 6-week history of progressive shortness of breath and a dry cough. There is no history of fever or weight loss. She has a past medical history of recently-diagnosed asthma for which she is taking regular salbutamol and beclomethasone inhalers although, she reports that they have had little effect on her symptoms. There is no history of smoking and she denies any allergies.

On examination, there is diffuse expiratory wheeze but no audible crackles. Her cardiovascular examination is unremarkable.

Laboratory tests:

Hb	136 g/L	(115 - 160)
Platelets	201 * 10 /L 9	(150 - 400)
WBC	9.1 * 10 /L 9	(4.0 - 11.0)
Lymphocytes	1.6 * 10 /L 9	(1.5 - 4.5)
Neutrophils	5.5 * 10 /L 9	(2.0 - 7.5)
Eosinophils	1.2 * 10 /L 9	(0 - 0.4)
CRP	12 mg/L	(< 5)
Aspergillus IgE		Raised

What is the most appropriate next step in the management of this patient?

A. Intravenous amphotericin B
B. Intravenous co-trimoxazole and methylprednisolone
C. Oral montelukast
D. Oral prednisolone
E. Salbutamol and ipratropium nebulisers

D. Oral prednisolone

Oral glucocorticoids are the treatment of choice for allergic bronchopulmonary aspergillosis

The diagnosis here is allergic bronchopulmonary aspergillosis (ABPA). It is a hypersensitivity reaction to the fungus *Aspergillus* causing an eosinophilic pneumonia. Presenting symptoms are similar to asthma and include dyspnoea, dry cough and wheeze. Patients with ABPA are commonly misdiagnosed as having asthma and standard treatments for asthma (e.g. salbutamol inhalers) have little benefit. This patient describes similar symptoms of shortness of breath and a dry cough. Furthermore, her blood tests demonstrate a raised eosinophil count and IgE level, both of which point towards ABPA. The treatment of choice is oral prednisolone to help facilitate the clearing of pulmonary infiltrates.

Intravenous amphotericin B is used in the treatment of systemic fungal infections, including invasive *Candida albicans* or invasive aspergillosis. Invasive aspergillosis is uncommon and is mostly seen in immunosuppressed patients and presents with systemic illness. Amphotericin B is not routinely given first-line to treat infections with *Aspergillus*. Instead, fluconazole or itraconazole can be given, if indicated. However, the combination of wheeze, shortness of breath, and dry cough are more in keeping with ABPA, for which oral corticosteroids are the most appropriate treatment.

Intravenous co-trimoxazole and methylprednisolone are used in the treatment of *Pneumocystis jiroveci* pneumonia (PCP). PCP presents in a similar way to this patient with dyspnoea, fever and a dry cough. However, PCP is mostly seen in immunocompromised patients, such as those with HIV or on immunosuppressant medications. There is nothing in this patient's history to suggest immunosuppression, therefore it is likely that PCP is not the underlying diagnosis.

If asthma is not controlled with salbutamol and inhaled corticosteroid inhalers, the dose of the corticosteroid can be increased. Failing this, the next step in the management of asthma includes the addition of a leukotriene antagonist such as montelukast. However, this patient's history and laboratory findings point toward a diagnosis of ABPA over poorly controlled asthma, for which oral corticosteroids is the preferred method of treatment.

Salbutamol and ipratropium nebulisers are used in the acute treatment of asthma. However, it plays no role in the treatment of ABPA.

Question 25 of 133

A 35-year-old female with a past medical history of sinusitis and asthma for four years is admitted with a pyrexia and new onset dyspnoea and ankle swelling. Two weeks prior to admission she had noticed blood streaks were present in her sputum.

On examination, she had widespread wheeze and bi-basal crepitations on auscultation of her chest. Her saturations are 94% without oxygen but come up to 99% after treatment with salbutamol and ipratropium bromide nebulisers and oxygen therapy.

She has a heart rate of 112 beats per minute, normal heart sounds and a raised JVP. She has pitting oedema up to her knees. Examination of her abdominal system is unremarkable.

Haemoglobin	102 g/L
White cell count	11.2 Ã— 109/L
Eosinophil count	1.9 Ã— 109/L
Platelet count	478 Ã— 109/L
International normalised ratio	1.3
Serum sodium	135 mmol/L
Serum potassium	5.5 mmol/L
Serum urea	21 mmol/L
Serum creatinine	211 umol/L
CRP	22 mg/l
Blood cultures	Coagulase-negative staphylococci
ANCA positive	immunostaining awaited

Urine dip- positive for protein and blood

CXR: Bi-basal non specific shadowing

What is the most likely diagnosis?

A. Churg-Strauss syndrome
B. Systematic inflammatory response syndrome
C. Systematic lupus erythematous
D. Granulomatosis with polyangiitis
E. Microscopic polyangiitis

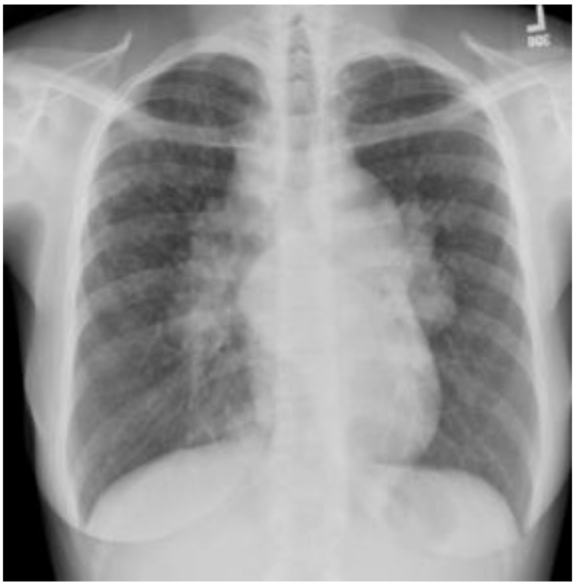
A. Churg-Strauss syndrome

This patient has essentially presented with acute kidney injury and is ANCA positive. ANCA may be positive in granulomatosis with polyangiitis, Churg Strauss syndrome and microscopic polyangiitis all of which can affect the kidneys. However, the history of asthma and sinusitis coupled with a raised eosinophil count make Churg Strauss syndrome the most likely option.

Systematic Inflammatory response syndrome is unlikely to explain the entire clinical picture. Additionally, although blood cultures are positive this is most likely to be a contaminant considering the organism and the trivial C-reactive protein.

Question 26 of 133

A 51-year-old woman is being investigated by the respiratory team. She reports a four-month history of dry cough with associated lethargy and weight loss. She has no relevant past medical history and has never smoked. A chest x-ray is displayed below:



Which further test would be most appropriate to aid in diagnosis?

A. Cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) 3%
B. Interferon-gamma release assay (IGRA) 6%
C. Perinuclear antineutrophil cytoplasmic antibodies (pANCA) 2%
D. Serum angiotensin-converting enzyme (ACE) 84%
E. Sputum microscopy, culture, and sensitivity (MCS) 5%

D. Serum angiotensin-converting enzyme (ACE)

This woman has sarcoidosis. This explains her clinical symptoms and is confirmed by the bilateral lymphadenopathy on her chest x-ray. Serum ACE is a specific blood biomarker for sarcoidosis and is, therefore, the correct answer in this instance.

cANCA is a biochemical marker for granulomatosis with polyangiitis (previously known as Wegner's granulomatosis). This classically presents with haemoptysis, rhinitis, epistaxis, and potentially renal involvement. The typical x-ray findings include nodules with or without cavitations, pulmonary haemorrhages, and peripheral consolidation. As none of these symptoms or imaging features are to be found in this case, this is not the diagnosis and therefore pANCA is incorrect.

IGRA is a test used to diagnose tuberculosis (TB) infection. Although the symptoms here could be indicative of active pulmonary TB, this classically presents with upper lobe consolidation on chest x-ray. As this is not present, TB is not the diagnosis here. Therefore an IGRA would not be an appropriate test to order in this instance.

pANCA is a biochemical marker for eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome). This typically presents with asthmatic features as well as other sequelae of vasculitis. The x-ray findings in eosinophilic granulomatosis with polyangiitis include peripheral consolidation and pleural effusions. As none of these symptoms or imaging features are to be found in this case, this is not the diagnosis and therefore pANCA is incorrect.

The x-ray here shows bilateral hilar lymphadenopathy rather than focal areas of consolidation and is, therefore, more indicative of sarcoidosis. Sputum MCS is very effective in identifying organisms and assessing sensitivities in infective pathologies however have no role in sarcoidosis as this is an autoimmune process. This is therefore an incorrect answer.

Question 27 of 133

A 50-year-old gentleman presents with shortness of breath. He is a current smoker of 20 cigarettes per day and used to work a coal miner. His body mass index (BMI) is 40 kg/m². His spirometry results are as follows:

Forced expiratory volume in 1 second (FEV1)	3.05 (79% predicted)
Forced vital capacity (FVC)	3.27 (70% predicted)
Diffusion capacity of the lung (DLCO)	86% predicted
Rate of carbon monoxide uptake (KCO)	105% predicted

What is the likely cause of this gentleman's shortness of breath?

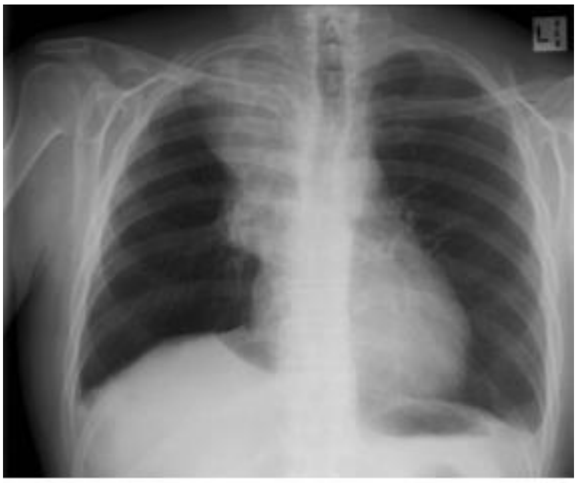
A. Obesity
B. Pneumoconiosis
C. Chronic obstructive pulmonary disease (COPD)
D. Idiopathic pulmonary fibrosis
E. Asthma

A. Obesity

This gentleman has evidence of restrictive lung disease on his spirometry results. A low DLCO but a high KCO implies that he has an extra-pulmonary cause of his restriction. Obesity is the only extra-pulmonary cause of a restrictive deficit from the list of options. COPD and asthma cause obstructive lung disease and pneumoconiosis and idiopathic pulmonary fibrosis and intrapulmonary causes of restrictive lung disease.

Question 28 of 133

A 79-year-old is investigated for weight loss.



What is the most likely diagnosis?

A. Paget's disease of the bone
B. Lung cancer
C. Liver cancer
D. Reactivation of pulmonary tuberculosis
E. Mesothelioma

B. Lung cancer

The x-ray shows a large right sided hilar mass with resultant collapse of the right upper lobe. As a consequence the hyperexpanded right middle and lower lobes are hyperlucent ('blacker').

Question 29 of 133

A 56-year-old woman presents to clinic for review following investigations and MDT discussion. She has chronic exertional dyspnoea and following a restrictive pattern detected on spirometry and changes on high-resolution CT scanning she has been diagnosed with idiopathic pulmonary fibrosis.

What medication can be used to modify disease progression?

A. Azathioprine
B. Prednisolone
C. Co-trimoxazole
D. Sildenafil
E. Pirfenidone

E. Pirfenidone

The correct answer is pirfenidone. Guidelines recommend supportive care, pulmonary rehabilitation and supplementary oxygen, but in very selective patients pirfenidone can be used. All of the other medication options have been attempted, but are advised by NICE that there is insufficient evidence to recommend their use. Patients are commonly prescribed azathioprine and prednisolone but this does not affect the disease course and does not help symptom control. Cotrimoxazole is useful primarily in immunosuppression from HIV to prevent infection, whilst sildenafil, a type 5 phosphodiesterase inhibitor, is more useful in pulmonary arterial hypertension.

Question 30 of 133

A 52-year-old woman presents to the respiratory clinic with breathlessness. She was referred from her GP who was concerned about breathlessness and a chest X-ray demonstrating left pleural effusion. She had recently undergone a left-sided wide local excision with axillary clearance for ductal carcinoma in sit.

She has unilaterally reduced breath sounds with dullness on percussion and deviation of the trachea away from that side of her chest. A plural aspirate is obtained and is milky white in colour. The two possibilities considered are chylothorax from pseudochylothorax.

What investigation would aid in distinguishing chylothorax from pseudochylothorax?

A. pH
B. Albumin
C. Microscopy
D. Triglycerides
E. Amylase

D. Triglycerides

The correct answer is triglycerides. Chylothorax is the accumulation of lymph in the pleural space. This can occur following damage to the thoracic duct in surgery or in malignant melanoma. It is most likely that the recent surgery is relevant to this. A chylothorax is high in triglycerides and chylomicrons whilst a pseudochylothorax would be high in cholesterol. A pseudochylothorax occurs with longstanding fibrotic pleura. pH would be most useful in determining the presence of empyema, amylase in pancreatitis associated effusions, whilst microscopy would help in malignant effusions.

Question 31 of 133

You are asked to review a 78 year-old male on the respiratory ward during a night shift. He is currently an inpatient being treated for an infective exacerbation of pulmonary fibrosis. You review his chest X-Ray which shows extensive left sided consolidation. His co-morbidities include endstage renal failure (haemodialysis dependent) secondary to type 1 diabetes mellitus. He escalation plan has been discussed previously and he did not want escalation to ICU or CPR in the event of a cardiac arrest.

He has been treated with high flow oxygen and intravenous antibiotics for the past few days but nursing staff inform you he has been deteriorating in the last 24 hours. On examination he is very dyspnoeic and distressed with saturations of 72% on 80% high flow humidified oxygen.

What is the correct course of action?

A. Increase the inspired oxygen concentration
B. 2.5mg midazolam subcutaneously
C. 2.5mg morphine subcutaneously
D. 5mg morphine orally
E. 100mcg alfentanil subcutaneously

E. 100mcg alfentanil subcutaneously

This gentleman is approaching the end of his life. He is on maximal oxygen therapy and has expressed a wish not for escalation beyond ward based care. His renal failure means that he is likely to accumulate morphine and the most appropriate option for palliation of his breathlessness is alfentanil - a short acting opiate.

Question 32 of 133

A 56-year-old lady is brought into the emergency department with a Glasgow Coma Scale of 5. She was found by a friend this morning unconscious and purple with no response. She had been unwell the previous days with an exacerbation of her COPD in which she was developing severe pleuritic chest pain. She had recurrent exacerbations of her COPD and had been hospitalised three times this year with one admission to ITU for intubation and ventilation.

In addition, she had hypertension, hypothyroidism and chronic regional pain syndrome. Her medications include fostair, ventolin, gabapentin, codeine, paracetamol, amlodipine, ramipril, levothyroxine and morphine sulfate. She had taken extra doses of oramorph to control her pleuritic pain. She has started a rescue pack of amoxicillin and prednisolone one day prior

On examination, she does not open her eyes which have 2mm pupils bilaterally that are reactive. She groans to pain but there is no motor response. Her chest has some wheeze across and her respiratory rate is 9 breaths per minute. She is saturating at 88% on 4 litres oxygen via nasal cannulae and there is no accessory muscle use. She has mild pitting oedema and is centrally cyanosed. She has a capillary refill of two seconds and there are no murmurs.

Hb	160 g/l	Na +	138 mmol/l
Platelets	310 * 10 /l 9	K +	5.1 mmol/l
WBC	9.0 * 10 /l 9	Urea	7.8 mmol/l
Neuts	7.8 * 10 /l 9	Creatinine	110 µmol/l
Lymphs	1.0 * 10 /l 9	CRP	30 mg/l

ABG (on arrival) pH	7.25
pO2	7.91 kPa
pCO2	7.6 kPa
HCO3	31mmol/l

Chest x-ray	poor inspiration, no overt consolidation
ECG	sinus rhythm

What is your first step in management?

A. Salbutamol nebuliser
B. Intubation and ventilation
C. Intravenous antibiotics
D. Naloxone
E. Non-invasive ventilation

D. Naloxone

Opioids can precipitate respiratory failure in patients with chronic respiratory disease

This lady has entered type 2 respiratory failure. A lot of the options are suitable here but the key is identifying what the quickest solution may be. Ventilation is key but there are some other actions that should be tried first. Intravenous antibiotics are useful but she is haemodynamically stable and not overtly septic. Salbutamol nebulisers will help her air entry. However, there are several clues in the question. She is taking lots of opioids and other sedatives and has increased her uptake of oramorph because of pleuritic pain. She has pin point pupils and bradypnoea and a stat dose of naloxone may rapidly recover her respiratory drive and allow her to recover without needing the other options.

Question 33 of 133

A 22-year-old man presents to rheumatology clinic with chronic lower back pain and early morning stiffness. He has past medical history of asthma and is on regular steroid inhalers and suffers from multiple exacerbations annually. He is due to see a respiratory physician to help better manage his symptoms. Clinical examination shows demonstrate Schober's sign. Pelvic Xrays demonstrate sacroiliitis. A diagnosis of ankylosing spondylitis is made.

The patient is concerned about using NSAIDs to control his symptoms; what factor may suggest that NSAIDsensitive asthma?

A. Previous reaction to beta-blockers
B. High frequency of exacerbations
C. Presence of nasal polyps
D. Adult-onset asthma
E. Previous ITU admission

C. Presence of nasal polyps

The correct answer is nasal polyps. Asthmatics are typically taught to be aware that NSAID's can worsen asthma but not all patients are sensitive. The presence of nasal polyps is associated with a higher chance of reaction to NSAID's, whilst having had NSAID's and suffered no reaction within the last 12 months reduces the chance of further reactions. The other options do not predict a reaction ITU admissions and high frequency of admissions can suggest poorly managed or brittle asthma.

Question 34 of 133

A 48-year-old male presents to the respiratory clinic with his partner. They are concerned as he has lost 5 kgs in weight over the last three months. He also reports a productive cough which has been troubling him for a similar time period. He reports that he is currently producing approximately half a cup of phlegm each day. He denies fevers or night sweats and systems review is unremarkable.

You send the patient for a chest X-ray which is reported as showing multiple cavitating lesions. Sputum microscopy, sensitivities and culture (MC&S) are all negative and a HIV test is negative. You refer the patient for a bronchoscopy and bronco-alveolar lavage (BAL) to aid your diagnosis. Several weeks later you receive a call from the microbiology registrar on call to inform you that the patients sputum has cultured a non-tuberculous mycobacterium (Mycobacterium intracellulare).

You call the patient back into clinic and find that his symptoms have persisted since his last visit.

What is the most appropriate management plan for this individual?

A. Rifampicin, isoniazid, ethambutol, pyrazinamide
B. Repeat sputum cultures
C. Clarithromycin monotherapy
D. Rifampicin, clarithromycin and ethambutol

E. Rifampicin and isoniazid

D. Rifampicin, clarithromycin and ethambutol

This question tests your understanding of the diagnostic criteria for non-tuberculous mycobacteria (NTM) and appropriate treatment of common causative species. Diagnosis can be made by following the joint American Thoracic Society / Infectious Diseases Society of America (ATS/IDSA) guidelines which were published in 2007. Diagnosis requires a range of clinical, radiological and microbiological characteristics to be fulfilled as described below:

Clinical: Pulmonary symptoms (e.g. cough, sputum, or constitutional) and exclusion of alternative diagnosis

Radiological: Chest X-ray or HRCT demonstrating cavities, bronchiectasis and or nodules Microbiological: Two or more positive sputum samples for an NTM species taken on separate days (or one of more positive sample from bronco-alveolar lavage or tissue biopsy)

Once a diagnosis of NTM is reached, it is important to know the basic treatment for common pulmonary NTM infections. It is important to have a basic understanding of two commonly identified groups: Mycobacterium avium complex (MAC) and Mycobacterium kansasii.

- MAC: Rifampicin, clarithromycin and ethambutol. Treatment should continue until the patients sputum has remained negative for MAC for 12 months

- M.kansasii: Rifampicin, isoniazid and ethambutol. Treatment should continue until the patient has been sputum culture negative for 12 months.

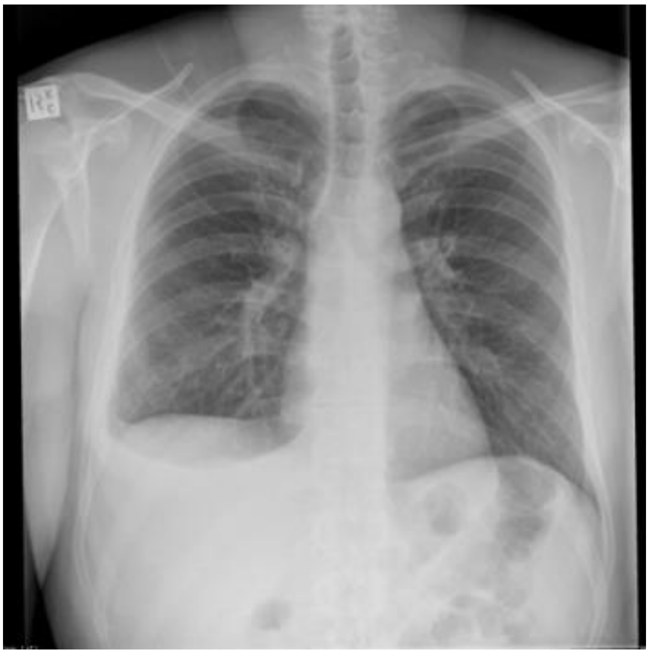
It is important that patients with NTM infection should never receive clarithromycin monotherapy due to concerns over development of resistance.

Question 35 of 133

You review the chest x-ray of a 35-year-old man who started treatment for a chest infection two weeks ago. He completed a one week course of antibiotics but still feels short-of-breath on exertion. He has a 15 pack-year history of smoking.

On examination his respiratory rate is 16/min, saturations 98% on room air and auscultation of his chest is unremarkable.

His chest x-ray is shown below:



What does the chest x-ray show?

A. Right lower lobe collapse
B. Lung tumour
C. Pleural effusion
D. Elevated right hemidiaphragm
E. Persistent consolidation

C. Pleural effusion

The chest x-ray shows a right basal opacity obscuring the right costodiaphragmatic recess with a meniscus, findings consistent with a pleural effusion. Lungs and pleural spaces are otherwise unremarkable. Cardiomediastinal contour within normal limits

Question 36 of 133

A 72-year-old gentleman presents for review in the medical clinic. He has had COPD for five years and is on regular bronchodilator treatment with a combination budesonide and formoterol fumarate inhaler and salbutamol inhaler as needed. He has found that he suffers from regular coughing bouts and finds his exercise tolerance has reduced.

His past medical history includes macular degeneration, osteoarthritis, mild memory impairment and diverticulosis. He has noticed that the distance he can walk has reduced from being able to go to the local shop, roughly one mile away, to having to stop half-way to catch his breath.

What investigation would be most useful to help determine the severity of his COPD?

A. FEV1/FVC
B. Chest X-ray
C. High resolution CT scan of the chest
D. Partial pressure of oxygen on arterial blood gas
E. FEV1% of predicted

E. FEV1% of predicted

The correct answer is FEV1% of predicted. All of the mentioned investigations, in addition to routine blood tests, can be useful in assessing COPD, but the primary investigation standard for COPD is FEV1% of predicted. This compares the patient's ability to exhale over one second with what someone of the same sex, height, weight and ethnicity. It is a marker of the extent of airway obstruction and therefore a marker of COPD severity.

FEV1/FVC is useful in diagnosis but not the severity of COPD.

Imaging can show radiological changes, but these are not as standardised as spirometry changes.

Hypoxia on arterial blood gases is more useful in establishing the need for home oxygen than COPD severity.

Question 37 of 133

A 68-year-old female attends the acute medical unit with dyspnoea. She states that the dyspnoea is present at rest and exacerbated by exertion. She has a past medical history of hypothyroidism, recurrent urinary tract infections, and anxiety. Her drug history includes nitrofurantoin, levothyroxine, paracetamol, bisoprolol and sertraline. On examination you note right basal crepitations and stony dull percussion at the right lung base.

A chest x-ray demonstrates a right sided pleural effusion. What drug is the most likely cause of the pleural effusion?

A. Levothyroxine
B. Bisoprolol
C. Sertraline
D. Paracetamol
E. Nitrofurantoin

E. Nitrofurantoin

Several drugs are known to cause pleural effusion including nitrofurantoin, methotrexate, and amiodarone

Several drugs are known to cause pleural effusion including nitrofurantoin, methotrexate, and amiodarone. None of the other options are known to cause pleural effusions.

Nitrofurantoin is sometimes used long term for prophylaxis of urinary tract infections. Respiratory complications of nitrofurantoin include acute pulmonary reactions (e.g. consolidation) and chronic reactions (e.g. fibrosis and effusions). Patients should have spirometry every 3-6 months while on nitrofurantoin.

Question 38 of 133

A 57-year-old is admitted with confusion, fever and decreased oral intake. HIs past medical history is significant for type 2 diabetes mellitus, hypertension, osteoarthritis and gout. Blood cultures are positive for *E. coli*. Despite antibiotic therapy, he slips into respiratory failure. He is intubated and placed on mechanical ventilation with an FiO of 70%, tidal volume of 370 ml and respiratory rate of 14/min.

His current arterial blood gases are:

pH	7.45
pO_2	7.86 kPa
pCO_2	3.99 kPa
HCO_3	21 mmol/l

Which of the following is the best next step in managing this patient?

A. Increase tidal volume
B. Increase respiratory rate
C. Increase the fraction of inspired oxygen
D. Add positive end-expiratory pressure
E. Decrease the fraction of inspired oxygen

D. Add positive end-expiratory pressure

Fever, confusion, decreased food intake and blood cultures positive for *E. coli* all point towards a diagnosis of sepsis, a common cause of acute respiratory distress syndrome (ARDS). ARDS is characterised by diffuse injury to the pulmonary capillary endothelium and alveolar epithelium that ultimately leads to alveolar collapse and impaired pulmonary gas exchange.

The patients blood gases reflect hypoxaemia and a slight respiratory alkalosis, meaning that despite high FiO settings and sufficient ventilation, his arterial oxygenation remains inadequate. Generally speaking, oxygenation may be improved by further increasing the FiO or by adding positive end-expiratory pressure (PEEP). High FiO is contraindicated due to the risk of pulmonary oxygen toxicity. Thus, the goal in managing mechanically ventilated patients should be to keep the FiO below 40% at all times. Adding PEEP is the next best step here. PEEP prevents alveolar collapse, directly counteracting the means by which ARDS causes hypoxaemia. It may also reopen some alveoli that have already collapsed.

Choice 1: This patients level of ventilation is adequate as confirmed by a slightly low pCO . Increasing the tidal volume would unnecessarily increase the minute ventilation and peak inspiratory pressure, thereby worsening the respiratory alkalosis and increasing the risk of barotrauma respectively.

Choice 2: This patients level of ventilation is adequate as confirmed by a slightly low pCO . Increasing the respiratory rate would worsen the respiratory alkalosis and would not improve oxygenation.

Choice 5: Decreasing the FiO at this point would further reduce the patients oxygenation. This patients FiO does need to be reduced soon in order to avoid pulmonary oxygen toxicity, but this should be accomplished by first increasing oxygenation by another means, such as by increasing PEEP.

Question 39 of 133

A 73-year-old woman presents to the respiratory clinic with progressive breathlessness over the last 18 months. Her past medical history includes angina, breast cancer 14 years ago (treated with mastectomy and radiotherapy) and rheumatoid arthritis (on sulfasalazine and methotrexate). She previously smoked 15 cigarettes per day for 20 years but stopped after her diagnosis of breast cancer.

On examination, the patient has evidence of clubbing with a regular pulse of 68 beats per minute. She is not cyanosed and has no evidence of CO2 retention. On examination of her lungs, there are fine end-inspiratory crackles most affecting the upper zones.

What is the most likely cause of this patient's lung disease?

A. Chronic obstructive pulmonary disease
B. Idiopathic pulmonary fibrosis
C. Methotrexate pneumonitis
D. Radiation pneumonitis
E. Rheumatoid arthritis'

D. Radiation pneumonitis

radiotherapy may result in radiation pneumonitis, typically causing upper zone lung fibrosis

This patient likely has interstitial lung disease (ILD) as evidenced by clubbing and fine endinspiratory crackles.

Of the causes listed, **radiation pneumonitis** is a cause of ILD which is most likely to affect the upper zones and the patient has a history of previous radiotherapy, making radiation pneumonitis the most likely cause.

Chronic obstructive pulmonary disease (COPD) does not fit with the clinical findings of clubbing and end-inspiratory crackles.

Idiopathic pulmonary fibrosis is a form of ILD which typically affects the lower zones more than the upper zones and is, therefore, less likely to be the cause.

Rheumatoid arthritis is a form of ILD which typically affects the lower zones more than the upper zones and is, therefore, less likely to be the cause.

Methotrexate pneumonitis typically presents with cough, breathlessness and fever. Methotrexate can also cause lung fibrosis but this would also typically affect the lower zones more than the upper zones so would be the less likely diagnosis in this instance.

Question 40 of 133

A 74-year-old ex-miner is reviewed in the Respiratory Clinic with a 4-month history of episodic dyspnoea and dry cough. The attacks last for several days at a time and are accompanied by fever, malaise, and chest tightness. He recovered from the most recent episode 2 weeks ago.

His past medical history is unremarkable and he states that he is generally well between episodes. He does report some long-standing shortness of breath on exertion, but this has been stable for the past 6 years and he estimates his exercise tolerance at 200 yards.

He worked as a miner until the early 1980s and then retrained as a plumber. He continued to work until his retirement in the early 2000s. He now enjoys housing pigeons in his back garden. He does not smoke.

On examination, his respiratory rate is 14/min and his oxygen saturations are 95% breathing room air. His fingers are clubbed and there are bibasal crackles on auscultation of the chest. His heart sounds are dual with nil added.

A high-resolution CT (HRCT) scan of the thorax is reported as showing subpleural bibasal reticular opacities with some evidence of honeycombing but no appreciable ground-glass opacification.

What is the most likely cause of his symptoms?

A. Asbestosis
B. Hypersensitivity pneumonitis
C. Silicosis
D. Coal worker's pneumoconiosis
E. Idiopathic pulmonary fibrosis

B. Hypersensitivity pneumonitis

the key to successfully answering this question is to appreciate that it is asking you to explain his symptoms rather than the examination and investigation findings. MRCP questions often include varying amounts of distracting information in order to simulate the complexity of clinical practice, although in this case there is enough information in the opening paragraph to make the diagnosis irrespective of the confounding information presented in the rest of the vignette.

The occurrence of episodic dyspnoea, cough, and flu-like symptoms in response to an environmental antigen is consistent with the acute presentation of hypersensitivity pneumonitis. Patients are well in between episodes and during the early phase of the disease examination and investigation can be normal.

The abnormalities on the HRCT are consistent with usual interstitial pneumonia (UIP); a pathological pattern of interstitial lung disease rather than a diagnosis in itself. UIP has numerous causes, including asbestosis and idiopathic pulmonary fibrosis (IPF). Both of these diagnoses would be in keeping with the clubbing and bibasal crepitations found on examination, but neither would cause the relapsing and remitting symptoms described.

The patient does describe some longstanding dyspnoea on exertion, which would be more in keeping with asbestosis or stable IPF. The absence of ground glass on the HRCT implies there is no active lung inflammation and also suggests stable disease.

Silicosis and coal worker's pneumoconiosis cause upper zone fibrosis. Both conditions typically cause chronic rather than episodic symptoms.

Question 41 of 133

A 58-year-old smoker was referred to the respiratory outpatient clinic by his GP with a history of progressively worsening shortness of breath. His symptoms started several months ago with shortness of breath on extreme exertion but he gradually developed shortness of breath with minimal activity. He also complained of increasing tiredness and a non-productive cough had lost approximately 3 pounds in 6 months. He denied the presence of sputum production, haemoptysis or chest pain, and also denied the presence of both orthopnoea and paroxysmal nocturnal dyspnoea. He had a past medical history comprising ankylosing spondylosis diagnosed 30 years ago as well as hypertension and hypercholesterolaemia. His drug history comprised naproxen 500mg BD, lansoprazole 30mg OD, felodipine M/R 2.5mg OD and atorvastatin 20mg OD. He stated that he had been trialled with a course of methotrexate a few years ago for his ankylosing spondylosis and was subsequently stopped.

Examination revealed the presence of a well male with a blood pressure of 146/86 mmHg, heart rate 74 bpm and respiratory rate of 18/min. His oxygen saturations were 93% on air. There was no BCG scar seen on examination of his arm. Examination of his respiratory system revealed the presence of bilateral fine upper zone crackles but nil else and no respiratory distress. Examination of his cardiovascular system revealed no abnormalities including a normal JVP and the absence of pedal oedema, and examination of his gastrointestinal system was likewise unremarkable.

Initial investigations revealed the following:

Hb	166 g/l
Platelets	341 * 10 /l9
WBC	6.3 * 10 /l9
ESR	34 mm/hr
CRP	26 mg/l

Chest x-ray: Bilateral apical fibrosis

Pulmonary function testing

- FEV1 2.4 l (predicted value 2.3)
- FVC 2.6 l (predicted value 4.8)
- FEV1/FVC ratio 92%
- TLCO transfer factor 86% of predicted value

What is the most likely diagnosis?

A. Pulmonary hypertension
B. Pulmonary tuberculosis
C. Pulmonary fibrosis secondary to methotrexate
D. Extrinsic allergic alveolitis (EAA)
E. Pulmonary fibrosis secondary to ankylosing spondylosis

E. Pulmonary fibrosis secondary to ankylosing spondylosis

Upper zones lung fibrosis: ankylosing spondylitis

This gentleman has presented with a gradual history of progressing worsening shortness of breath on exertion and a dry cough. His spirometry illustrates a restrictive picture and chest x-ray confirms bilateral apical fibrosis. Of the above options, the most likely option is being secondary to ankylosing spondylosis. Methotrexate causes a lower zone fibrosis and of the remaining options, there is little evidence of exposure to suggest a diagnosis of EAA. There is little evidence to suggest the presence of clinically symptomatic pulmonary hypertension as manifest by the presence of a normal JVP and absence of peripheral oedema

. Question 42 of 133

A 10-year-old patient is referred to the respiratory outpatient clinic with recurrent chest infections associated with purulent sputum. His family life is chaotic and his parents frequently did not bring him to routine hospital appointments.

On examination, there are bilateral coarse crackles heard on chest auscultation, which clear on coughing. He is of thin body habitus. The nails are normal.

A chest x-ray shows evidence of bronchiectasis. A sputum sample grows *Burkholderia cepacia* . Genetic testing reveals that he is homozygous for the delta F508 mutation.

Given the likely diagnosis, which of the following is an appropriate treatment option?

A. Low calorie, low fat diet
B. Lumacaftor/Ivacaftor
C. Lung transplant
D. Mepolizumab
E. Octreotide

B. Lumacaftor/Ivacaftor

Lumacaftor/Ivacaftor (Orkambi) can be used to treat cystic fibrosis patients who are homozygous for the delta F508 mutation

Lumacaftor/Ivacaftor is the correct answer. The patient has cystic fibrosis as evidenced by recurrent chest infections, bronchiectasis and homozygosity for the delta F508 mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. It is known as 'Orkambi'. It has been shown to improve pulmonary function, increase weight and decrease pulmonary exacerbations. This patient's chaotic family life explains the delayed diagnosis.

Lung transplant is incorrect. This patient is colonized with *Burkholderia cepacia* , which is a CF contraindication to lung transplant.

Mepolizumab is incorrect. This is an IL5 inhibitor that is used in the treatment of refractory asthma, rather than CF. Given it is an immunosuppressant medication, it would probably have deleterious effects in CF where infections are common.

Low calorie, low-fat diet is incorrect. Patients with CF are often of low body weight and should be encouraged to have a high fat, high-calorie diet.

Octreotide is incorrect. This has been postulated to be of benefit in yellow nail syndrome, which is a rare cause of bronchiectasis. However, the nails are normal in this case and there are no pleural effusions, making this diagnosis unlikely

Question 43 of 133

A 27-year-old non smoker Chinese lady presents to the emergency department with sudden onset left pleuritic chest pain and shortness of breath. She explains that she has suffered from gradual deterioration in her exercise tolerance over the last year.

Chest x-ray demonstrated a large pneumothorax that is aspirated successfully. Repeat chest x-ray shows resolution of the pneumothorax but reticulonodular changes in the bases bilaterally.

CT chest: cystic changes in the lung bases with a minimal left sided pleural effusion

. What is the most likely diagnosis?

A. Neurofibromatosis
B. Alveolar proteinosis
C. Langerhans cell histiocytosis
D. Lymphangioleiomyomatosis
E. Hermansky Pudlak Syndrome

D. Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) affects premenopausal women causing proliferation of atypical smooth muscle cells in the lungs, lymphatics and uterus, most likely caused by oestrogens. There is associations with tuberous sclerosis and renal angiomyolipomas.

Presentation is with dyspnoea due to progressive interstitial lung disease, pneumothorax or chylous pleural effusion. Lung damage is similar to emphysema with pulmonary function tests showing reduced FVC, TLCO and KCO with increased TLC.

Medroxyprogesterone is an anti-oestrogen used to delay disease progression.

It is important to exclude metastatic sarcoma and atypical Langerhans cell histiocytosis. Langerhans cell histiocytosis affects smokers 20-40 years due to proliferation of Langerhans cells (antigen presenting cells containing Birkbeck bodies on electron microscopy). Presentation of LCH is with exertional dyspnoea and cough, spontaneous pneumothorax, clubbing and manifestation of granuloma infiltration in bones and the hypothalamus (diabetes insipidus is commonly seen).

Alveolar proteinosis most commonly affects males and can be secondary to insecticides, silica, HIV.

There is accumulation of lipoproteinaceous material in the alveolar spaces. Presentation involves dyspnoea, chest pain, haemoptysis and clubbing. Chest x-ray shows bat wings and diagnosis is confirmed with bronchoalveolar lavage (milky fluid, PAS positive material).

Hermansky Pudlak syndrome consists of oculocutaneous albinism, abnormal platelet function and interstitial lung disease.

Question 44 of 133

A 28-year-old man is referred by A&E to the acute medical team. He is a Swedish student studying for his PhD at the local university. He complains of a 6-week history of a non-productive cough associated with fevers. He denies haemoptysis or weight but admits that his exercise tolerance has reduced over the same period. He also reports pains in his knees, ankles and wrists and some painful red swellings on his legs. He admits to having had these before several years ago but they went away without any medical treatment and left no scars. He denies any bowel symptoms. On examination, he is afebrile and cardiovascularly stable. His respiratory rate is 18 at rest and his saturations are 96% on air. He has no palpable lymphadenopathy and his respiratory examination is normal, as is cardiovascular and abdominal examinations. His shins have bilateral tender red nodules on them.

His bloods results done by A&E are:

Hb	145 g/l
Platelets	365 * 10 /l9
WBC	9.1 * 10 /l9
Neuts	5.1 * 10 /l9
Na +	140 mmol/l
K +	4.2 mmol/l
Urea	5.4 mmol/l
Creatinine	82 µmol/l
Bilirubin	4 µmol/l
ALP	59 u/l
ALT	23 u/l
Albumin	43 g/l
CRP	5 mg/l
Adjusted calcium	2.65 mmol/l

His chest x-ray shows bilateral hilar lymphadenopathy with some small bilateral pulmonary infiltrates.

He goes on to have a CT chest which confirms the above findings. A bronchoscopy is performed

which is normal and transbronchial biopsies of the hilar lymph nodes show non-caseating granulomas.

What is the most appropriate treatment for this gentleman?

A. Prednisolone
B. NSAIDs
C. R-CHOP
D. Methotrexate
E. Nothing

A. Prednisolone

This gentleman has Lofgren's syndrome a presentation of Sarcoidosis characterised by Arthralgias, fevers, erythema nodosum and bilateral hilar lymphadenopathy. It is typically more common in Scandinavian patients and less common in Afro-Caribbean patients and typically has a much better prognosis. This gentleman has stage 2 sarcoidosis as indicated by the presence of BHL and pulmonary infiltrates on CXR. In this case, oral corticosteroids are the preferred treatment. For less symptomatic patients then supportive measures and NSAIDs for arthralgia are the preferred treatment options. For patients who are not responsive to steroids or steroid intolerant then immunosuppressant agents such as methotrexate can be tried. RCHOP is a chemotherapy regime used in lymphoma patients but the presence of non-caseating granulomas should suggest a diagnosis other than lymphoma

. Question 45 of 133

A 52-year-old woman presents to the respiratory clinic for review. She recently had a cough for which she received a week-long course of amoxicillin by her GP. As the cough had not settled within ten days, she returned to the GP who organised a chest X-ray. Afterwards, she was referred to the respiratory clinic due to the findings on it. This surprised her as by this point all of her symptoms had resolved. She has a past medical history of idiopathic intracranial hypertension, polycystic ovaries and type 2 diabetes mellitus. She takes only metformin and has no allergies. She has never smoked and has no occupational exposure of note. She drinks roughly one glass of wine per day. On examination she is obese but her chest is clear on auscultation. The chest X-ray demonstrates bilateral hilar lymphadenopathy.

Hb	127 g/l
Platelets	417 * 10 /l9
WBC	6.2 * 10 /l9
ESR	43 mm/hr
Na +	138 mmol/
K +	3.7 mmol/l
Urea	4.8 mmol/l
Creatinine	82 µmol/l
Corrected calcium	2.1 mmol/l

What is the most appropriate management plan?

A. Discharge without further investigation
B. Start ACE inhibitors
C. Monitoring of lung function tests
D. Start methotrexate
E. Start corticosteroids

C. Monitoring of lung function tests

he correct answer is to monitor lung function tests. This is a patient who has X-ray features consistent with sarcoidosis. As these are stage I X-ray features, there is no involvement of other

organs and the calcium is normal there is no need to start treatment with corticosteroids. Corticosteroids would be the mainstay of treatment if indicated. Sarcoidosis patients should have lung function assessed and a decline in lung function should warrant treatment.

Question 46 of 133

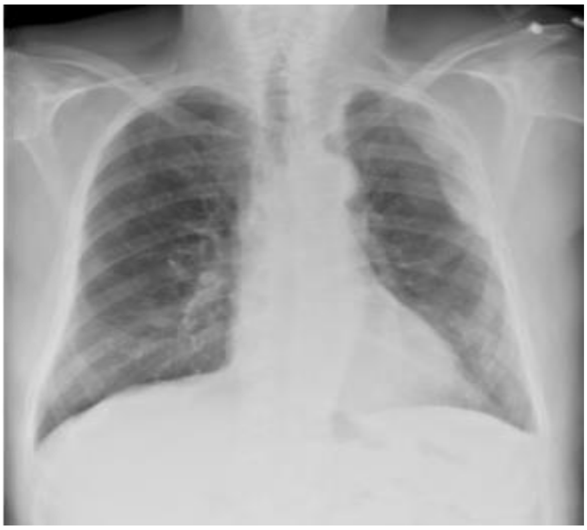
A 68-year-old builder presents to the emergency department with a 2-week history of worsening left-sided chest pain. The pain is sharp in nature and worsens on inspiration and movement, making him almost restricted to sitting down all day. He feels occasionally short of breath. His past medical history consists of peripheral vascular disease and chronic obstructive pulmonary disease (COPD).

On examination, he is afebrile. His heart rate is 88bpm with a blood pressure of 116/77mmHg. His respiratory rate is 21 breaths per minute with saturations of 91% on room air. On auscultation, there is mild wheeze bilaterally but no coarse crackles. Heart sounds are normal and abdominal examination is unremarkable. There is mild reproducible left-sided chest wall tenderness.

A number of investigations are requested. Laboratory results:

Hb	101 g/L	Male: (135-180)
MCV	71 fL	(80-100 fL)
Platelets	299 * 10 /L	(150 - 400)
WBC	8.1 * 10 /L	(4.0 - 11.0)
D-Dimer	501 ng/mL	(< 400)
Na	136 mmol/L	(135 - 145)
K	4.1 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	98 µmol/L	(55 - 120)
CRP	67 mg/L	(< 5)

Chest x-ray



What is the most likely diagnosis?

A. Asbestosis
B. Loculated pleural effusion
C. Mesothelioma
D. Pulmonary embolism
E. Small cell carcinoma

C. Mesothelioma

This patient has mesothelioma, a type of malignancy of the mesothelium, the tissue surrounding visceral organs including the lungs and chest wall, heart and abdominal cavity. Most commonly the pleura are affected. The biggest risk factor is asbestos exposure. With this patient having worked as a builder, it is very possible that he has come into contact with asbestos during his career. There is a visible opacification on the left lateral chest wall of the chest x-ray, in keeping with a pleural mass. Unlike other types of pulmonary malignancy that commonly affect the bronchi and lung parenchyma, mesothelioma affects the pleura and would therefore be located peripherally. One of the most common and important symptoms to recognise is severe chest wall pain as the tumour invades into the intercostal nerves.

Asbestosis is characterised by the development of lung fibrosis secondary to asbestos exposure. Important distinguishing features between asbestosis and mesothelioma are the presence of chest pain, progressive shortness of breath and constitutional symptoms such as fever, weight loss and night sweats. This patient is experiencing chest pain, fatigue and shortness of breath. Furthermore, his full blood count demonstrates microcytic anaemia which suggests the possibility of an underlying malignancy.

A pleural effusion is a collection of fluid within the pleural space. An exudative pleural effusion is more likely to become loculated. Appearances of loculated pleural effusions can sometimes appear similar to the chest x-ray shown in the question. However, the absence of a raised white cell count, in combination with a significant history of chest wall pain suggests an alternative diagnosis.

A pulmonary embolism is an important differential diagnosis given the raised D-dimer and pleuritic-sounding chest pain. Occasionally, a pulmonary embolism may have chest x-ray findings such as a wedge infarction. However, a raised D-dimer can also indicate an underlying malignancy. Furthermore, a peripherally-located lesion is unlikely to represent a pulmonary embolism.

Small cell carcinoma is a pulmonary malignancy commonly associated with tobacco use. As this patient has a history of COPD, it is likely that he has a significant smoking history. Asbestos exposure and tobacco use are synergistic to one another and increase the risk of malignancy. A small cell carcinoma tends to be located more centrally on chest x-ray films compared to mesothelioma as seen here

Question 47 of 133

A 62-year-old man was admitted to the hospital with a productive cough. Chest x-ray showed

right basal pneumonia. He responded well to intravenous antibiotics and was discharged after

being successfully weaned off oxygen.

What, if any, follow-up should this man receive?

A. CT thorax in 6 weeks to exclude malignancy
B. No follow-up required
C. Repeat chest x-ray in 6 weeks
D. Repeat chest x-ray in 6 weeks and routine respiratory clinic follow up
E. Respiratory clinic follow up routinely

D. Repeat chest x-ray in 6 weeks

All cases of pneumonia should have a repeat chest X-ray at 6 weeks after clinical resolution

Repeat chest x-ray in 6 weeks: the British Thoracic Society recommends repeating a chest x-ray for patients with confirmed pneumonia 6-12 weeks after clinical resolution. This is to exclude malignancy which can be obscured by active consolidation.

CT thorax in 6 weeks to exclude malignancy: a CT wound not be indicated in the absence of any other signs or symptoms. There would be no justification for the high level of radiation.

No follow up required: a chest x-ray is required to exclude underlying malignancy.

Repeat chest x-ray in 6 weeks and routine respiratory clinic follow up: there is currently no recommendation to arrange routine clinic follow up for pneumonia patients.

Respiratory clinic follow up routinely: there is currently no recommendation to arrange routine clinic follow-up for pneumonia patients.

Question 48 of 133

A 72-year-old gentleman presents with a five month history of dry cough and worsening shortness of breath on exertion. He undergoes extensive investigations and is diagnosed with idiopathic pulmonary fibrosis.

Bloods performed as part of the diagnostic work up show:

Hb	141 g/l
Platelets	255 * 10 /l9
WBC	5.2 * 10 /l9
ESR	32 mm/h
Na +	139 mmol/l
K +	3.6 mmol/l
Urea	4.7 mmol/l
Creatinine	92 µmol/l
CRP	15 mg/L

His lung function tests show a forced vital capacity (FVC) of 65% of predicted.

On examination the patient has obvious finger clubbing and fine end-inspiratory crepitations on auscultation of the chest.

Of note in his past medical history he smoked for ten years between the ages of 20 and 30.

He is understandably very distressed by the diagnosis and asks about potential therapies. He is enrolled on a pulmonary rehabilitation programme but is keen to try a pharmacological therapy.

Which drug should be considered in this patient?

A. Azathioprine
B. Prednisolone
C. Bosentan
D. Pirfenidone
E. Sildenafil

D. Pirfenidone

Idiopathic pulmonary fibrosis (IPF) is a chronic progressive disease with a dismal prognosis. In the UK the median survival is three years from diagnosis although a sub -group (approximately 20%) survive over five years. The disease rarely presents below the age of 45 and presenting symptoms include; breathlessness on exertion, persistent cough and fatigue.

Management of IPF has changed dramatically over the last decade. Previous small trials had shown small benefits of using a combination of corticosteroids with azathioprine and this combination remained the only pharmacological therapy for many years. Later larger trials demonstrated that this treatment regime confers no benefit and may actually cause harm thus the National Institute for Clinical Excellence (NICE) states that immunosuppressant therapies such as azathioprine, prednisolone and mycophenolate mofetil should not be used in IPF.

The only pharmacological therapy that has shown any benefit in IPF is pirfenidone, an immunosuppressant that has been shown to have anti-inflammatory and antifibrotic effects. The mechanism of action of pirfenidone is not completely understood but is thought that it suppresses fibroblast proliferation thus reducing the production of fibrosis-associated proteins and cytokines.

The only other therapeutic option for patients is lung transplantation and NICE recommends that any patients wishing to explore this option should be referred providing they have no absolute contraindications. Unfortunately, the speed of progression of the disease and availability of suitable organs means that this treatment modality is only used in a very small minority of patients.

It is clear from these guidelines that pirfenidone is the correct answer. Bosentan is an endothelin receptor antagonist used in the treatment of primary pulmonary hypertension. Sildenafil is a phosphodiesterase inhibitor which has vasodilating effects and is best known for its use in the treatment of erectile dysfunction. It was initially devised as a therapy for primary pulmonary hypertension and it has beneficial effects in this disease.

Question 49 of 133

A 78-year-old man with Chronic Obstructive Pulmonary Disease is reviewed in Respiratory clinic. He is complaining of decreased exercise tolerance with shortness of breath at rest. He suffers from exacerbations infrequently and does not have a productive cough. Oxygen saturations on air are 90%. His FEV 1 is 27% predicted.

He has a past medical history of osteoarthritis, ischaemic heart disease and chronic kidney disease.

His medications include Paracetamol, Ramipril, Aspirin, inhaled long acting beta agonist with inhaled corticosteroid and inhaled long acting muscarinc agonist. He has previously undergone pulmonary rehabilitation. He does not smoke

Investigations:

Hb	19.8 g/dL
WCC	6.0 *10^9/l
Platelets	180 *10^9/l
MCV	88fL

Echocardiogram: No abnormality seen.

CT Chest: Widespread mild bullous disease throughout upper and lower lung fields. Arterial blood gas on air:

Current	Four weeks previously	
pH	7.40	7.37
pCO2	5.1 kPa	4.7 kPa
pO2	7.5 kPa	7.4 kPa
HCO3	25 mmol/l	24 mmol/l

What is the most appropriate treatment?

A. Lung volume reduction surgery
B. Mucolytic therapy
C. Long term antibiotic prophylaxis
D. Oral corticosteroids
E. Long term oxygen therapy

E. Long term oxygen therapy

Lung volume reduction surgery. This is a possibility for patients with optimal medical therapy with symptomatic dyspnoea and severe COPD. It has improved mortality in patients with upper lobe predominant emphysema. This patient also has significant co-morbidities that make this option incorrect.

Mucolytic therapy. This patient is not suffering from a chronic productive cough, therefore, this is less likely to benefit the patient. It would be advisible to trial in patients for 3-4 weeks with a productive cough e.g. Carbocisteine.

Long term antibiotic prophylaxis. Minimal exacerbations in this patient and poor overall data make this option incorrect.

Oral Corticosteroids. This patient is not suffering from an exacerbation. Maintenance corticosteroids may be required in advanced disease if unable to wean off after an exacerbation.

Long term Oxygen therapy. This patient is suffering from severe COPD (FEV1 <30%). He has polycythaemia, it is likely to be secondary to COPD as he has normal platelets and MCV. LTOT is indicated in COPD if the pO2 is <7.3 on two separate ABGs 3 weeks apart. It can be offered to patients with a pO2 7.3-8 kPa with secondary polycythaemia, peripheral oedema, nocturnal hypoxaemia or pulmonary hypertension. He will need to be monitored on oxygen for hypercapnia and acidosis.

Question 50 of 133

A 54-year-old woman is reviewed in gastroenterology clinic following the insertion of a transjugular intrahepatic portosystemic shunt (TIPS). She is known to have alcohol related hepatic cirrhosis with portal hypertension and was found to have large varices on endoscopy and therefore underwent the insertion of a TIPS two months ago. However, she has started to feel breathless in the last month and found that her exercise tolerance has been reduced. She has otherwise felt well and denies any pain, confusion or nausea. On examination, there is evidence of chronic liver disease including palmar erythema, Dupuytren's contracture, spider naevi and leukonychia. Her chest is clear on auscultation. There is a loud P2 sound but otherwise, there are no abnormalities on cardiac auscultation.

What is the most likely cause of breathlessness?

A. Hepatorenal syndrome
B. Pulmonary hypertension
C. Anaemia
D. Pleural effusion
E. COPD

B. Pulmonary hypertension

The correct answer is pulmonary hypertension. This is a known complication of TIPS as the procedure causes an increased cardiac preload by diverting blood past the cirrhotic liver, thereby significantly reducing peripheral resistance. This can lead to pulmonary hypertension which can explain the patient's breathlessness. The absence of respiratory findings makes pleural effusion and COPD unlikely. With effusions, dullness and reduced air entry would be expected and COPD could occur with cirrhosis in anti-trypsin deficiency, but the absence of wheeze makes this very unlikely. Anaemia can occur, but is unlikely to be related to TIPS.

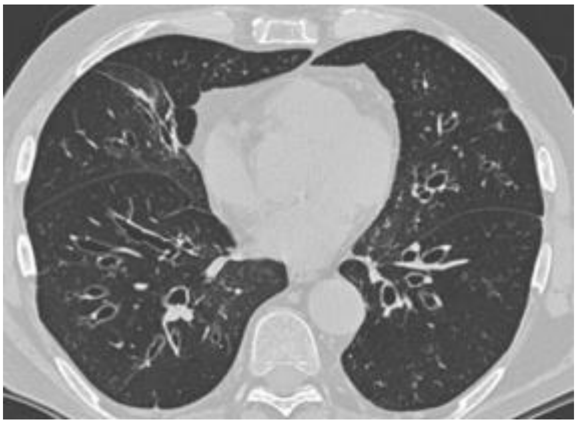
Question 51 of 133

A 45-year-old man is referred to the respiratory department due to increasing shortness-of-breath and frequent chest infections. He is a smoker (20 cigarettes/day). When he was a child he used a salbutamol inhaler but stopped this around the age of 6-7 years. He also had whooping cough as a child. Pulmonary function tests performed by his GP show the following:

FEV1	3.6 L (predicted 3.8 L)
FVC	4.3 L (predicted 4.5 L)
FEV1/FVC	84% (normal > 75%)

On auscultation of his chest scattered crepitations are noted. His oxygen saturations are 96% on room air.

A CT chest is requested:



What is the most likely diagnosis?

A. Lung cancer
B. Previous Bordetella pertussis infection
C. Emphysema
D. Kartagener's syndrome
E. Cystic fibrosis

B. Previous Bordetella pertussis infection

The CT scan shows signet-rings and tram-tracks consistent with bronchiectasis. This, in combination with normal pulmonary function tests makes a diagnosis of emphysema less likely.

We can also exclude cystic fibrosis (CF). Some patients with CF now survive to 45 years but it would be very unusual to reach this age without significant respiratory problems in the past. An exam question would never include such a bizarre history for CF.

There is also no evidence of situs inversus excluding Kartagener's syndrome.

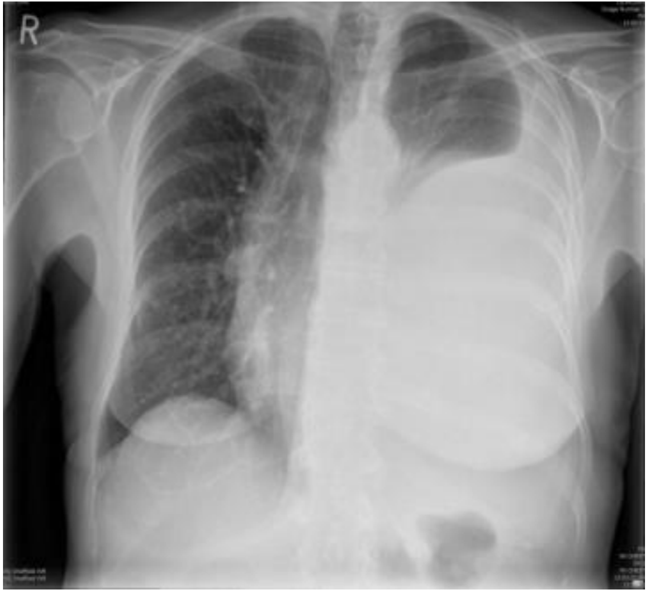
The bronchiectasis associated with lung cancer is confined to the area distal to the tumour. It would therefore not explain the bilateral symptoms.

The most likely diagnosis is therefore *Bordetella pertussis* infection, a known cause of bronchiectasis.

Question 52 of 133

A 52-year-old woman is referred to the Acute Medical Unit after developing progressive dyspnoea over the past 4 weeks. She has no significant past medical history of note.

On examination her respiratory rate is 18/min, pulse 84/min, blood pressure 102/64 mmHg and oxygen saturations 96% on room air. Temperature is 37.1ºC. A chest x-ray is performed:



What is the most appropriate initial management?

A. Insert a 26F chest drain after performing a thoracostomy
B. Arrange a high resolution CT chest
C. Prescribe intravenous antibiotics
D. Insert a 18F chest drain using the Seldinger technique
E. Pleural aspiration

E. Pleural aspiration

The first step in the management of this patient is pleural aspiration, preferably under ultrasound

guidance. This will help guide further management and determine the aetiology of the effusion.

There is no need for immediate chest drain insertion as she is stable.

The x-ray shows a large left-sided pleural effusion. The meniscus is well demonstrated on the superolateral aspect indicating fluid in the pleural space.

Question 53 of 133

A 60-year-old man is diagnosed with idiopathic pulmonary fibrosis after presenting with an 18- month history of progressive dyspnoea. His latest FVC is 60% of predicted.

What is the average life expectancy for such a patient from the time of diagnosis?

A. 3-6 months
B. 6-12 months
C. 12-18 months
D. 3-4 years
E. 8-12 years

D. 3-4 years

The correct answer in this case is **3-4 years**. Idiopathic pulmonary fibrosis (IPF) is a progressive, irreversible lung disease characterized by fibrosis of the lung parenchyma, leading to worsening dyspnoea and reduced lung function. The prognosis for IPF varies widely, but on average, the median survival from the time of diagnosis is around 3-4 years. In this patient with an FVC of 60% predicted, his life expectancy would also fall within this range.

The option **3-6 months** is incorrect because it represents a significantly shorter life expectancy than what is typically seen in patients with IPF. While some patients may have rapidly progressive disease or other complicating factors that could lead to a shorter survival time, the average life expectancy for someone with IPF is longer than this.

Similarly, the option **6-12 months** is also incorrect as it underestimates the average life expectancy for a patient with IPF. Although some patients may have a more aggressive form of the disease or other comorbidities that contribute to a worse prognosis, most patients can expect to live longer than one year following their diagnosis.

The option **12-18 months** still underestimates the typical life expectancy for someone diagnosed with idiopathic pulmonary fibrosis. While there are cases where individuals may experience rapid progression of their disease or have additional health issues that impact their prognosis, on average, individuals diagnosed with IPF tend to live longer than 18 months.

Lastly, the option **8-12 years** overestimates the average life expectancy for someone with idiopathic pulmonary fibrosis. Although there are cases where individuals may survive beyond this timeframe due to various factors such as early diagnosis and effective management strategies, these cases are less common and do not represent the average life expectancy for a patient with IPF

Question 54 of 133

A 63-year-old is reviewed following admission with an infective exacerbation of COPD. He originally presented with shortness of breath, tight-chestedness and feeling generally unwell. He was initially managed with medical treatment including IV piperacillin with tazobactam, IV hydrocortisone, IV fluids, nebulised salbutamol and nebulised ipratropium bromide but his hypercapnia and acidosis failed to improved. He was then initiated on non-invasive ventilation (NIV) starting with IPAP of 10 cm H2O and EPAP of 4 cm H2O. He has managed to have the IPAP increased to 14 cm H2O but he is struggling to tolerate this as he is feeling increasingly anxious. He has only had NIV for three hours so far.

Arterial blood gas results:

On admission	Current	
pH	7.11	7.23
pCO_2	14.7	12.1
pO_2	8.4	10.7

What is the most appropriate method to help him settle him?

A. Give him haloperidol
B. Give him diazepam
C. Increase IPAP
D. Increase EPAP alone
E. Stop NIV

A. Give him haloperidol

The correct answer is to give him haloperidol. Many patients struggle to tolerate an NIV mask as it is tight-fitting and blows air uncomfortably at the patient and it can be difficult to accustom too. When first introducing the mask to the patient explain what is happening to the patient as they may be confused, especially if hypercapnic, and gently place the mask on the patient's face. It can help to place the mask in the patient's hand and guide it to their face to facilitate cooperation. Show the patient how to take on and off the mask if they are able to do so as this may ease the process. In the acute phase it is important that there are frequent reviews to ensure the mask is being used. Many can begin to tolerate the mask over time.

Increasing the IPAP would make it more uncomfortable and would likely make him refuse the treatment entirely, even though it is likely to be needed to help relieve the hypercapnia as it creates greater ventilatory support.. Decreasing the IPAP or stopping NIV would be more comfortable but would be inappropriate as treatment is then likely to fail with greater hypoxia and acidosis. Diazepam is contraindicated in this situation as the added drowsiness can be dangerous, but haloperidol or morphine may help settle him sufficiently to tolerate the mask. Increasing EPAP without increasing IPAP would reduce the amount of ventilatory support and would be inappropriate

. Question 55 of 133

A 68-year-old is seen in a cardiology clinic. He has a part history of long-standing atrial fibrillation, hypertension and ischaemic heart disease. He describes progressive shortness of breath over the past year and a dry cough. His medication history includes aspirin, amiodarone, ramipril, doxazosin and gliclazide.

On examination, he is comfortable on lying flat but is noticeably dyspnoeic when mobilising. He has minimal ankle oedema, his heart rate is 78 beats per minute and he has fine bibasal crepitations on auscultation of his chest. His oxygen saturations on air are 92%.

An echocardiogram reveals a left ventricular ejection fraction of 45%, a mildly hypertrophied left ventricle and well established right ventricular hypertrophy, pulmonary artery pressures are raised at 32 mmHg (normal: < 25 mmHg). A chest x-ray shows non-specific changes on both bases.

What is the most appropriate next investigation?

A. Exercise stress test
B. Cardiac MRI
C. Overnight oximetry
D. Repeat echo
E. HRCT chest

A. HRCT chest

The raised pulmonary artery pressures and right ventricular hypertrophy points to a respiratory pathology. Despite the history of atrial fibrillation a cardiac cause is less likely to be causing his dyspnoea in view of the fact that he is comfortable when lying flat (i.e. no orthopnoea), he has minimal ankle oedema and that his left ventricular function is only mildly impaired. This patient should be investigated for interstitial lung disease in view of his history of amiodarone use. In light of this an exercise stress test, a cardiac MRI and a repeat echo are unlikely to be of any benefit and there is no indication to perform overnight oximetry. An HRCT is warranted to help aid establish a diagnosis.

Question 56 of 133

A 65-year-old lady with known severe emphysema attends the emergency department with breathlessness and is diagnosed with a non-infective exacerbation of chronic obstructive pulmonary disease. It is her 6th exacerbation this year. She tells you that she has been referred by her respiratory team for lung volume reduction surgery and is awaiting an appointment

Which of the following criteria would make the patient an unsuitable candidate for lung volume reduction surgery?

A. Predominantly upper lobe emphysema and high exercise capacity.
B. Non-upper lobe emphysema and high exercise capacity.
C. Predominantly upper lobe emphysema and low exercise capacity.
D. Upper lobe emphysema and carbon monoxide diffusing capacity 40%
E. Non-upper lobe emphysema and low exercise capacity

B. Non-upper lobe emphysema and high exercise capacity

The National Emphysema Treatment Trial was a prospective, randomised, multi-centre trial which compared the results of lung volume reduction surgery to medical therapy which showed that there were 3 groups of patients that tend to benefit:

Group 1: Upper lobe emphysema and low exercise capacity. These patients show improvement in both functional outcomes and survival after lung volume reduction surgery compared to medical therapy.

Group 2: Patients with predominantly upper lobe emphysema and high exercise capacity. These patients have improved functional outcomes but no difference in survival compared to medical therapy.

Group 3: Patients with non-upper lobe emphysema and low exercise capacity. These patients have improved survival after surgery but there is no difference in survival compared to medical therapy.

The trial also identified patients with emphysema that are unlikely to do well from lung volume reduction surgery and have a high risk of death. This includes:

1. Patients with non-upper lobe emphysema and high exercise capacity.

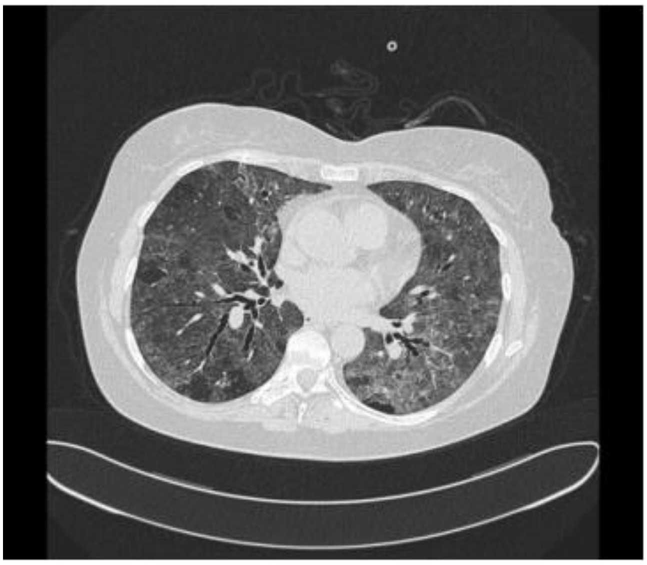
2. Patients with extremely poor pulmonary function (forced expiratory volume in 1 second (FEV1) 20% or less than predicted) and either homogenous distribution of emphysema on

Question 57 of 133

A 60-year-old woman is investigated for recurrent episodes of dyspnoea. She describes becoming progressively more short-of-breath over the past two years with frequent exacerbations associated with fever, lethargy and coughing bouts. Her symptoms often settle down for a time but she does feel her breathing is getting worse over time.

She smokes 20 cigarettes/day, drinks 10 units of alcohol per week and works in a poultry farm. Her past medical history includes hypothyroidism and depression.

On examination her oxygen saturations on air are 94%. A CT scan is requested:



What is the most likely diagnosis?

A. Bronchiectasis
B. Hypersensitivity pneumonitis
C. Sarcoidosis
D. Histiocytosis
E. Histoplasmosis

B. Hypersensitivity pneumonitis

This lady most like had acute hypersensitivity pneumonitis to start with which has now progressed to the sub-acute/chronic form. The diagnosis is suggested by her occupation, intermittent symptoms and CT findings which show multuple centrilobular ground glass nodules.

Question 58 of 133

A 54-year-old male is reviewed in the respiratory clinic. He originally presented with progressive shortness of breath and a dry cough, while having no other significant history or exposure to chemicals or environmental triggers. He is a non-smoker and does not take any medications.

Examination is consistent with bibasal inspiratory crackles and there is evident clubbing. There is no signs of cardiac failure. He currently saturates at 94% on air and has a known FVC of 70% measured at his last appointment.

His pulmonary function test reveals a restrictive pattern and a high resolution CT is undertaken concluding:

'Bilateral lung volume loss with >5% honeycombing extensively at the bases and subpleural areas with evidence of peripheral traction bronchiectasis, extensively at the lung bases'.

Prior blood investigations have been negative with regards to any connective tissue disease.

He has already been referred for pulmonary rehabilitation but is wondering whether any medication could potentially alter the course of his disease.

Which medication can be used to reduce functional decline in this group of patients?

A. Azathioprine
B. Sildenafil
C. Prednisolone
D. Bosentan
E. Pirfenidone

E. Pirfenidone

Pirfenidone and nintedanib can be used as drug management options in idiopathic pulmonary fibrosis as they may decrease the functional decline, prolong survival and potentially reduce acute exacerbations

The patient in question suffers from idiopathic pulmonary fibrosis (usually interstitial pneumonia type) as evident by the restrictive pattern, lack of history suggestive of other causes of fibrosis alongside the pathognomonic CT features. Therefore the question really focuses on the pharmacological management of this disease bearing in mind its irreversible nature.

Pirfenidone and nintedanib are two antifibrotic agents currently licensed for use in the UK provided the forced vital capacity (FVC) between 50% and 80% predicted given the evidence in literature currently.

Sildenafil is a phosphodiesterase-5-inhibitor that has been trialled in such patients in order to examine the potential of improved oxygen delivery; a study in 2010 concluded that there was no potential benefit in the use of sildenafil in such patients, except where pulmonary hypertension exists. Prednisolone and steroid use in

patients with idiopathic pulmonary fibrosis as a disease modifier has not been proven to be beneficial.

Bosentan is a dual endothelin receptor antagonist that is currently licensed for the treatment of pulmonary arterial hypertension. As per the BUILD-3 trial, the use of bosentan does not delay idiopathic pulmonary fibrosis progression or death.

Azathioprine is a purine analogue which is used in a variety of autoimmune conditions. It has been used extensively in the past in caring for patients with idiopathic pulmonary fibrosis as part of the triple therapy of prednisolone/azathioprine/N-acetylcysteine; however due to PANTHER-IPF study and the increased hospitalisation of patients with side-effects of immunosuppression the study has been put on hold and this treatment is encouraged to be avoided.

Question 59 of 133

A 24-year-old male is reviewed on the trauma ward 5 days after a road traffic collision. He suffered multiple injuries most significant of which included an extradural haematoma, right-sided pneumothorax, and a femoral fracture. The patient was initially intubated, had a chest drain inserted, and underwent intramedullary nailing. The extradural haematoma was managed conservatively.

The patient was successfully extubated 3 days ago and has had his oxygen requirements progressively weaned. Today on the ward round the patient reports his breathing is improving but he has still some dyspnoea on exertion and is requiring 2L via nasal prongs. The chest drain is swinging and has on-off bubbling. There is good air entry heard throughout the chest.

What is the most appropriate course of action?

A. Apply suction to the drain
B. Remove the chest drain
C. Reposition the drain and increase the patient oxygen delivery
D. Seek a thoracic surgical opinion
E. Leave the drain in situ and review in 24 hours

D. Seek a thoracic surgical opinion

When draining a pneumothorax, if after 3-5 days there is persistent air leak (e.g. bubbling chest drain) or failure of the lung to re-expand, a thoracic surgical opinion should be sought

Repositing of the drain is incorrect as there is no evidence that the drain has moved or become displaced. Oxygen delivery can assist resolve a pneumothorax however as it has been over 5 days further management may be required.

The drain could be left in situ and review in 24 hours however it has already been 5 days since it was originally inserted and there is evidence of a persistent leak and therefore surgical opinion should be sought.

Question 60 of 133

An 82-year-old gentleman with known chronic obstructive airways disease (COPD) is about to be discharged from hospital after being admitted with an infective exacerbation. He is now off antibiotics and has just completed a seven-day course of prednisolone. He remains hypoxic on room air S 0 91%.

Bloods show:

Hb	134 g/l
Platelets	350 * 10 /l9
WBC	10.2 * 10 /l9

Arterial blood gas analysis shows:

P 0 a 2	7.8 kPa
P CO a 2	6.5 kPa
HCO 3 -	30 mmol/L

The patient's wife asked about having oxygen at home.

What other investigations are needed to assess whether this patient would benefit from long-term oxygen therapy?

A. Oxygen saturations before and after exercise
B. Pulmonary function tests
C. Computed tomography (CT) of the chest
D. Chest x-ray
E. Echocardiogram

E. Echocardiogram

Long-term oxygen therapy (LTOT) refers to the prolonged domiciliary use of oxygen for patients with medical conditions that result in a state of chronic hypoxaemia (P 0 at or below 7.3kPa). The patient is assessed so that the flow rate of oxygen they receive results in a waking oxygen tension above 8kPa. LTOT is usually prescribed indefinitely and to be of benefit has to be used for a minimum of 15 hours a day including at night time. The indications for LTOT are well established.

The British Thoracic Society (BTS) advises that LTOT may be of benefit in patients with the following conditions:

- Chronic obstructive pulmonary disease
- Severe chronic asthma
- Interstitial lung disease
- Cystic fibrosis
- Bronchiectasis
- Pulmonary vascular disease
- Primary pulmonary hypertension
- Pulmonary malignancy
- Chronic heart failure

Patients with any of the above conditions can be assessed to see if they would benefit from LTOT.

BTS guidelines currently state that patients should have a P 0 consistently at or below 7.3kPa on air at a time when they are clinically stable (absence of exacerbation in previous five weeks).

Another group of patients who can be prescribed LTOT are those with chronic hypoxaemia and a Pao2 between 7.3kPa and 8kPa and the presence of either secondary polycythaemia or clinical and/or echocardiographic evidence of pulmonary hypertension.

In the above case, the patient has chronic hypoxaemia. Ideally, this patient would have his arterial blood gases analysed five weeks following this exacerbation, but assuming that his results are similar and his haemoglobin remains the same then he would require evidence of pulmonary hypertension to benefit from LTOT thus an echocardiogram is the best answer to this question.

Question 61 of 133

A 62-year-old man with metastatic small cell lung cancer is admitted with a shortness of breath, cough and purulent sputum.

His chest x-ray shows a right lower lobe pneumonia with partial collapse of the right lung. He has a bulky primary tumour at the right hilum and extensive hilar lymphadenopathy.

He is treated with IV antibiotics, fluids and oxygen. His symptoms improve over the next 5 days and his breathing is comfortable on 2 litres of oxygen via nasal cannulae. His pain is controlled on 20mg long-acting morphine sulphate twice daily. The decision is made to discharge him to a hospice for end-of-life care. However, due to the proximity of his lung tumour to major vessels, he is at risk of a major terminal bleed.

Which medication should the hospice be advised to give in the event of a major bleed?

A. Haloperidol
B. Midazolam
C. Morphine
D. Tranexamic acid
E. Vitamin K

B. Midazolam

This patient may experience a terminal catastrophic bleed due to erosion of his lung tumour through a major vessel. Patients at risk of such an event should be issued with a 'crisis pack' containing midazolam and green or blue towels which can help soak up blood whilst masking some of the colour. Midazolam can be administered intravenously if access available or otherwise intramuscularly. The aim is to minimise the anxiety and distress.

Haloperidol is a useful anxiolytic and antiemetic in end-of-life care but is not as effective in this situation. Morphine is used for pain and breathlessness in the terminal setting.

Tranexamic acid may be given is cases of slow gastrointestinal bleeding due to malignancy. Vitamin K is used to lower the INR in patients with a bleed on warfarin or with liver failure.

Question 62 of 133

A 38-year-old woman is referred to the respiratory clinic due to a pulmonary nodule detected on a CT scan. She was admitted to her local hospital two months ago with aspiration pneumonia and treated with intravenous antibiotics. A chest X-ray demonstrated left-sided consolidation. She was also managed for alcohol withdrawal. She required three days of in hospital before being discharged with oral antibiotics and community alcohol liaison services to follow-up. Her GP repeated her chest X-ray six weeks following discharge and was concerned that an area of consolidation remained on the repeat chest X-ray. The GP, therefore, arranged for a CT chest which demonstrated a pulmonary nodule 5mm in diameter on the right side. There was no evidence of consolidation.

How should this nodule be investigated or monitored?

A. Urgent CT-PET
B. Urgent image-guided biopsy
C. CT chest in three months
D. CT chest in one year
E. No further investigations needed

D. CT chest in one year

The correct answer is CT chest in one year. As the patient has a pulmonary nodule 5mm in size there will need to be further monitoring. As it is 5-6mm in size this means that monitoring should take form in terms of a CT scan in one year

Question 63 of 133

An 83-year-old man attends hospital with an infective exacerbation of COPD. He had become increasingly short of breath with an episode of rigors and a dry cough. He is started on salbutamol and ipratropium nebulisers and steroids but fails to improve clinically. After careful discussion, he is offered non invasive ventilation and he tolerates this well. He is slow to improve and 36 hours later, he starts to become more breathless.

On examination, he has crackles and wheeze on the right hemithorax. The left hemithorax has reduced air entry throughout and is resonant to percuss. There are no added sounds., no JVP or leg oedema that can be seen but there is accessory muscle use. He is tired and feels 'absolutely awful'. The non-invasive ventilation is currently set at IPAP 26 cm H2O and EPAP 6 cm H2O. The mask is well adjusted and there is no significant mask leak. A repeat chest x-ray is pending.

Chest X-ray (on admission): hyperinflation, no consolidation seen
ABG (admission)

pH	7.32
PaO2	7.6kPA
PaCO2	7.4 kPA
HCO3	30mmol/L

ABG (1hr after starting NIV)

pH	7.36
PaO2	9.2kPA
PaCO2	6.2 kPA
HCO3	28mmol/L

ABG (now)

pH	7.34
PaO2	6.5kPA
PaCO2	7.0 kPA
HCO3	28mmol/L

What is the cause of this deterioration?

A. Poor compliance with NIV Poor compliance with NIV
B. Patient-ventilator dyssynchrony
C. Pneumothorax
D. Aspiration
E. Hospital acquired pneumonia

C. Pneumothorax

Pneumothorax can occur following high pressure non-invasive ventilation

The patient has deteriorated from a respiratory viewpoint on NIV despite earlier improvement. First, we must consider if he is breathing against the machine (dyssynchrony) but we are told he is tolerating it well. There is no evidence to suggest that he has not complied with the NIV. He may have aspirated but there is no history of vomiting or copious secretions. He examination signs are consistent with a pneumothorax on the left side rather than a hospital acquired pneumonia. Pneumothorax is a recognised complication of NIV particularly when higher inflation pressures are used. Please not that initial pressures started are 12cm H20 IPAP and 4 cm H2O EPAP and this gentleman was on significantly higher pressures.

Question 64 of 133

You are called by the general surgical registrar for a medical consult for their patient.

A 19-year-old Caucasian male presented with a two-day history of epigastric pain associated with nausea and vomiting. He was found to have an elevated serum amylase level and thus admitted under the surgical team for management of acute pancreatitis. The surgical team have asked for a medical consult due to the patient reporting worsening productive cough.

Upon your review, the patient reports that this is his third presentation with acute pancreatitis. He does not drink alcohol and an ultrasound of the abdomen did not reveal any gallstones. The cough has been present for several months. Initially, this was a dry cough but more recently has been become productive of green sputum with no haemoptysis. He denies fever, chills, chest pain and dyspnoea. Three weeks prior to this presentation he had received a course of oral antibiotics from his General Practitioner after presenting with nasal congestion and mild facial pain. He states having had multiple courses of antibiotics in the past for similar presentations.

There is no further past medical history or family history of note.

He takes no regular medications and has been receiving simple analgesia and intravenous crystalloid fluids whilst under the care of the surgical team. He is a lifelong non-smoker and works full time in administration.

On examination his height was 178cm with a weight of 58kg, heart rate 90/minute, blood pressure 100/60 mmHg, temperature 37.2ºC, respiratory rate 16/min and oxygen saturation 94% on room air. Respiratory examination revealed early clubbing, no cervical lymphadenopathy, a central trachea, normal chest expansion, mild coarse inspiratory crepitations that improved somewhat after coughing at both posterior bases. Abdominal examination revealed mild epigastric tenderness but no signs of peritonism. Remaining clinical examination was unremarkable.

Hb	130 g/l	Na	136 mmol/l
Platelets	400 * 10 /l	K	4 mmol/l
WBC	12 * 10 /l	Urea	6 mmol/l
Neuts	10 * 10 /l	Creatinine	65 µmol/l
Lymphs	1 * 10 /l	CRP	30 mg/l
Eosin	1 * 10 /l		

Chest x-ray was normal.

Sputum microscopy and culture results revealed *Pseudomonas aeruginosa*

Which of the following would be the most appropriate management for this patient?

A. Intravenous ceftazidime and nebulised tobramycin for 14 days
B. Intravenous benzylpenicillin and oral doxycycline for 7 days
C. Oral ciprofloxacin for 7 days
D. Nebulised saline
E. Observe and repeat sputum microscopy and culture in the community once fullyrecovered from the acute pancreatitis

A. Intravenous ceftazidime and nebulised tobramycin for 14 days

Attempts at *Pseudomonas aeruginosa* eradication are important in patients with cystic fibrosis

This patient who presents with recurrent sinusitis, recurrent pancreatitis, clubbing and signs of bronchiectasis on examination likely has undiagnosed cystic fibrosis. *Pseudomonas aeruginosa* eradication is important in such patients and should be treated aggressively.

Whilst traditionally cystic fibrosis (CF) is considered a paediatric disease, it is becoming increasingly important for adult physicians to be aware of the clinical manifestations and complications of CF for two main reasons:

- 10% of patients are still identified when they are more than 18 years of age
- With advances in diagnosis and treatment, the median age of survival for patients with CF is around 40 years, meaning you are likely to care of adult patients with CF during your clinical practice

Patients born before widespread neonatal screening became available are the cohort that may present with CF in adulthood. They also tend to have a more mild phenotype therefore not attracting medical attention earlier in life and may present with other CF complications, such as pancreatitis, sinusitis, intestinal obstruction or male infertility.

Chronic infection with *Pseudomonas aeruginosa* in patients with CF is associated with more rapid loss of lung function, frequent pulmonary exacerbations and a shorter median survival. It is also very difficult to eradicate *Pseudomonas aeruginosa* once chronic infection has been established. The key is to try to eradicate the organism once it is a first isolated, which requires acute aggressive treatment. In this case, given the diagnosis of CF is new, it should be presumed that this is a new sputum isolate of *Pseudomonas aeruginosa* .

There is no consensus on which anti-microbial strategy is best for *Pseudomonas aeruginosa* eradication. Options include:

- Intravenous anti-pseudomonal antibiotic plus inhaled aminoglycoside for 14 days
- A prolonged course of oral Ciprofloxacin (e.g. 6 weeks)

Option 1 is the correct answer.

Option 2 is a regime used more commonly for moderate community acquired pneumonia and would not be effective at eradicating *Pseudomonas aeruginosa*

Option 3 would have anti-pseudomonal cover but the duration is too short

Option 4 may help with sputum clearance but would not eradicate the *Pseudomonas aeruginosa*

Option 5 would increase the likelihood of chronic *Pseudomonas aeruginosa* infection developing and adversely affect the patient's prognosis

Question 65 of 133

A 23-year-old gentleman presents with severe shortness of breath and tight-chestedness. On examination, he is very wheezy, his respiratory rate is high but he is speaking in full sentences. He is a known to have asthma and was out in a storm when he suddenly noticed shortness of breath, wheezing and felt his chest becoming tight. His asthma is normally well controlled only occasionally requiring the use of a salbutamol inhaler. He is thought to have thunderstorm asthma.

What is thought to be the aetiological cause?

A. exacerbation
B. Electrical charge causing irritation
C. Sudden spore and pollen release due to pressure changes
D. Increase in winds causing exacerbation
E. Anxiety triggering asthma attack

C. Sudden spore and pollen release due to pressure changes

The correct answer is sudden spore and pollen release due to pressure changes. Thunderstorm asthma is a rare event in which the pressure changes in a thunderstorm causes the release of pollen and spores which trigger asthma exacerbation, which can occur in people not previously known to have asthma. The wet conditions at the beginning of a thunderstorm can cause pollen grains to rupture leading to increased amounts of allergen as well. Cold air and anxiety may also provoke asthma attacks, but these causes are not specifically associated with thunderstorms.

Question 66 of 133

A 45-year-old man presents to the emergency department with a 48-hour history of shortness of breath, wheezing, and chest tightness. He has a past medical history of asthma.

Upon arrival his observations are as follows; respiratory rate 30/min, oxygen saturations 88% on room air, heart rate 110/min. Auscultation revealed decreased air entry with wheeze throughout both lung fields.

Oxygen was administered via a non-rebreather mask. Nebulised salbutamol and ipratropium bromide were administered back-to-back. He also received intravenous corticosteroids and magnesium sulphate.

Following initial therapy, his oxygen saturations are 98% on 15L via a non-rebreather, his respiratory rate is 34/min, his heart rate is 108/min, and his blood pressure is 112/73mmHg. An arterial blood gas is performed.

pH	7.40	(7.35 - 7.45)
pO2	15.7kPa	(>8)
pCO2	5.0 kPa	(4.5 - 6.0)
HCO3-	22.7mEq/L	(22 - 26)
Base excess	-1.2mEq/L	(-2 to +2)

What is the most appropriate ongoing management plan for ongoing respiratory support?

A. Bi-level positive airway pressure (BiPAP)
B. Continue current management
C. Continuous positive airway pressure (CPAP)
D. Referral to intensive care to intubation and ventilation
E. Wean oxygen

D. Referral to intensive care to intubation and ventilation

Patients with features of acute life-threatening asthma who fail to respond to treatment, should be referred to intensive care for potential intubation and ventilation

Despite being tachypnoeic, this patient has a normal pCO2 which is a sign of life-threatening asthma. This is despite therapy with bronchodilators, corticosteroids, and magnesium. Therefore, this patient needs **referral to intensive care for intubation and ventilation**.

BiPAP is not generally used in the treatment of asthma as there is significant potential for air trapping so ventilation should be carried out in intensive care. Therefore this option is incorrect.

To **continue current management** would not be an appropriate response in this instance. This patient has failed to respond to therapy and is showing signs of life-threatening asthma. Therefore, this patient needs a referral to intensive care.

CPAP, similar to BiPAP, is not routinely used in the management of asthma. CPAP does not help with ventilation and therefore CO2 clearance. It also poses a significant risk of air trapping in asthmatics. Therefore, referral to intensive care would be more appropriate.

Although this patient has adequate saturations, it would be inappropriate to **wean oxygen** as this does not address the normal pCO2 which is a life-threatening sign.

Question 67 of 133

A 76-year-old woman presents to clinic with shortness of breath. This has been progressing over the last 18 months and is associated with a non-productive cough. She is still able to complete her usual day-to-day tasks but struggles with more exertional activities such as gardening.

She finished chemotherapy for non-Hodgkin's lymphoma two years ago. She has no other relevant medical history.

Her current medications include allopurinol, bisoprolol, aspirin, simvastatin, paracetamol and codeine.

On examination, she has finger clubbing and diffuse fine crackles on chest auscultation.

Given the likely diagnosis, which of the following spirometry results would you expect?

A. FEV1 - 1.4L (71%), FVC - 2.5L (102%), FEV1/FVC ratio - 56%, DLCO - 90% of predicted
B. FEV1 - 1.3L (66%), FVC - 1.6L (65%), FEV1/FVC ratio - 81%, DLCO - 75% of predicted
C. FEV1 - 1.9L (97%), FVC - 2.4L (98%), FEV1/FVC ratio - 79%, DLCO - 110% of predicted
D. FEV1 - 0.9L (45%), FVC - 2.1L (86%), FEV1/FVC ratio - 42%, DLCO - 90% of predicted
E. FEV1 - 0.9L (45%), FVC - 1.1L (45%), FEV1/FVC ratio - 81%, DLCO - 120% of predicted

B. FEV1 - 1.3L (66%), FVC - 1.6L (65%), FEV1/FVC ratio - 81%, DLCO - 75% of predicted

The patient likely has a restrictive lung defect, caused by pulmonary fibrosis. This may be due to a chemotherapy agent, such as bleomycin from her chemotherapy.

Obstructive spirometry:

- FEV1 reduced (<80% predicted normal)
- FVC is usually reduced but to a lesser extent than FEV1
- FEV1/FVC ratio reduced (<0.7)

Restrictive spirometry:

- FEV 1 reduced (<80% predicted normal)
- FVC reduced (<80% predicted normal)
- FEV 1 /FVC ratio normal (>0.7)

DLCO (diffusing capacity of the lung for carbon monoxide) measures the ability of the lungs to transfer gas from inhaled air to the red blood cells in pulmonary capillaries

Decreased DLCO

Restrictive lung disease

- Idiopathic pulmonary fibrosis
- Occupational lung disease
- Hypersensitivity pneumonitis
- Miliary tuberculosis
- Pneumonectomy

Obstructive lung disease

- Cystic fibrosis
- Emphysema

Other causes

- Chronic pulmonary embolism
- Congestive heart failure
- Primary pulmonary hypertension

Increased DLCO

Causes

- Pulmonary haemorrhage
- Polycythaemia
- Left to right cardiac shunting

Answer 1 and 4 both show obstructive patterns. Answer 3 is a normal spirometry pattern. Answers 2 and 5 both show a restrictive pattern. However, answer 5 has a raised transfer factor. In druginduced restrictive lung disease this would be low.

Question 68 of 133

A 32-year-old man is admitted to the acute medical unit with acute shortness of breath. Blood cultures are positive for Staphylococcus aureus. He has a pan systolic murmur heard loudest over the left sternal edge.

A chest x-ray confirms a cavitating mass in the right lung with associated pleural effusion. You perform a pleural tap which is as follows:

pH	7.15
Protein	42 g/l
Appearance	Serous

What test can be performed to assess if the effusion is an empyema?

A. Video-assisted Thoracoscopic Surgery (VATS)
B. Thoracic ultrasound
C. Chest x-ray
D. Centrifugation of the pleural aspirate
E. Plasma C-reactive protein (CRP)

D. Centrifugation of the pleural aspirate

If the pleural fluid is turbid or milky it should be centrifuged. If the supernatant (liquid which lies above the sediment) is clear, the turbid fluid was due to cell debris and empyema is likely

The history and clinical features are suggestive of right sided endocarditis with septic emboli to the lungs. The pleural fluid is an exudate, and the pH < 7.20 indicates that this is a complicated parapneumonic effusion which requires drainage.

Aspiration of frank pus is diagnostic of an empyema and no other investigations are required to establish the diagnosis, with the exception of pleural fluid microbiology to guide antibiotic therapy. If the aspirate does not reveal frank pus, further analysis is required to assess whether it is a complicated parapneumonic effusion. This involves measurement of the pleural fluid pH, total protein concentration, LDH level, glucose concentration, and white cell differential.

If an effusion is not frankly purulent, but empyema is suspected, then the sample should undergo centrifugation and if the supernatant becomes clear, empyema is the most probable diagnosis; otherwise, the differential diagnosis is between lipid pleural effusions and

Question 69 of 133

A 70-year-old lady with a background of type 2 diabetes mellitus and alcohol abuse presents with a fever and productive cough. She reports no weight loss or haemoptysis. She was born in England and has never travelled outside of the United Kingdom. She has never smoked cigarettes. On examination, she has crackles in her right upper lobe but is otherwise well and stable. A chest radiograph reveals consolidation which is cavitating in her right upper lobe.

What is the most likely diagnosis?

A. Lung cancer
B. Tuberculosis
C. Pneumococcal pneumonia

D. Klebsiella pneumonia
E. Aspergillosis

D. Klebsiella pneumonia

Klebsiella most commonly causes a cavitating pneumonia in the upper lobes, mainly in diabetics and alcoholics

Klebsiella pneumonia is particularly associated with diabetic and alcoholic patients. It leads to a cavitating upper lobe pneumonia. Differentials for this lady would include lung cancer and tuberculosis but these would usually be associated with weight loss and travel to eastern Europe or Asia respectively. the optimal treatment for Pneumocystis jirovecii which can cause severe bilateral pneumonia. However, it is most commonly seen as an opportunistic infection in patients with impaired cellmediated immunity, classically patients with HIV infection. In this case, there is no suggestion of significant immunocompromise and a typical pathogen has been isolated. It is therefore more appropriate to target therapy against this organism.

Change to IV ertapenem is incorrect. Ertapenem is a carbapenem (the same class as meropenem) with extremely broad-spectrum antimicrobial activity. However, the main difference between ertapenem and meropenem is that the former lacks activity against Pseudomonas species. It would therefore not be effective in this case

Question 70 of 133

A 65-year-old man presents to his GP after his wife complains he snores very loudly and occasionally stops breathing at night. He also falls asleep easily during the day while watching television or reading. He had bilateral tonsillectomies and adenoidectomy as a child. On examination, his height is 1.80m and his weight is 100kg. He has lost 15kg of weight in the last six months but his symptoms have persisted. His GP refers him for a sleep study which is suggestive of moderate sleep apnoea.

What initial management option should be recommended?

A. Further weight loss and repeat sleep study thereafter
B. Lifestyle advice including sleep hygiene
C. Mandibular advancement splint
D. Referral for CPAP
E. Referral to ENT for surgery

D. Referral for CPAP

Following weight loss, CPAP is the first-line treatment for moderate/severe obstructive sleep apnoea

Patients with symptoms suggestive of obstructive sleep apnoea (OSA) that affect their quality of life should be offered continuous positive airway pressure (CPAP) if they have moderate or severe OSA, in addition to lifestyle advice.

Weight loss as part of lifestyle advice may be appropriate as first-line treatment for patients with mild sleep apnoea. However, this patient has already tried to lose weight without any benefit. Furthermore, they have moderate sleep apnoea and should be offered CPAP alongside lifestyle advice. Patients who feel that their OSA has resolved following lifestyle modification can have a trial of stopping treatment for two weeks and then an evaluation of their symptoms or a repeat sleep study.

Lifestyle advice regarding sleep hygiene, reducing alcohol and smoking and weight loss is important but NICE recommends that it should be provided alongside CPAP in patients with moderate to severe OSAA mandibular advancement splint is not first-line in treating sleep apnoea but can be offered to those who do not tolerate CPAP and have good dental health. This patient should thus be offered CPAP first.

Question 71 of 133

A 57-year-old male presents with a three-month history of unintentional weight loss (13kg over 3 months) and a chronic non-productive cough. He has just returned from a months holiday in India. He denies haemoptysis or chest pain. He is a lifelong smoker. He has no past medical history except a period of generalised limb weakness two years ago when he was referred to outpatient neurology clinic and diagnosed with Lambert-Eaton myasthenic syndrome following investigations. His blood tests are unremarkable. However, his chest x-ray demonstrates a rounded opacity in his right midzone, about 4 cm from his right main bronchus.

What is the most likely diagnosis?

A. Tuberculosis
B. Aspergilloma
C. Small cell lung carcinoma
D. Non-small cell carcinoma
E. Pneumocystis jirovecii infection

C. Small cell lung carcinoma

The patient was treated four years ago for Lambert-Eaton syndrome (LEMS), a neurological disorder characterised by limb weakness that improves with exercise, affecting proximal muscles more than distal muscle. It is caused by antibodies directed against voltage-gated calcium channels and has a strong association with malignancy. Up to half of all LEMS patients has an underlying malignancy, the most common of which is small cell lung carcinoma. Neurological symptoms often precede malignancy diagnosis by around 5 years

Question 72 of 133

A 32-year-old taxi driver attends the emergency department with pleuritic right-sided chest pain. He is a current smoker of 15 cigarettes/day. He reports feeling unwell for 10 days with a cough and fever. The chest pain started gradually over the last 2 days becoming slowly more severe. A chest x-ray shows right sided consolidation and an effusion. He is commenced on penicillin antibiotics. Pleural aspirate under ultrasound guidance shows a simple effusion and the following results:

Appearance	Serous
pH	7.30
Protein	46 g/l
LDH	400 IU/l
Glucose	3.7mmol/l
Gram stain	No organisms or malignant cells seen

Culture	No growth

What is the next best step?

A. Intercostal drain
B. Continue antibiotics and observe
C. CT thorax with contrast
D. Repeat pleural aspirate in 24 hours
E. Further investigation with bronchoscopy

B. Continue antibiotics and observe

This patient has evidence of pneumonia. The unilateral effusion is confirmed as an exudate and can be assumed to be a parapneumonic effusion. There is no indication for chest drain currently (purulent fluid, pH<7.2, organisms on Gram stain or culture) so he can continue antibiotics and be observed. If he fails to improve he would need repeat pleural sampling. If there was no clear infective cause a CT thorax with contrast would be performed to look for underlying malignancy. Bronchoscopy is only performed when there is suspicion of bronchial obstruction.

Question 73 of 133

A 45-year-old lady presented to clinic with a four-month history of worsening cough with bloodstained sputum and exertional dyspnoea. She reported having lost over 8 kg in weight during this time, with a reduced appetite. She started smoking as a teenager and currently has 15 cigarettes daily. She has been diagnosed with small cell lung cancer. Her staging CT reveals a classification of T1a N2 M0. She attends for a follow-up appointment to see you in the oncology clinic

Which of the following treatment options should be considered first line?

A. Pembrolizumab
B. Cisplatin
C. Consider surgery
D. Thoracic radiotherapy
E. Palliation of symptoms

B. Cisplatin

Stage	Treatment
Early stage (T1-2a,N0,M0)	Surgery
Early stage (T1-2a,N0,M0)-Limited disease (T1-4,N0-3,M0)	4-6 cycles cisplatin based chemotherapy carboplatin if poor renal function/poor performance status +/- radiotherapy
Extensive disease (T1-4, N0-3, M1a/b)	6 cycles platinum based combination chemotherapy +thoracic radiotherapy if good response

Pembrolizumab is an example of an immunosuppressant therapy currently being researched for use in non-small cell lung cancer.

Question 74 of 133

A 28-year-old presents to Accident and Emergency with symptoms of increasing shortness of breath, wheeze and a cough.

This is her first hospital attendance with asthma which is usually well controlled. She has a past medical history of perennial rhinitis.

She has no known drug allergies and takes beclomethasone (200 micrograms inhaled twice a day) and salbutamol which she rarely uses. She has never smoked

On examination her respiratory rate is 24, her pulse is 98 bpm and has widespread wheeze on auscultation of her chest. Her oxygen saturations on air are 93%. She is quiet, anxious and seems disoriented.

Blood tests reveal a raised white cell count of 11 x 10 /L, her chest x-ray is normal.

She is started on nebulised salbutamol and ipratropium bromide and given an oral dose of prednisolone.

An arterial blood gas is taken 5 minutes after being started on 40% oxygen:

pH	7.36
PaO2	16.0 kPa
PaCO2	5.98 kPa
Bicarbonate	19 mmol/l

What would be the most appropriate next step?

A. Secure a cannula and give 200mg of hydrocortisone IV
B. Start empirical antibiotics
C. Magnesium infusion
D. Arrange a review by an anaesthetists/intensivist
E. Repeat an arterial blood gas after 10 minutes

D. Arrange a review by an anaesthetists/intensivist

The PaCO2 level which is at the upper limit of normal is very worrying and categorises this patient as having life-threatening asthma according to British Thoracic Society (BTS) guidelines. While a magnesium infusion may be of benefit, the description that she is anxious and possibly disoriented are concerning features and may indicate that shes tiring. In light of this getting a timely review by an anaesthetist/intensivist is of the utmost importance and should be the next immediate step. Giving hydrocortisone intravenously is unlikely to be of any benefit and considering antibiotics is not a priority in this situation where time is of the essence. Hence waiting another 10 minutes to do another arterial blood gas with to preceding action may potentially be fatal.

Question 75 of 133

A 57-year-old woman is admitted with an infective exacerbation of bronchiectasis. Multiple sputum cultures in the community have grown *Pseudomonas aeruginosa* and her GP had started oral ciprofloxacin. However, despite 4 days of this, she has developed worsening breathlessness, hypoxia, and fever and is now requiring oxygen.

Widespread coarse crepitations are heard and her chest x-ray demonstrates bilateral infiltrates.

What is the most appropriate course of action?

A. Add IV clarithromycin
B. Add IV vancomycin

C. Add high-dose trimethoprim/sulphamethoxazole and prednisolone
D. Change to IV ertapenem
E. Change to IV piperacillin-tazobactam

E. Change to IV piperacillin-tazobactam

Appropriate treatment of *Pseudomonas* positive bronchiectasis failing to respond to ciprofloxacin includes IV tazocin, ceftazidime, aztreonam or meropenem

The correct answer is **change to IV piperacillin-tazobactam**. *Pseudomonas aeruginosa* is a recognised cause of complex respiratory tract infections in patients with bronchiectasis or cystic fibrosis. Where oral treatment with ciprofloxacin fails, options include IV piperacillin-tazobactam, ceftazidime, or meropenem.

Add IV clarithromycin is incorrect. This is active against common pathogens causing communityacquired pneumonia as well as some atypical organisms. However, in this case, an organism has been isolated and it would be more appropriate to convert to IV therapy active against this. The combination of clarithromycin with quinolones also increases the risk of QT interval prolongation.

Add IV vancomycin is incorrect. This has purely gram-positive cover and is not active against *Pseudomonas aeruginosa*.

Add high-dose trimethoprim/sulphamethoxazole and prednisolone is incorrect. This would bethe optimal treatment for Pneumocystis jirovecii which can cause severe bilateral pneumonia.

However, it is most commonly seen as an opportunistic infection in patients with impaired cellmediated immunity, classically patients with HIV infection. In this case, there is no suggestion of significant immunocompromise and a typical pathogen has been isolated. It is therefore more appropriate to target therapy against this organism.

Change to IV ertapenem is incorrect. Ertapenem is a carbapenem (the same class as meropenem) with extremely broad-spectrum antimicrobial activity. However, the main difference between ertapenem and meropenem is that the former lacks activity against Pseudomonas species. It would therefore not be effective in this case.

Question 76 of 133

A 45-year-old woman presents to the emergency department with abdominal pain. It is severe and progressed to its maximum intensity over six hours. She has not noticed any associated vomiting or diarrhoea. She last opened her bowels yesterday. She has a history of alcoholic liver disease and has had previous admissions for decompensated liver failure. She is not jaundiced or confused currently. She has generalised abdominal tenderness, worse towards the epigastrium. A chest Xray demonstrates a right-sided pleural effusion. It is aspirated and found to have a protein count of 37g/l.

What is the most likely cause of the effusion?

A. Meig's syndrome
B. Hepatic failure
C. Pancreatitis
D. Nephrotic syndrome
E. Metastatic cancer

C. Pancreatitis

The correct answer is pancreatitis. This is a patient with epigastric abdominal pain and an exudative pleural effusion on a background of heavy alcohol intake. Exudative effusions occur due to increased leakiness of pleural capillaries. This can be due to infection, inflammation or malignancy. Of the available options, this includes pancreatitis and metastatic cancer. Transudates are caused by increased venous pressure, occurring in cardiac failure, renal failure, hepatic failure, as well as in Meig's syndrome, hypothyroidism and fluid overload. Given the epigastric pain and alcohol history, pancreatitis is a more likely cause than cancer and should be confirmed with serum and fluid amylase

Question 77 of 133

A 62-year-old gentleman presents to clinic with increasing shortness of breath on exertion. His symptoms have progressed over three months and he has now become concerned as he is struggling to walk through the park without stopping to catch his breath. He has also noticed a new, raised lesion on his chin. He has a few unexplained temperatures within the last week as well and has noticed mild joint pain. He assumed that the latter was arthritis but has not suffered from this before. He has a past medical history of hypertension, glaucoma and has been hospitalised with pneumonia within the last year.

On examination, he has a 1cm wide, raised lesion on his chin which is purple in colour with some telangiectasia. He does not have a fever currently and his observations are all within normal limits. There is no finger clubbing. There is bilateral cervical lymphadenopathy and auscultation demonstrates bibasal fine inspiratory crackles. These do not shift with coughing. A chest X-ray is requested.

What is it most likely to show?

A. Cavitating lesion
B. Pleural effusion
C. Bilateral consolidation
D. Bilateral hilar lymphadenopathy
E. Apical fibrosis

D. Bilateral hilar lymphadenopathy

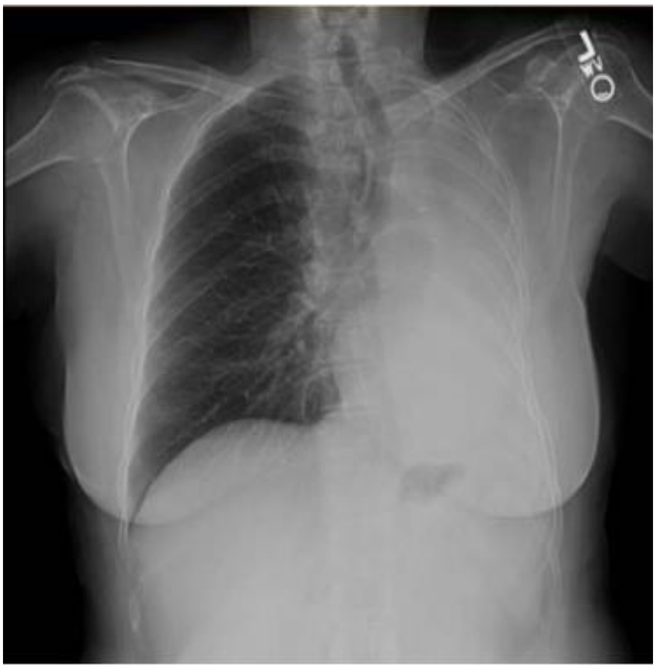
The correct answer is bilateral hilar lymphadenopathy. This is a patient who has presented with typical symptoms and signs of sarcoidosis: progressive exertional dyspnoea, arthralgia, unexplained pyrexia and fine inspiratory crepitations that do not shift on coughing. The absence of a cough, the fact that the crepitations do not shift, and the absence of clubbing all make bronchiectasis a much less likely diagnosis. The skin lesion described is likely to be lupus pernio.

The most common X-ray finding in sarcoidosis is bilateral hilar lymphadenopathy, but pleural effusions can also occur. However, pleural effusion is not supported by the examination findings.

Again, the fact that the crepitations are basal makes apical fibrosis a less likely finding to see on imaging, and hilar lymphadenopathy is a far more common radiological sign.

Question 78 of 133

A 65-year-old woman is admitted to the Emergency Department after collapsing in a department store. A chest x-ray is done shortly after arriving in the department:



What is the most likely explanation for the abnormality on the left side?

A. Rotated film
B. Massive pleural effusion
C. Pneumonectomy
D. Mesothelioma
E. Pneumonia

C. Pneumonectomy

The key to making the correct diagnosis is to look at the trachea. In the film it is clearly pulled to the left side. This makes a diagnosis of pleural effusion, pneumonia or mesothelioma unlikely. A rotated film would not give such dramatic findings

Question 79 of 133

A 56-year-old woman with severe asthma attends with two days of shortness of breath and a tight feeling in her chest. She has a history of multiple exacerbations and was intubated three months ago for a severe exacerbation. She usually takes montelukast, beclometasone and salbutamol.

On arrival, she is cyanosed and saturating at 92% in air. There is accessory muscle use and she is not able to vocalise beyond groans. Her respiratory rate is 22/min and there is quiet wheeze heard bilaterally in the chest. She has failed to respond to nebulisers, steroids and magnesium sulfate. She is planned for intubation and initiation of aminophylline.

Hb	156 g/l	Na^+	145 mmol/l
Platelets	561 * 10 /l 9	K^+	3.2 mmol/l
WBC	10.0 * 10 /l 9	Urea	4.5 mmol/l
Neuts	7.6 * 10 /l 9	Creatinine	65 µmol/l
Lymphs	0.8 * 10 /l 9	CRP	32 mg/l
Eosin	1.4 * 10 /l9		
Chest x-ray	hyperexpanded film with no consolidation or pneumothorax		

What recording is essential when administering aminophylline?

A. Liver function tests
B. Aminophylline levels
C. Repeat potassium
D. Serial ECGs
E. Cardiac monitor

E. Cardiac monitor

Aminophylline loading dose should be done with cardiac monitoring

Aminophylline is a methylxanthine and acts as a phosphodiesterase inhibitor and adenosine receptor antagonist. It therefore can act oppositely to adenosine in the heart and induce tachyarrhythmias. Therefore, for loading of aminophylline, a cardiac monitor needs to be applied. Aminophylline levels would be needed if this patient was already taking theophylline and are used to check maintenance levels. Aminophylline can induce hypokalaemia but this is less important than cardiac monitoring. Aminophylline can induce the liver but monitoring of LFTs is not usually required.

Question 80 of 133

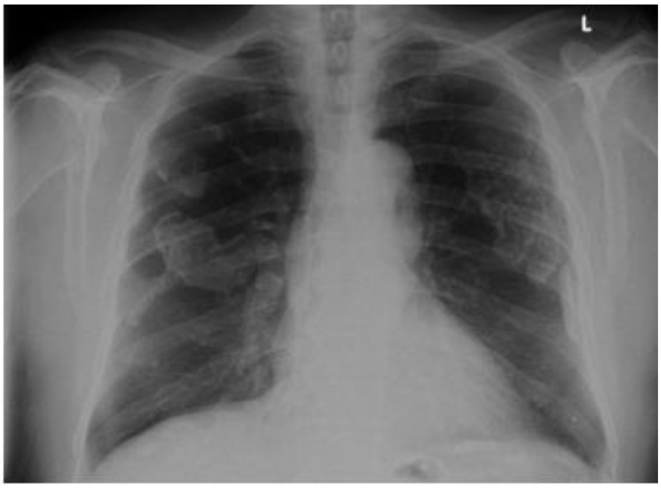
A 67-year-old retired plumber is seen in the respiratory clinic following an incidental finding of a chest x-ray ordered by his general practitioner. He recently recovered from an infection with *Mycobacterium tuberculosis* 6 weeks ago and reports to have been feeling well since with no complications. The remainder of his past medical history includes mild gastritis and hypertension.

On examination, his observations are recorded as follows:

- Temperature 36.1ºC
- Heart rate 89bpm
- Respiratory rate 22 breaths/min
- Blood pressure 118/65mmHg
- Saturations 99% on room air

On auscultation, chest sounds are clear and heart sounds are normal. Calves are soft and nontender.

A repeat chest x-ray is ordered (shown below):



What is the single biggest risk factor for this patient's investigation findings?

A. Mycobacterium tuberculosis
B. Asbestos
C. Aspergillus
D. Silica
E. Tobacco

B. Asbestos

This chest x-ray demonstrates multiple pleural plaques. They appear as slightly opacified pleural markings of a variety of different shapes with a visible contrast between their outlining border and adjacent normal lung markings. This patient's pleural plaques are most visible in the lateral aspect of the left upper zone and throughout the middle zone of the right lung. Pleural plaques are areas of thickened pleural tissue which arise secondary to asbestos exposure. This patient is a retired plumber and it is likely that his profession was the means of exposure to asbestos. The development of pleural plaques is not immediate and can take up to 20-40 years until visible on imaging. Pleural plaques do not undergo malignant change. Therefore, no follow-up is required for these patients.

Mycobacterium tuberculosis can cause a variety of lung pathology ranging from miliary tuberculosis to parenchymal calcification and necrosis. The infection does not give rise to pleural plaques as demonstrated in this chest x-ray, making it incorrect.

Aspergillus is a fungal infection responsible for a variety of different presentations including invasive aspergillosis and aspergillomas. An aspergilloma is a round mass of the fungus Aspergillus that occupies existing lung cavities such as those from previous *Mycobacterium tuberculosis* infections. It can be detected on a chest x-ray as a spherical or ovoid mass, commonly in the upper zones of the lung.

Silica exposure can lead to silicosis, the progressive inflammation of lung tissue. Stonemasons, mining, pottery and ceramics are the most common routes of silica exposure. Silicosis commonly causes an upper zone pulmonary fibrosis which is not seen here.

Tobacco use is most commonly associated with chronic obstructive pulmonary disease and malignancy (usually squamous cell carcinoma of the lung or small cell carcinoma). Asbestos and tobacco exposure are synergistic with one another the risk of malignancy. However, tobacco use alone is not associated with pleural plaques

Question 81 of 133

A 65-year-old man presents to the respiratory clinic with worsening haemoptysis the past 3 months. He is also concerned as he has noticed a loss of 6kg in the past 2 months. He previously completed a course of tuberculosis (TB) treatment 20 years ago, and he is currently a smoker, with a 50 pack year history.

On examination he is cachectic. Temperature is 36.8ºC, heart rate 80 bpm, respiratory rate 18 breaths per minute. There are decreased breath sounds and dullness to percussion over the right upper lobe, and conjunctival pallor. His fingers are clubbed. The rest of his examination is unremarkable.

Investigations:

Na+	131 mmol/l
K+	4.3 mmol/l
Urea	6.1 mmol/l
Creatinine	102 µmol/l
Serum corrected calcium	2.35 mmol/l
Serum bilirubin	21 µmol/l
Serum alkaline phosphatase	85 IU/l
Serum aspartate aminotransferase	16 IU/l
C Reactive protein (CRP)	15 mg/l
Haemoglobin	110 g/l
Mean Corpuscle Volume	77 fL
White cell count	11.2 x 10^9/L
Neutrophils	7.5 x 10^9/L
Eosinophils	1.9 x 10^9/L
Lymphocytes	1.1 x 10^9/L
Basophils	0.0 x 10^9/L
Platelets	490 x 10^9/L
INR	1.0

Chest x-ray: Intracavitary mass in the right upper zone

What is the next most useful diagnostic test?

A. Aspergillus precipitins
B. Bronchoalveolar lavage
C. Sputum cultures
D. Bronchoscopy and biopsy
E. Skin prick test

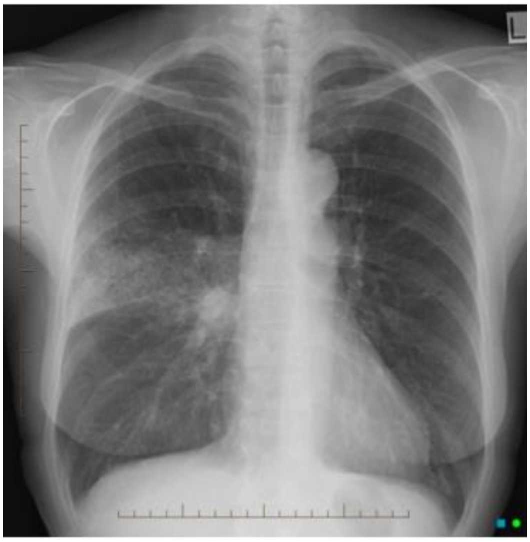
A. Aspergillus precipitins

This gentleman has haemoptysis, weight loss, previous TB and a mass in the right upper zone. The differentials would include recurrent TB, malignancy or an aspergilloma. In view of his eosinophilia in the differentials, the most likely diagnosis would be an aspergilloma, where a fungal ball of aspergilli grows in a pre-existing pulmonary cavity unchecked, as the immune system is unable to penetrate the cavity.

The diagnosis of aspergillosis includes the finding of eosinophilia on the full blood count, as well as raised IgE. Skin prick tests for aspergillus spp. may not be positive in patients with an aspergilloma. Serological tests for aspergillus precipitins are more sensitive than sputum cultures for diagnosing aspergillomas. Bronchoalveolar lavage and bronchoscopy are less effective in diagnosing aspergillomas. Another useful test is a CT scan of the chest, which can also reveal malignancy if suspected.

Question 82 of 133

A 71-year-old woman is admitted with shortness-of-breath to the acute medical unit. Her carers report that she has been feverish and confused for the past two:



What is the main finding on the film?

A. Bronchiectasis
B. Right middle lobe consolidation
C. Tuberculosis
D. Pulmonary abscess
E. Right upper lobe consolidation

E. Right upper lobe consolidation

This film demonstrates classical signs of right upper lobe consolidation - abnormal opacity within the right upper lobe abutting the horizontal fissure.

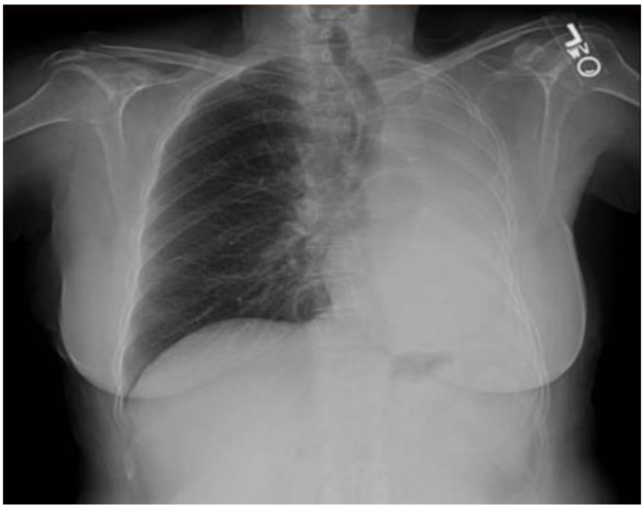
Question 83 of 133

A 70-year-old homeless woman is admitted to the Emergency Department after being found

unconscious by staff at a local homeless shelter. She has a history of alcohol excess according to

staff. On arrival in the department she appears to be intoxicated and confused. On examination you noticed heavy tar staining of the fingers and a pulse of 110/min which is irregularly irregular.

Her respiratory rate is 16/min with oxygen saturations of 92% on room air. Breath sounds are reduced on the left side of the chest. A chest x-ray shows the following:



What is the most likely diagnosis?

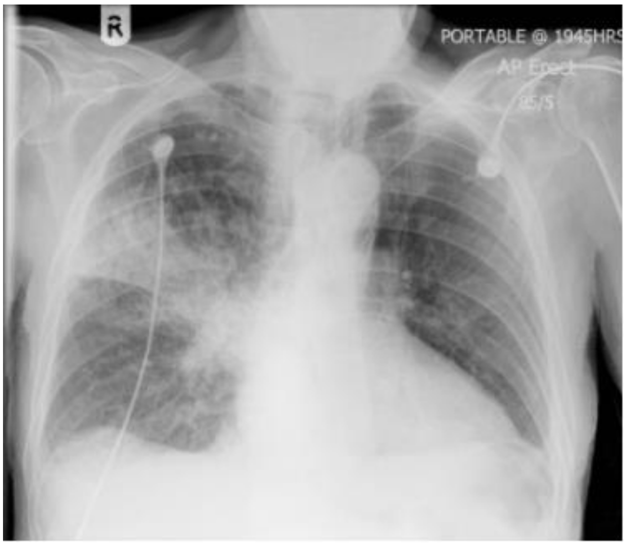
A. Pleural effusion
B. Pneumonia
C. Pneumonectomy
D. Diaphragmatic hernia
E. Mesothelioma

C. Pneumonectomy

The x-ray shows an opacified left hemithorax with mediastinal and tracheal shift towards the affected side. Crowding of the ribs over the affected side with compensatory overinflation of normal lung is also seen.

Question 84 of 133

A 75-year-old man is admitted to the Emergency Department with dyspnoea. A chest x-ray is performed upon arrival:



What is the main finding on the film?

A. Bronchiectasis
B. Right sided pleural effusion
C. Right upper lobe consolidation
D. Pulmonary oedema

E. Right middle lobe collapse

C. Right upper lobe consolidation

This film demonstrates classical signs of right upper lobe consolidation - abnormal opacity within the right upper lobe abutting the horizontal fissure.

Question 85 of 133

A 66-year-old man is referred to the Acute Medical Assessment Unit for progressive shortness of breath by their GP. Previous medical history includes ischaemic heart disease, left ventricular hypertrophy with reduced ejection fraction, hypertension and type 2 diabetes. He is a retired dockworker and has smoked 20 cigarettes a day for the last 50 years.

Hb	150 g/L	Male: (135-180)Female: (115 - 160)
Platelets	254 * 10^9/L	(150 - 400)
WBC	11.6 * 10^9/L	(4.0 - 11.0)
Na^+	132 mmol/L	(135 - 145)
K^+	3.9 mmol/L	(3.5 - 5.0)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	119 µmol/L	(55 - 120)
CRP	15 mg/L	(< 5)

A chest x-ray shows bilateral pleural effusions, cardiomyopathy and pleural plaques.

He is admitted for intravenous diuresis to treat his pleural effusions. He initially responds to treatment but there is a significant residual pleural effusion on the right-hand side.

What investigation would you undertake next for the residual right-sided pleural effusion?

A. Bronchoscopy
B. Chest drain with a sample of pleural fluid sent for investigation
C. Continue diuresis and review
D. Diagnostic aspiration
E. High resolution computed tomography of the thorax

D. Diagnostic aspiration

In the assessment of a pleural effusions, if the clinical picture suggests a transudate, then you should treat the cause initially. If this does not resolve the effusion then perform a diagnostic aspiration

Diagnostic aspiration is correct. A pleural aspiration is appropriate now that a malignant or exudate pleural effusion is suspected. Initially, the bilateral pleural effusions were suspected to be transudate due to the patient's cardiovascular history and were treated with diuresis. However, the residual effusion, which fails to resolve despite the resolution of the left-sided effusion, needs further investigation. This can either be a small or large volume aspiration depending on the patient's clinical picture and degree of respiratory compromise. A small volume would be for diagnostic purposes, if the patient remains compromised by the effusion, for example, work of breathing, oxygen requirement or exercise tolerance, then a large volume aspiration can be performed. It is very important to ensure that you have all the sampling equipment ready at the time of the intervention as multiple sample collection devices are often required. A chest drain may be required based on the results of the diagnosis aspiration.

Bronchoscopy is incorrect as this does not investigate pleural effusions. Uses for bronchoscopy include; suspected tumour, biopsy (including end-bronchial ultrasound), foreign body, infection or inflammation. Indications for this include localised wheeze from a possible foreign body, haemoptysis, biopsy of proximal tumour seen on CT, mucus sample collection for atypical infections and diagnosis of sarcoidosis.

Chest drain with a sample of pleural fluid sent for investigation is incorrect. The initial investigation for a possible malignant or exudate effusion would be a pleural aspiration and a review of samples taken. Should this continue to be a transudate effusion chest drain insertion would not be the next step.

Continue diuresis and review is incorrect. The initial suspicion was that the patient had bilateral transudate effusions. These do not need aspiration of the fluid and the patient was treated with a diuretic. However, there has been a failure to resolve unilaterally and given the patient's pleural plaques and, likely asbestos exposure in his employment, further investigation is warranted.

High resolution computed tomography of the thorax is incorrect. This investigation would be more appropriate to investigate idiopathic interstitial pneumonia, asbestosis, inflammation, drug reaction or diffuse alveolar damage.

Question 86 of 133

You are reviewing a 70-year-old man in the respiratory outpatient clinic.

He recently presented to the hospital with dyspnea. This has been gradually getting worse over several months and then acutely worsened in the days leading up to his hospital admission. His exercise tolerance had changed from a baseline MRC dyspnoea score of 3 to 5. There was an associated productive cough of white sputum. There was no history of a purulent cough, fevers or chest pain. He is a smoker with a 50 pack year history and his previous jobs were in administration. He has no pets. He denies any other medical or surgical conditions.

Examination at the time of hospital presentation revealed reduced breath sounds globally, expiratory wheeze and fine bibasal crepitations that did not change with coughing.

You reviewed this gentleman in the hospital and he was managed as a non-infective exacerbation of newly diagnosed chronic obstructive pulmonary disease, with nebulized bronchodilators and a short course of prednisolone. He was discharged on a combination Glycopyrronium and Indacaterol inhaler and you had arranged further outpatient investigations.

The results of these tests are available in today's clinic:

Tests	Result
FEV1	108% predicted
FVC	107% predicted
Total lung capacity	121% predicted
Diffusion capacity for carbon monoxide	36% predicted
High-resolution CT thorax	centrilobular emphysematous change in the upper lobes bilaterally. There

	are subpleural reticular opacities and honeycombing in both lung bases, with no traction bronchiectasis or ground glass opacities

Whilst his dyspnoea is improved, he still has an MRC dyspnoea score of 3-4. Repeat examination today in the clinic is unchanged from his examination findings in hospital.

The patient and his wife are very concerned about the deterioration in his breathing.

Which of the following is correct regarding his condition?

A. He has combined pulmonary fibrosis and emphysema (CPFE)
B. He has emphysema with non-specific interstitial pneumonia (NSIP)
C. His risk of developing lung cancer is similar when compared to patients with emphysemaalone
D. His risk of developing pulmonary arterial hypertension is similar when compared topatients with emphysema alone
E. The changes seen in the upper lobes on the high resolution CT thorax are atypical forsmoking related emphysema.

A. He has combined pulmonary fibrosis and emphysema (CPFE)

Combined pulmonary fibrosis and emphysema (CPFE) has a much higher rate of lung cancer than emphysema alone

This gentleman has a syndrome called combined pulmonary fibrosis and emphysema (CPFE). Patients with CPFE have significantly higher rates of lung cancer compared to those with emphysema (or idiopathic pulmonary fibrosis) alone. They also have an increased risk of developing pulmonary arterial hypertension, which is often less responsive to medical treatments, meaning lung transplantation should be considered in such cases.

CPFE is characterized by exertional dyspnoea, upper-lobe emphysema and lower-lobe fibrosis, preserved lung volume and severely reduced capacity of gas exchange. The preserved lung volumes are thought to arise because of the counterbalanced effects of hyperinflation from emphysema and the restrictive effects of pulmonary fibrosis. Both mechanisms lead to reduced gas exchange, hence the significantly reduced DLCO.

Option A - the correct answer

Options B - the HRCT findings of basal predominance fibrosis and honeycombing is consistent with a usual interstitial pneumonia (UIP) pattern. Traction bronchiectasis may or may not be present in UIP. Non-specific interstitial pneumonia (NSIP) is radiologically characterized by symmetric bilateral areas of ground-glass opacity with superimposed fine reticular opacities but with no or only minimal honeycombing

Options C and D - as described above, patients with CPFE have a significantly higher risk of developing lung cancer and/or pulmonary arterial hypertension

Option E - Emphysema secondary to smoking is typically upper lobe predominant, centrilobular and commonly manifests as small, localized areas of low attenuation within the central portion of the secondary pulmonary lobule on HRCT

Question 87 of 133

A 76-year-old man presented with vague lower abdominal pain. He was known to have underlying type 2 diabetes mellitus,hypertension and severe chronic obstructive pulmonary disease(COPD). He was a smoker with 50 pack years smoking history.

A CT abdomen was taken which showed diverticular disease of the colon. Incidentally it also showed a 2.5 cm mass in the periphery of the lower lobe of the left lung. Subsequently he underwent a positron emission tomography(PET) scan which showed the lung lesion with standardised uptake value(SUV) of 12.5 which was highly suspicious of cancer. There was no evidence of spread to lymph nodes or distant sites. A CT guided biopsy of the lung lesion was done which showed squamous cell carcinoma. His performance status was 2 in Eastern Cooperative Oncology Group(ECOG) scale. His lung functions showed an FEV1 of 0.8L(25% predicted) and FVC of 1.3L(30% predicted). TLCO was 30% predicted.

Which of the following is a suitable choice of treatment for him?

A. Submit answer
B. Lobectomy
C. Chemotherapy
D. Radical radiotherapy
E. Lobectomy+chemotherapy
F. Best supportive care

C. Radical radiotherapy

This is a stage IB lung cancer. Surgery is the best curative option provided the lung functions and performance status are suitable for surgery.

NICE guidelines says- 'Patients who have poor lung function but are otherwise suitable for radical radiotherapy should still be offered radiotherapy, provided the volume of irradiated lung is small'.

European Society for Medical Oncology (ESMO) guidelines-2014 says 'in those patients who are not suitable for surgery and with a peripheral tumour(like the patient in the question), Stereotactic Ablative Radiotherapy(SABR) given at a biologically equivalent dose of >100Gy is the preferred treatment of choice. A systematic review comparing outcomes of SABR and surgery in patients with severe COPD revealed a higher 30-day mortality following surgery but similar overall survival at 1 and 3 years. NCCN(National Comprehensive Cancer Network) guidelines-2015 for non-small cell lung cancer says SABR is an appropriate option for patients with high surgical risk. SABR and sublobar resection both achieve comparable cancer specific survival and primary tumour control.

Question 88 of 133

A 64 year-old female patient with known chronic obstructive pulmonary disease presents for routine review at respiratory outpatients. She is currently taking inhaled tiotropium and salmeterol/fluticasone at optimal doses. You note she has had two exacerbations in the previous 12 months requiring oral steroids and antibiotics. A recent high resolution CT showed severe emphysema affecting all lobes.

Her ABGs in clinic today is a follows:

pH	7.38
pO2	7.91 kPa
pCO2	6.7 kPa

HCO3	30.1 mmol/L
Sats	88%

Her blood tests today show:

Hb	16.6 g/dL
Platelets	256 x 10 9 /L
WCC	6.7 x 10 9 /L

How would you optimise her management further?

A. Refer to lung volume reduction surgery
B. Make no changes to current management
C. Consider long term oxygen therapy
D. Start prophylactic antibiotics
E. Refer for assessment for home non-invasive ventilation

C. Consider long term oxygen therapy

This lady is polycythaemic and has a resting pO2 less than 8.0kPa and therefore is a candidate for long term oxygen therapy. It may be prudent to repeat an ABG in one month to ensure a findings are similar prior to staring oxygen.

Question 89 of 133

A 72-year-old man was admitted to hospital with an exacerbation of his longstanding chronic obstructive airways disease. The patient's regular treatment for COPD included home oxygen, home bronchodilator nebulisers and high-dose inhaled steroids. Normal exercise tolerance was very limited with the patient becoming profoundly breathless after mobilising only short distances around his house. Following an admission to the intensive care unit for respiratory support the previous winter the patient had expressed a wish that he would not want non-invasive ventilation or intubation in the future and stated that control of his symptoms was his priority.

Treatment with prednisolone, nebulised bronchodilators and antibiotics was started on admission. Having been profoundly dyspneoic at rest at admission the patient's symptoms improved gradually over the next week until the patient returned to his baseline of dyspnoea on minimal physical exertion. He again requests if there is any other treatments that can ameliorate his symptoms.

Recent investigations are summarised below.

Forced vital capacity: 115 % predicted Forced expiratory volume (1s): 34 % predicted FEV1 / FVC: 30 % predicted

Haemoglobin	170 g / dL
White cell count	15.8 * 10 /l9
Platelets	167 * 10 /l9
Urea	6.7 mmol / L
Creatinine	98 micromol / L
Sodium	140 mmol / L
Potassium	4.1 mmol / L
Packed cell volume	0.42

What treatment is the best choice for relief of dyspnoea in this patient?

A. Short-acting liquid morphine sulphate prn
B. Venesection
C. Diazepam 2mg qds
D. High-flow oxygen (15L, 100%)
E. Refer to thoracic surgery for consideration of pleurodesis

A. Short-acting liquid morphine sulphate prn

The patient has end-stage COPD and has himself indicated that control of symptoms is his priority. As such, consideration of the use of opioid or benzodiazepine medications for symptomatic relief of breathlessness is appropriate. A recent prospective study demonstrated that lower dose opioid use (< 30 mg daily oral morphine equivalent) does not increase risk of hospitalisation or increase mortality in patients with COPD on long-term oxygen therapy.

Clinical Knowledge Summaries also support this approach:

Offer an opioid as first-line treatment to help breathlessness in people with end-stage chronic obstructive pulmonary disease (COPD) that is unresponsive to other medical treatment.

Benzodiazepines were shown to not increase admission rates but did increase mortality. The patients packed cell volume is normal; therefore venesection has no role in this case

Question 90 of 133

A 63 year old gentleman presented to the acute medical unit with a 3 day history of increasing shortness of breath and cough. He is known to have chronic obstructive pulmonary disease (COPD) and is treated as an infective exacerbation of COPD.

He has a past medical history of ischaemic heart disease, type 2 diabetes mellitus, hypothyroidism, hypercholesterolaemia, hypertension, epilepsy and osteoarthritis.

Despite nebulisers, steroids and antibiotics, he remains acutely breathless and his oxygen saturations are only 83% on air.

Blood gas analysis is as follows:

pH	7.21
pCO2	10.1 kPa
pO2	7.3 kPa
BE	-4.2 mmol/l
HCO3-	36 mEq/l

You opt to try non invasive ventilation (NIV) and he is transferred to the NIV unit. Initial settings on NIV are IPAP (inspiratory positive airways pressure) 10 cm H2O and EPAP (expiratory positive airways pressure) 4 cm H2O. He remains tachypnoeic and has oxygen saturations of 88%. His repeat blood gas after 1 hour is as follows:

pH	7.25	
pCO2	9.9 kPa	
pO2	9.3 kPa	
BE	-4.0 mmol/l	
HCO3-	35 mEq/l	

Firstly, how would you adjust* the *NIV settings?

A. Increase IPAP by 2 cm H2O
B. Increase EPAP by 2 cm H2O
C. Increase IPAP and EPAP by 2 cm H2O
D. No change in settings
E. Add extra inspired oxygen to NIV at 24%

A. Increase IPAP by 2 cm H2O

This gentleman is in type 2 respiratory failure secondary to an infective exacerbation of COPD. Initial treatment has failed and NIV is commenced. This helps somewhat initially, but an adjustment in NIV settings is required for optimisation. Given that his main issue is CO2 retention, an increase in IPAP is the correct response as this helps 'blow off' CO2. increasing EPAP splints the airways open and is effectively PEEP and therefore increases oxygenation. This is not particularly required in this gentleman as, although his pO2 is low, this is probably approaching normal for a COPD patient.

Question 91 of 133

A 91-year-old man is admitted into hospital with a severe exacerbation of his COPD. He is breathless on rest and although alert and orientated, is starting to become drowsy. His observation reveal a temperature of 37.9ºC, a heart rate of 82 beats per minute, blood pressure of 116/74 mmHg, respiratory rate of 28 breaths per minute and oxygen saturations of 84% on a 28% Venturi mask.

An arterial blood gas is performed and reveals a PaO2 of 9.0 kPa, PCO2 of 11.4kPa, HCO3 of 31 mmol/l and a pH of 7.29.

A decision is made to commence the man on non-invasive ventilation –

which of the following is the most appropriate management for this patient?

A. Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airways pressure (EPAP) of 4cm water at 60% flow rate of oxygen
B. Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airwayspressure (EPAP) of 4cm water at 20% flow rate of oxygen
C. Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airwayspressure (EPAP) of 4cm water at 40% flow rate of oxygen
D. Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airwayspressure (EPAP) of 6cm water at 40% flow rate of oxygen
E. Inspiratory positive airways pressure (IPAP) of 4cm water and expiratory positive airwayspressure (EPAP) of 10cm water at 40% flow rate of oxygen

C. Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airwayspressure (EPAP) of 4cm water at 40% flow rate of oxygen

The British Thoracic Guidelines state that oxygen saturations of 90-92%, with an initial noninvasive ventilation setting of Inspiratory positive airways pressure (IPAP) of 10cm water and expiratory positive airways pressure (EPAP) of 4cm water. To assess the effect of the treatment, an arterial blood gas should be taken an hour after the non-invasive ventilation is set up.

Question 92 of 133

A 24 year-old student was referred to the Acute Medical Unit by his general practitioner with a 4- week history of increasing cough and breathlessness. The cough was generally non-productive but he had coughed up a small amount of blood on 3 occasions. His past medical history consisted only of asthma which was well controlled with a salbutamol inhaler. There was no family history of venous thromboembolism. His recent travel history included a trip to Sierra Leone 3 months ago. He was a non-smoker and drank 20 units of alcohol per week.

On examination, his temperature was 37.6oC, heart rate 80 beats per minute, blood pressure 124/88 mmHg, respiratory rate 22 breaths per minute and oxygen saturations 92% on room air. He was able to talk in full sentences. A few bibasal crackles were evident on auscultation of the chest. His JVP was not elevated and heart sounds were normal.

Investigations:

Haemoglobin	144 g/L (130-180)
White cell count	7.0 * 10 /l
Neutrophil count	3.5 * 10 /l
Lymphocyte count	1.6 * 10 /l
Eosinophil count	1.3* 10 /l
Platelets	330 * 10 /l
Sodium	138 mmol/L
Potassium	3.9 mmol/L
Urea	7.0 mmol/L
Creatinine	65 mol/L
Alkaline phosphatase	40 IU/L
Alanine aminotransferase	33 IU/L
Gamma-glutyl transferase	18 IU/L
Bilirubin	14 mol/L
Albumin	40 g/L

Chest x-ray: Bilateral lower zone haziness ECG: Normal sinus rhythm

What is the most appropriate treatment for the underlying ***condition?***

A. Mebendazole
B. Low molecular weight heparin
C. Fluconazole
D. Doxycycline
E. Artesunate

A. Mebendazole

This patient has presented with features of eosinophilic pneumonia secondary to parasite infection, also known as Loefflers syndrome. The most likely causative organism in this case is the roundworm *Ascaris lumbricoides*, which can cause Loefflers syndrome during the pulmonary migration phase of its life cycle. The clinical features and eosinophilia could also point to idiopathic pulmonary eosinophilia or allergic bronchopulmonary aspergillosis, but the treatment for both of these (corticosteroids) is not listed as a potential answer. The chest x-ray findings and normal ECG make pulmonary embolism a less likely diagnosis.

Question 93 of 133

A 63-year-old man has a check chest x-ray 6 weeks after being treated for community-acquired pneumonia. He reports feeling much better in himself from a chest point of view. However, he has noticed his face has been getting rounder and he has put on weight, particularly in his abdominal region. He has also noticed purplish stripes on his abdomen which has alarmed him.

He has recently been diagnosed with hypertension and reports his GP told him he was borderline diabetic. His medications at present are ramipril. He drinks 4-6 units of alcohol per week, has a 40 pack-year smoking history and is a retired salesman.

Initial chest x-ray	Bibasal patch opacification in keeping with pneumonia. Clinical correlation advised.
Check chest x-ray	Compared to the previous x-ray, the consolidation has resolved. However, there is a right hilar mass suspicious for malignancy. Further investigation advised.

The patient has been informed of his chest x-ray results and understands that he will be referred urgently to the lung cancer clinic.

Given the presentation, what type of lung cancer is the patient likely to have?

A. Metastatic deposits
B. Mesothelioma
C. Adenocarcinoma of the lung
D. Squamous cell lung cancer
E. Small cell lung cancer

E. Small cell lung cancer

Small cell lung carcinoma secreting ACTH can cause Cushing's syndrome

his man has a significant smoking history and the repeat chest x-ray has revealed a suspicious mass, highlighting the importance of getting a follow-up x-ray for patients 6 weeks after community-acquired pneumonia (to check for resolution and any evidence of underlying lesions). The central adipose deposition, 'moon face', new hypertension and impaired glucose tolerance are all in keeping with Cushing's syndrome, This is a paraneoplastic phenomenon seen in small cell lung cancer due to the tumour secreting ACTH.

If these were metastatic deposits, the chest x-ray would show multiple lesions rather than a solitary hilar mass.

Mesothelioma is a cancer of the pleura due to asbestos exposure. There is nothing in the vignette to suggest asbestos exposure. In questions where asbestosis exposure may be relevant, the occupation of the patient is usually that of a plumber or builder.

Adenocarcinoma of the lung is associated with gynaecomastia.

Squamous cell lung cancers can secrete parathyroid hormone-related peptide which causes hypercalcaemia.

Question 94 of 133

A 58-year-old gentleman presents with shortness of breath and haemoptysis which has worsened over ten days. He is currently coughing up an estimated 200ml of fresh red blood every day. He has night sweats and feels cold and sweaty at times. He has not lost any weight and was well prior to this.

He has mild COPD and takes fostair twice a day with no exacerbations in the past 5 years. He moved to the UK 15 years ago but lived 10 years in Louisiana as a mining operator extracting minerals with exposure to bats and birds during this time. He drinks 10 units of alcohol a week and was born in Syria where he received a BCG vaccine as a child. He has not been around any ill contacts and lives with his wife and two children. There is no recent foreign travel and he keeps no pets.

On examination, he has crepitations in the right side mid and upper zones. He has palpable lymph nodes in his axillae and neck but his abdomen is non tender with no hepatosplenomegaly. He is breathing rapidly and appears cachectic. His observations show temperature 38.3ºC, respiratory rate 28/min, heart rate 98/min, saturations 88% in air. An arterial blood gas has not been done.

Hb	110 g/l	Na +	139 mmol/l
Platelets	450 * 10 /l 9	K +	3.4 mmol/l
WBC	13 * 10 /l 9	Urea	4.1 mmol/l
Neuts	9.8 * 10 /l 9	Creatinine	78 µmol/l
Lymphs	0.78 * 10 /l 9	CRP	130 mg/l
Eosin	0.1 * 10 /l9		
HIV serology	negative		
Sputum culture	no acid fast bacilli or other growth seen		
Chest x-ray	bilateral hilar lymphadenopathy with patchy right upper zone consolidation		
Beta-D-glucan	strongly positive		

What is the likely ***diagnosis?***

A. Aspergillosis
B. Tuberculosis
C. Histoplasmosis
D. Pneumocystis jirovecii
E. Lung carcinoma

C. Histoplasmosis

Histoplasmosis can affect the lung and present with acute respiratory failure

This gentleman has an acute history of respiratory failure with deterioration. All the causes above are possible but he is not HIV positive so *pneumocystis* is unlikely. This presentation is very acute for lung carcinoma. He has been vaccinated against tuberculosis.

The raised Beta-D-glucan suggests a fungal cause of infection. Given his previous exposure to bats and their droppings in the Mississippi area, he is likely to have developed invasive histoplasmosis which is known to present many years after initial exposure to the fungus.

Question 95 of 133

An 18-year-old male is referred to the medical assessment unit by the emergency department.

He presents with a 3-day history of a cough productive of green sputum, haemoptysis, subjective fevers, exertional dyspnea and right-sided pleuritic chest pain. This is the third presentation in 12 months. The first time he presented to his general practitioner and his symptoms improved with a course of oral amoxicillin. The second presentation was a few months ago where he required inpatient management with intravenous antibiotics. He failed to attend follow up as he became busy with his studies. Over the last 12 months, he has also noticed increasing lethargy and weight loss. He denies any other past medical or surgical history. He admits to smoking when he goes out with his friends at the weekends and to binge drinking at the weekends. There is no history of intravenous or other illicit drug use.

He was born in Nigeria and has been living in the United Kingdom for the last 12 months. He is studying for his undergraduate degree in mathematics and also works part-time in a restaurant.

On examination, observations revealed a respiratory rate of 19/min, oxygen saturation 94% on air, heart rate 110/min, blood pressure 100/60 mmHg and a temperature of 38ºC. Examination of the respiratory system revealed no clubbing or cervical lymphadenopathy. There were reduced breath sounds and dullness to percussion at the right base. Cardiovascular examination was normal. Calves were soft and non-tender, with no pedal oedema.

Hb	140 g/l	Na	136 mmol/l
Platelets	400 * 10 /l	K	4 mmol/l
WBC	12 * 10 /l	Urea	6 mmol/l
Neuts	11 * 10 /l	Creatinine	70 µmol/l
Lymphs	1 * 10 /l	CRP	30 mg/l

Chest x-ray showed an elevated right hemidiaphragm, depressed right hilum and obliteration of the right costophrenic angle.

Computed tomography (CT) of the thorax is obtained. This shows a small right pleural effusion, right lower lobe collapse and a smooth round mass in the proximal right main bronchus, partially obscuring its lumen, which had marked post-contrast enhancement. There was no hilar or mediastinal lymphadenopathy.

Three early morning sputum samples are sent which are negative for acid-fast bacilli. Mycobacterial culture is awaited. No malignant cells were seen on sputum cytology. Bronchoscopy is performed and biopsy of the mass is obtained.

What is the most likely histological diagnosis?

A. Adenocarcinoma
B. Squamous cell carcinoma
C. Small cell carcinoma
D. Large cell carcinoma
E. Carcinoid tumour

E. Carcinoid tumour

Bronchial carcinoid is the most common lung cancer in adolescents and can present with recurrent pneumonia

Bronchial carcinoid is a rare form of lung cancer but is much more common in younger patients, typically presenting in late adolescence. They are typically slow growing, well-differentiated tumours, explaining the protracted history we see in this patient. The majority (approximately 75%) of bronchial carcinoid tumours arise in the proximal airways, hence why symptoms include dyspnea, wheeze, cough, haemoptysis and/or recurrent pneumonia. Patients may receive several courses of antibiotics to treat recurrent pneumonia before the tumour is diagnosed, as in this case.

Studies have shown a positive association with smoking and the development of bronchial carcinoid, but causality has not been proven as with smoking and more common types of lung cancer.

Cavitation is rare. Pleural effusion is also uncommon but may be seen as a complication of pneumonia caused by the obstruction from the tumour. The chest x-ray description, in this case, is consistent with right lower lobe collapse and a right pleural effusion.

Only 5-20 per cent of typical low-grade lung neuroendocrine tumours (NETs) are associated with hilar or mediastinal adenopathy. Another clue in this case to carcinoid is that contrast-enhanced CT scans frequently show marked enhancement due to the vascular nature of the tumours.

Lung NETs tend to produce lower quantities of serotonin compared to intestinal NETs, which explains why lung NETs have lower rates of carcinoid syndrome, which is characterized by flushing, diarrhoea, bronchospasm and can reflect metastases to the liver. Option 1-4 - unlikely given the patient's age, relatively light smoking history and absence of lymphadenopathy. Central carcinomas are more likely to provide positive sputum cytology for malignant cells, whereas that is not the case with central bronchial carcinoid due to an intact bronchial mucosa usually overlying NETs.

Option 5 - the correct answer

Question 96 of 133

A 60-year-old man comes to his GP complaining of cough and dyspnoea on exertion. He has had the cough for over 2 years, but it has gotten worse recently along with increasing shortness of breath. He has no haemoptysis, chest pain or leg swelling. The patient has a 60 pack-year smoking history and drinks a moderate amount of alcohol. His temperature is 37.2ºC, blood pressure is 140/80 mmHg, pulse is 80/min, and respirations are 20/min.

Chest x-ray shows prominent bronchovascular markings and mild diaphragmatic flattening. Pulmonary function test results are as follows:

Forced expiratory volume in 1 second	67% of predicted
Forced vital capacity	95% of predicted
FEV1/FVC ratio	0.65

Carbon monoxide diffusion capacity is 100% of predicted value.

Which of the following is the most likely cause of this patients symptoms?

A. Asbestosis
B. Chronic bronchitis
C. Panacinar emphysema
D. Pulmonary fibrosis
E. Rheumatoid lung

B. Chronic bronchitis

The patients pulmonary function test (PFT) findings are consistent with obstructive lung disease. The carbon monoxide diffusing capacity of the lung (DLCO) measures the lungs ability to transfer gas to the blood. This patients normal DLCO indicates intact alveolar and capillary structure.
The patients chronic smoking, productive cough, dyspnoea on exertion and decreased FEV1/FVC ratio suggests COPD. COPD is a group of chronic disorders; the main subtypes being emphysema or chronic bronchitis. Patients with predominant emphysema are generally thin with severe dyspnoea, hyperinflated chest, decreased vascular markings, decreased DLCO (due to alveolar destruction) and moderate oxygen desaturation

Patients with predominant chronic bronchitis have chronic productive cough for 3 months over 2 consecutive years not due to other causes (e.g. bronchiectasis). It usually presents with prominent bronchovascular markings, mildly flattened diaphragm and normal DLCO (as seen in this patient).

Choices 1, 4 & 5: These conditions are examples of restrictive lung diseases that cause reduced lung volumes, normal FEV1/FVC ratio, decreased FVC and low DLCO.

Choice 3: Panacinar emphysema is typical for α-1-antitrypsin deficiency; centriacinar emphysema is more characteristic for smoking-induced COPD. Panacinar emphysema usually causes a low DLCO

Question 97 of 133

A 58-year-old woman presents to the acute medical take with chest pain and ongoing coryzal symptoms for the last few weeks. The chest pain is retrosternal in origin, dull in character, around 3/10 intensity and does not radiate. When questioned, the patient is having a cough with white sputum and small streaks of blood, which she says has become worse over the last two weeks.

For the past two years, she has been working in the Mississippi river basin with a team of geologists. She has never smoked, does not keep any pets and has not travelled anywhere else.

On examination, she is pyrexial at 38ºC, has bibasal crepitations with increased vocal resonance and dullness to percussion at both bases.

Troponin	3 ng/L	(<14)
Chest x-ray	Airspace shadowing with consolidation involving multiple lung segments	

What is the best* management *option?

A. Co-trimoxazole
B. Fluconazole
C. Itraconazole
D. Ivermectin
E. Pentamidine

C. Itraconazole

Amphotericin or itraconazole are the pharmacological agents of choice for histoplasmosis

Itraconazole is the correct answer as this is the preferred treatment for histoplasmosis. The main clue for the diagnosis of histoplasmosis is the endemic nature of the fungal spores to Mississippi with 80% of residents in this area having positive *Histoplasma* serology, but most remaining asymptomatic. This woman has chest symptoms so requires active treatment. If an individual is immunocompromised then the histoplasmosis can progress to involve the central nervous system

Co-trimoxazole is an incorrect option as this is the first-line treatment option for *Pneumocystis carinii* pneumonia (PCP).

Pentamidine is incorrect as this is indicated for the treatment of *Pneumocystis carinii* (PCP).

Fluconazole is an incorrect option, even though this is an antifungal agent like Itraconazole, it is less effective.

Ivermectin is incorrect as this is an anti-parasitic drug, not anti-protozoal, working effectively against *Strongyloides* and severe scabies infestations.

Question 98 of 133

A normally fit and well 32-year-old black woman complains of a fever and tiredness over the past month. Her temperature is 38.2ºC, blood pressure is 115/70 mmHg, pulse is 75/min and respirations are 18/min.

On examination there were multiple non-tender cervical and axillary lymph notes. Lung auscultation reveals fine crackles throughout bilaterally. A chest x-ray film demonstrated hilar lymphadenopathy with diffuse interstitial infiltrates. A subsequent lymph node biopsy showed non-caseating granulomas.

Which of the following is the most appropriate therapy?

A. Supportive therapy
B. Methotrexate
C. Ciclosporin
D. Glucocorticoids
E. Infliximab

D. Glucocorticoids

Indications for corticosteroid treatment for sarcoidosis are: parenchymal lung disease, uveitis, hypercalcaemia and neurological or cardiac involvement

The patient's presentation is consistent with sarcoidosis. Characteristically the patient is usually asymptomatic, with disease detection occurring via an abnormal chest x-ray film which demonstrates bilateral symmetric hilar adenopathy usually with para-tracheal adenopathy and/or parenchymal infiltrates. In this case, the patient has reached the threshold for starting steroid treatment. None of the other medications have been shown to be beneficial in treating this grade of sarcoidosis

Question 99 of 133

A 38-year-old man presents to his general practitioner with shortness of breath and a productive cough of yellow sputum. He normally has a dry cough only. This is his third episode this year and he has received four courses of steroids and antibiotics. He is has only ever smoked once or twice at university. He works in a factory producing computer parts.

He was fully vaccinated as a child and well until 3 years ago and is otherwise well. He has no other past medical history.

On examination, he has scattered wheeze but no crepitations. He has a resonant hyperinflated chest and respiratory rate is 28 breaths per minute with saturations of 94% in air. There is no clubbing or cyanosis. He is awaiting lung function testing.

Hb	140g/l	Na +	138 mmol/l
Platelets	340 * 10 /l 9	K +	4.7 mmol/l
WBC	14.1 * 10 /l 9	Urea	6.2 mmol/l
Neuts	12 * 10 /l 9	Creatinine	89 µmol/l
Lymphs	3.2 * 10 /l 9	CRP	50 mg/l

Eosin	1.0 * 10 /l9
Chest x-ray	hyperinflated lung fields, flattened hemidiaphragm, no consolidation seen
Sputum culture	Moraxella spp

What additional test would benefit the patient?

A. Alpha-1-antitrypsin
B. Sweat test
C. CFTR genotyping
D. Saccharin test
E. Immunoglobulins

A. Alpha-1-antitrypsin

COPD in a non smoker should prompt suspicion of alpha-1 antitrypsin deficiency

This young man has recurrent infective episodes with wheeze. The main differentials are cystic fibrosis, bronchiectasis and COPD. Importantly, he was well as a child and only recently has developed these episodes as an adult. He has some smoke exposure and is clearly hyperinflated with wheeze and no crepitations. He has no other features of cystic fibrosis/bronchiectasis. These features point towards COPD. The main cause of COPD is smoking but young patients with severe alpha-1-antitrypsin deficiency can develop COPD even in the absence of cigarette smoking.

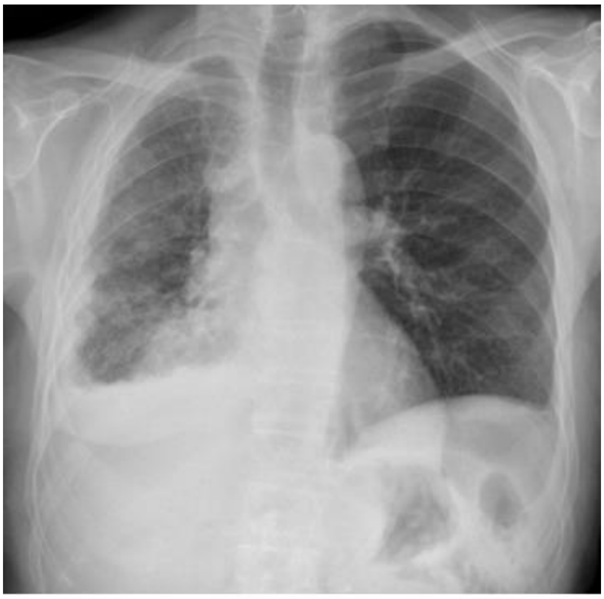
The sweat test and CFTR genotyping will diagnose cystic fibrosis. Saccharin testing is positive in ciliary dyskinesias and low immunoglobulins can cause bronchiectasis. The only test above that would explain this early COPD picture is the alpha-1-antitrypsin test

Question 100 of 133

A 71-year-old man presents to the hospital with a 4-month history of progressive shortness of breath. His wife brought him into the hospital today as he can no longer walk up the stairs without having to take a break. He has a past medical history of hypertension, hypercholesterolaemia and diet-controlled type 2 diabetes.

On examination, he has a heart rate of 101 beats/min with a blood pressure of 140/98mmHg. His oxygen saturations are 90% on air with a respiratory rate of 27 breaths/min. There is reduced air entry throughout the right lung field.

A chest x-ray is requested, as shown below:



What is the most likely diagnosis?

A. Congestive heart failure
B. Mesothelioma
C. Parapneumonic effusion
D. Pulmonary embolism
E. Pulmonary metastases

B. Mesothelioma

This patient has evidence of pleural thickening along the borders of the right lung which is most clear when making a comparison to the left lung field. There is also an associated pleural effusion on the right side with a visible fluid level that abuts the right costophrenic and costocardiac angles. Overall, this significantly reduces the volume of the right lung. This is most likely in keeping with a diagnosis of **mesothelioma** a rare pleural malignancy that is largely associated with asbestos exposure. The age of onset is typically between 60-85 years of age and presents with dyspnoea, cough and chest pain. Chest x-ray findings of mesothelioma include unilateral pleural thickening, reduced lung volume size and lower zone interstitial fibrosis.

Congestive heart failure can present with pleural effusions. However, more common chest x-ray findings include cardiomegaly, pulmonary venous congestion and bilateral pulmonary infiltrates. The unilateral findings on this patient's chest x-ray are more suggestive of an alternative diagnosis.

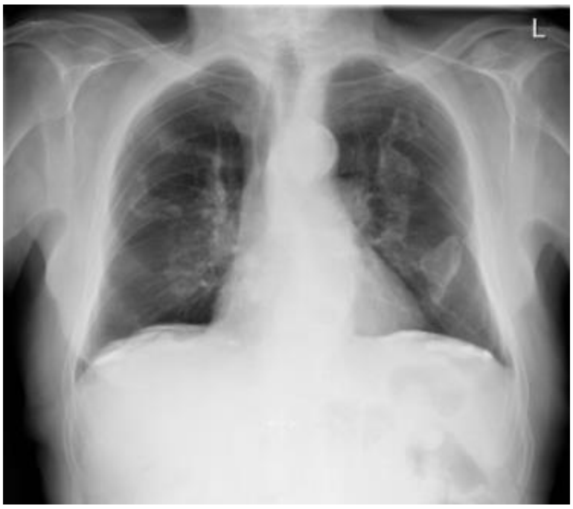
A **parapneumonic effusion** is a complication of viral or bacterial pneumonia when fluid collects in the pleural space due to increased permeability of the visceral pleura. Chest x-ray findings may be similar with signs of pleural effusion and an overall reduced lung volume. However, pleural thickening is not a feature of a parapneumonic effusion.

A **pulmonary embolism** (PE) does not frequently give rise to chest x-ray signs but can cause pleural effusions and Hampton hump sign (a wedge-shaped opacification secondary to lung infarction). However, the insidious onset of symptoms and pleural thickening make PE less likely.

Pulmonary metastases are relatively common but are not usually symptomatic unless advanced. Rather, the patient will experience constitutional symptoms and those of the primary malignancy. Chest x-ray findings of pulmonary metastases usually include multiple round nodules located in the peripheral lung fields. Unilateral pleural thickening with an associated effusion is unlikely to present pulmonary metastases

question 101 of 133

A 76-year-old retired boiler engineer presents with a 3-week history of a cough following a coryzal illness. He was a heavy smoker until around five years ago. An x-ray is performed:



What does the chest x-ray demonstrate?

A. Chronic obstructive pulmonary disease
B. Bronchiectasis
C. Asbestosis
D. Pleural plaques
E. Lung cancer

D. Pleural plaques

The correct answer is **Pleural plaques**. Pleural plaques are areas of fibrous thickening on the pleura (the lining of the lungs) and are often associated with exposure to asbestos. They are usually asymptomatic and do not typically affect lung function. The chest x-ray in the question shows bilateral pleural thickening, which is characteristic of pleural plaques. Their presence can indicate past exposure to asbestos, which would be consistent with the patient's history as a boiler engineer.

The first incorrect option is **Chronic obstructive pulmonary disease (COPD)**. Although the patient has a history of heavy smoking, which is a leading risk factor for COPD, this condition would not typically manifest as pleural plaques on an x-ray. Instead, one might expect to see hyperinflation of the lungs or potentially bullae (areas of emphysematous change), neither of which are evident in this image.

Next, we have **Bronchiectasis**, another incorrect choice. Bronchiectasis refers to permanent enlargement and damage to the airways (bronchi), often caused by recurrent infection or inflammation. On an x-ray, bronchiectasis may present as ring-like or tram-line shadows due to abnormally dilated bronchi; however, these signs are not visible in this case.

Asbestosis is also suggested but it is not correct either. Asbestosis refers specifically to interstitial lung disease caused by inhalation of asbestos fibres. While it shares a common cause with pleural plaques (asbestos exposure), its radiographic appearance differs significantly. Asbestosis typically presents as small irregular opacities predominantly in lower lobes and subpleural areas, rather than the discrete areas of pleural thickening seen here.

Lastly, **Lung cancer** was proposed as an option but it too does not fit with the findings on this xray. Lung cancers can take various forms on imaging - from solitary pulmonary nodules to larger masses - but they generally do not appear as bilateral pleural thickening like that seen in this image.

Question 102 of 133

A 68-year-old gentleman is presenting to the emergency department with a two month history of productive cough. He tells you that over the past week he is getting increasingly worse and feels feverish. He informs you that it is not unusual for him to cough copious amounts, but this time is much worse, and is wondering if he has an infection brewing. He also informs you that he is regularly under the care of the respiratory team, as he is suffering from a lung condition, however he cannot disclose further information. He is a non-smoker.

He appears sweaty and his temperature is 38.2ºC. He has a heart rate of 103/min and his capillary refill time is 3 seconds. Blood pressure is 102/54 mmHg. Examination indicates coarse crackles bilaterally and on the R mid-zone. Heart sounds are normal with no added sounds.

A chest x-ray is performed indicating increasing bronchovascular markings with bilateral consolidation.

You review his medicines and note that he is on salbutamol and ipratropium nebulisers, carbocisteine, aspirin and ramipril. You also notice that he is on ciprofloxacin, and when you enquire further he tells you that he has been on ciprofloxacin for 14 days so far as prescribed by the respiratory team because of an organism isolated in his sputum. You chase that up, and find out that he has previously grown Pseudomonas *aeruginosa*.

What antibiotic would you prescribe to this patient in this setting, given his status as penicillin allergic:

A. Intravenous meropenem
B. Intravenous co-amoxiclav
C. Intravenous tazocin
D. Intravenous metronidazole
E. Nebulised colomycin

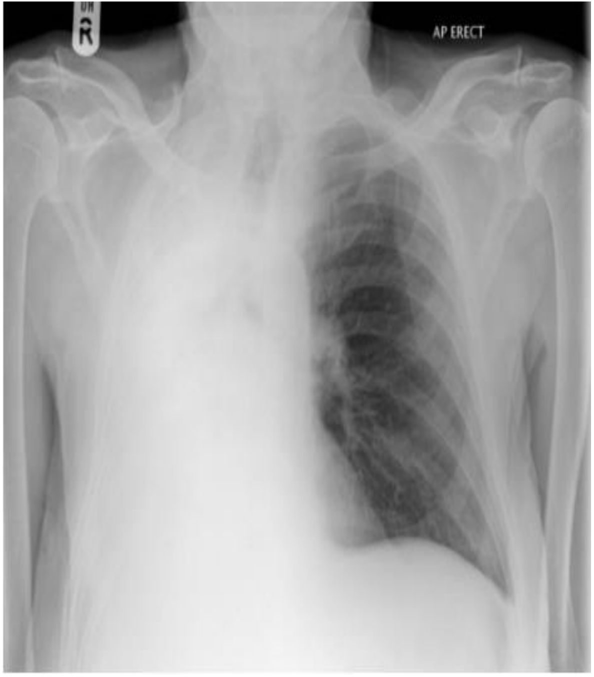
A. Intravenous meropenem

Appropriate treatment of *Pseudomonas* positive bronchiectasis failing to respond to ciprofloxacin includes IV tazocin, ceftazidime, aztreonam or meropenem

It is not uncommon in daily practice to meet patients that are aware of the fact that they suffer from a particular issue (in the case of this patient respiratory) without being able to exactly explain it (bronchiectasis). There are certain clues in this history pointing to a long term condition such as bronchiectasis (absence of smoking, bilateral crackles, copious productive cough, growth of pseudomonas, recent use of ciprofloxacin). As ciprofloxacin orally for 14 days has not worked for this patient the BTS guidelines suggest for the use of IV tazocin, ceftazidime, aztreonam or meropenem - given his penicillin allergic status, the safest choice is meropenem. Nebulised colomycin has a place in the treatment of these patients, not however in the acute setting

Question 103 of 133

An 82-year-old man is admitted with a three day history of increasing breathlessness, His past medical history includes ischaemic heart disease and rheumatoid arthritis. His current medications include aspirin, atorvastatin, bisoprolol, ramipril and methotrexate. On examination his heart rate is 80/min, blood pressure 111/80 mmHg, respiratory rate 24/min and oxygen saturations 89% on room air. There are reduced breath sounds on the right side of his chest. A chest x-ray is ordered:



What is the most likely diagnosis?

A. Mesothelioma
B. Methotrexate-induced pneumonitis
C. Multilobar pneumonia
D. Massive pleural effusion
E. Lung collapse

E. Lung collapse

The key to making the diagnosis, as with all white-outs, is to look at the position of the trachea. In this x-ray it is pulled towards the opacity making the diagnosis of a lung collapse likely.

Question 104 of 133

A 77-year-old active smoker with a 40 pack year history presents with his second non-infective exacerbation of COPD in 3 months. He was diagnosed with COPD two years ago and had been relatively well controlled using salbutamol as required prior to these two admissions. Two days after his admission, he reports that he is close to his baseline and would like to go home. His repeat pulmonary function tests reveal a forced expiratory volume in 1 second of 46%.

On reviewing his peak flow diary you note a significant (> 20%) diurnal variation in his peak flow.

Which would be most useful in optimising his COPD control?

A. No change to inhaler therapy, follow up in 3 months
B. Add beclometasone inhaler alone
C. Add salmeterol and fluticasone combination inhaler
D. Add salmeterol inhaler alone
E. Long term oxygen therapy

C. Add salmeterol and fluticasone combination inhaler

COPD - still breathless despite using SABA/SAMA and **asthma/steroid responsive features** → add a LABA + ICS

As this patient has a feature suggestive of asthma/steroid responsiveness (significant diurnal variation) the next step in management is a long-acting beta agonist (e.g. salmeterol) + an inhaled corticosteroid. NICE now recommend the use of combined inhalers where possible.

Question 105 of 133

A 46-year-old gentleman was referred by his GP to the respiratory clinic with deteriorating asthma control. He was diagnosed by his GP 2 years ago following complaints of feeling short of breath on exertion with wheeziness. Unfortunately, his symptoms deteriorated despite a trial of Clenil modulate 1000mcg BD, salmeterol 200mcg BD and montelukast 10mg OD. Upon further questioning, he stated that he had pins and needles in both hands as well as numbness of his fingertips for the last few weeks. His past medical history included hypertension, gout and sinusitis for which he was prescribed ramipril 5mg OD, allopurinol 100mg OD, salbutamol PRN and mometasone nasal spray 50mcg BD. He smoked 20 cigarettes per day and consumed 12 units of alcohol per week.

On examination, he appeared unwell. His heart rate was 98 bpm, respiratory rate 18/min, oxygen saturations 94% on air and blood pressure 146/82 mmHg. His heart sounds were normal with a normal JVP and examination of the chest revealed bilateral expiratory wheezes globally. Examination of the abdomen was normal. Examination of the peripheral nervous system demonstrated a peripheral neuropathy with a glove and stocking sensory loss of the upper limbs. Examination of the skin revealed the presence of purpura on his lower legs.

Initial investigations revealed the following results:

Hb	102 g/l
Platelets	342 * 10 /l9
WBC	12.1 * 10 /l9
Neutrophils 82% count	
Lymphocytes 7% count	
Eosinophils 10% count	
Monocytes 1% count	

ESR	42 mm/hr
Na +	141 mmol/l
K +	3.9 mmol/l
Urea	6.2 mmol/l
Creatinine	78 µmol/l

Chest x-ray: bilateral scattered pulmonary shadowing in lower zones

ECG: heart rate 97bpm, normal sinus rhythm, QRS interval 112ms, QTc interval 424ms

Which of the following tests is most likely to lead to the underlying diagnosis?

A. Anti glomerular basement membrane antibodies
B. p-ANCA antibodies
C. ANA antibodies
D. Anti Jo-1 antibodies
E. c-ANCA antibodies

B. p-ANCA antibodies

Churg-Strauss syndrome - positive pANCA serology

This gentleman presents with a combination of worsening asthma in combination with sinusitis. He has pulmonary infiltrates on his chest x-ray, as well as polyneuropathy and an eosinophilia. The diagnosis is strongly suggestive of Churg-Strauss syndrome, and of the following options, p-ANCA antibodies are the most sensitive and specific to this condition

Question 106 of 133

A 62-year-old gentleman is seen at the respiratory clinic after a mass lesion is identified by his GP on chest x-ray. He is a heavy smoker and has had a cough and weight loss for the past two months. On further questioning, he admits to feeling very weak and is having difficulty getting out of a chair. On examination, the consultant notices some proximal muscle wasting. Initial investigations reveal a blood pressure of 170/90mmHg and a low potassium. In addition to organising staging CT and bronchoscopy, he requests a 24-hour urinary cortisol test, which is raised.

Which of the following is the most likely underlying pathology?

A. Squamous cell bronchial carcinoma
B. Large cell bronchial carcinoma
C. Carcinoid tumour
D. Small cell bronchial carcinoma
E. Bronchial adenocarcinoma

D. Small cell bronchial carcinoma

The 24-hour urinary cortisol result here suggests a diagnosis of Cushing's syndrome. The coexistant presentation of lung cancer points to paraneoplastic Cushing's syndrome. The vast majority of paraneoplastic syndromes seen in lung cancer are caused by small cell bronchial carcinoma, a neuroendocrine tumour which can secrete a variety of hormones or antibodies. In paraneoplastic Cushing's syndrome, ectopic adrenocorticotrophic hormone (ACTH) production results in a syndrome characterised by muscle weakness, hypertension, hypokalaemia and oedema. The classical features of buffalo hump and moon face are often absent.

Question 107 of 133

A 29-year-old man presents to his GP with shortness of breath. This has been occurring for the past 6 months and is sometimes accompanied by wheezing, particularly later on during the day. He does not have any past medical history and occasionally takes over-the-counter antihistamines for hay-fever. His only recent travel history is a holiday to Greece, where he found he was less short of breath and he was less wheezy. His only family history of note is his mother who died of a heart attack aged 65. He works as a car mechanic and smokes 5 roll-up cigarettes per day and drinks on average 5-6 units of alcohol per week.

Examination of the chest is normal with good air entry bilaterally and no added sounds. Heart sounds I and II are present with no obvious murmurs.

What is the most useful investigation in determining this man's diagnosis?

A. Chest x-ray
B. Peak expiratory flow rate measurements at both home and at work
C. Pulmonary function testing
D. Serum IgE measurement
E. Skin prick testing

B. Peak expiratory flow rate measurements at both home and at work

The most likely diagnosis in this case is occupational asthma, as demonstrated by the timing of his breathlessness and wheeze as well as the improvement in symptoms when on holiday. The diagnosis of occupational asthma is best determined using peak expiratory flow rate measurements taken at home and work to determine the difference in the two - following this further investigation scan be performed to determine the allergen causing the occupational asthma

Question 108 of 133

A 55-year-old woman with poorly-controlled type 2 diabetes and a 50-pack-year smoking history presents to the Emergency Department with a three-day history of fever and productive cough. A chest radiograph shows right middle lobe pneumonia. She is prescribed a course of oral antibiotics and is discharged home.

She is reviewed in respiratory clinic two months later and has an ongoing dry cough.

What single investigation would be most appropriate to request during her consultation?

A. Arterial blood gas measurement
B. Pulmonary function tests
C. Referral for CT thorax
D. Repeat chest radiograph
E. Sputum culture

D. Repeat chest radiograph

All cases of pneumonia should have a repeat chest X-ray at 6 weeks after clinical resolution

This patient had lobar pneumonia and **a repeat chest radiograph should be arranged after about six weeks** for all patients with persistent symptoms, physical signs or at higher risk of malignancy such as smokers or older adults aged over 50 years old. Further investigation may be offered depending on their symptoms and radiology to rule out the presence of other conditions including malignancy. Although this patient does have a persistent cough, patients may take three to six months to feel back to normal and it would be most appropriate to request a chest radiograph first before any other radiological tests.

Arterial blood gas measurement is useful in patients with chronic lung disease to determine if they have chronic hypoxaemia. Such patients may be offered long-term oxygen therapy (LTOT) to improve survival. However, this patient does not have a diagnosis of chronic lung disease. Furthermore, if she continues smoking, it would not be appropriate to offer oxygen therapy as it is a fire hazard.

Pulmonary function tests such as spirometry should be offered to patients who smoke who have symptoms such as breathlessness, chronic cough, significant sputum production, wheeze and frequent chest infections. However, it would not be as important as ensuring her pneumonia has resolved or that lung cancer is not missed.

A **CT thorax** would be appropriate in patients with persistent changes on a repeat chest radiograph, or those with a normal chest radiograph but persistent symptoms. However, a chest radiograph should be repeated before a CT due to the high radiation dose involved.

Sputum culture may be helpful if the patient remains productive or if her symptoms fail to resolve with initial antibiotic therapy as she may have an atypical organism causing her chest infection, such as *Pseudomonas*. However, given that her cough is now dry this is unlikely to be feasible. A repeat chest radiograph would be more helpful in determining the possible causes of her symptoms in the first instance.

Question 109 of 133

A 45-year-old is referred to a respiratory clinic with 2 months of exertional shortness of breath. He has a past medical history of HIV. He is well controlled on Truvada. He has had an unprovoked pulmonary embolism three years ago and was treated with six months of warfarin. He smokes 15 cigarettes daily for the last 20 years. He recently completed his first mountaineering expedition and successfully reached the summit of Kilimanjaro.

On examination, there is a loud P2. The jugular venous pulse is raised and there is peripheral oedema. Chest auscultation is unremarkable and there are no murmurs.

A transthoracic echocardiogram is arranged, which demonstrates a mean pulmonary arterial pressure (PAPm) of 38 mmHg and mitral regurgitation with a regurgitant fraction of 14%.

An HRCT chest is normal. V/Q scanning demonstrates mismatched perfusion defects. The patient is referred for a right heart catheter, which confirms a PAPm of 38mmHg and also demonstrates a pulmonary arterial wedge pressure (PAWP) of 11 mmHg.

Given the likely diagnosis, what is the probable underlying aetiology?

A. COPD
B. Chronic thromboembolic disease
C. HIV
D. High altitude exposure
E. Mitral regurgitation

B. Chronic thromboembolic disease

Chronic pulmonary embolisms can lead to pulmonary hypertension

Chronic thromboembolic disease is the correct answer. The patient has pulmonary hypertension as evidenced by the clinical features and right heart catheter results (PAPm > =25mmHg). The patient has a history of pulmonary embolism and has been appropriately treated with warfarin for six months given his unprovoked VTE. However, the V/Q scan demonstrates mismatched perfusion defects suggesting chronic thromboembolic disease. This is therefore the most likely cause of pulmonary hypertension in this case.

COPD is incorrect. This is a cause of pulmonary hypertension. However, this is only seen in severe COPD. In a patient who has recently scaled a mountain and has a normal HRCT chest, COPD is unlikely.

HIV is incorrect. This is a cause of pulmonary hypertension. However, given he is well controlled on Truvada, this is slightly less likely in general. Additionally, it would not explain the mismatched perfusion defects on V/Q scanning and therefore it is a less likely cause than a chronic thromboembolic disease.

High altitude exposure is incorrect. He has only completed one mountaineering expedition. High altitude exposure can cause pulmonary hypertension but this is typically in people chronically exposed, living at high altitudes.

Mitral regurgitation (MR) is incorrect. The patient does not have clinically severe mitral regurgitation and the echocardiography findings are that of mild MR (regurgitant fraction < 30%). Therefore this is not the likely cause of pulmonary hypertension

Question 110 of 133

A 62-year-old man, with a 40-year heavy smoking history, presents to the emergency department. He's been troubled by a cough for the last five months associated with constant fatigue and weight loss. He reports coughing up blood on the morning of presentation.

On physical examination, the patient looks emaciated with notable finger clubbing. Auscultation reveals diminished air entry over the left lung with occasional wheezes. No murmurs are heard.

His vital signs are as follows:

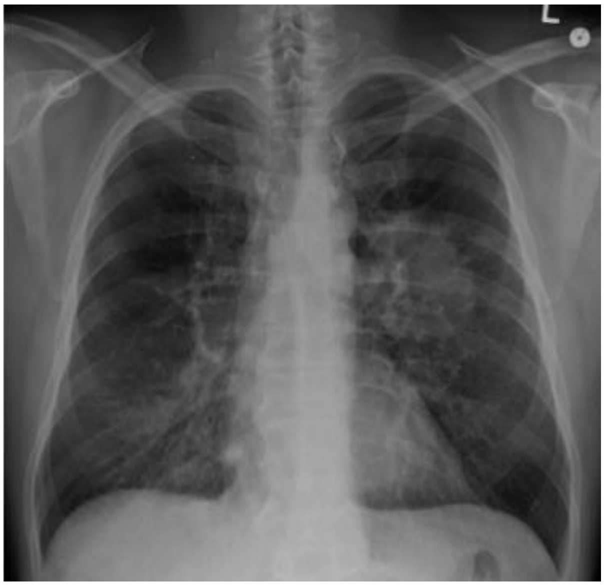
Temperature: 37.1°C.

Blood pressure: 115/75 mmHg. Heart rate: 101 beats/min, regular. Respiratory rate: 22 breaths/min. Oxygen saturation: 94 % on room air.

Labs are ordered and the results are the following:

Hb	125 g/L	Male: (135-180)
Platelets	680 * 10 /L	(150 - 400)
WBC	9.5 * 10 /L	(4.0 - 11.0)
Calcium	2.75 mmol/L	(2.1-2.6)

The chest x-ray is shown:



What is the most likely diagnosis?

A. Lung metastases
B. Sarcoidosis
C. Small cell lung cancer
D. Squamous cell lung cancer
E. Tuberculosis

D. Squamous cell lung cancer

Squamous cell lung cancer is the correct answer.

The patient's chest x-ray reveals a concerning mass in the left lung's hilar region. Considering the patient's extensive history of smoking coupled with respiratory symptoms, including haemoptysis, thrombocytosis, and the presence of hypercalcemia, a primary lung malignancy is the leading diagnostic consideration. While both small cell and squamous cell lung cancers could be potential culprits, hypercalcemia, which may be attributed to paraneoplastic secretion of parathyroid hormone-related protein, is more commonly associated with squamous cell lung cancer.

Lung metastases is not correct. While the x-ray findings and symptoms might suggest some form of lung disease, the patient's significant smoking history combined with hypercalcemia lean more towards a primary lung malignancy rather than metastatic disease.

Sarcoidosis is a viable differential diagnosis. The hypercalcemia and thrombocytosis associated with sarcoidosis make it a potential consideration. However, sarcoidosis typically presents with bilateral hilar lymphadenopathy. The unilateral presentation in this case, combined with the presence of haemoptysis, makes sarcoidosis less likely.

Small cell lung cancer is less likely. Although the patient's symptoms could be consistent with small cell lung cancer, the presence of hypercalcemia makes squamous cell lung cancer more likely.

Tuberculosis seems improbable in this case. While TB can indeed cause haemoptysis, chronic cough, weight loss, and hilar lymphadenopathy on imaging, other typical symptoms such as fever and night sweats are absent. The combination of a hilar mass and thrombocytosis with the patient's smoking history places lung cancer higher on the differential list.

Question 1 of 23

A 30-year-old man presents to the emergency department with a four-day history of subjective fevers, shortness of breath, non-productive cough and malaise.

On arrival to the emergency department, his observations revealed a temperature of 38.5ºC, heart rate 120/min, blood pressure 90/60 mmHg, respiratory rate 35/min and oxygen saturations of 80% on room air. An arterial blood gas revealed severe type 1 respiratory failure and the patient was intubated and placed on mechanical ventilation.

A post-intubation chest x-ray revealed bilateral pulmonary infiltrates and within the limits of a portable chest x-ray, a normal sized cardiac silhouette.
